Abstract

We describe a system for exact inference with relational Bayesian networks as defined in the publicly available PRIMULA tool. The system is based on compiling propositional instances of relational Bayesian networks into arithmetic circuits and then performing online inference by evaluating and differentiating these circuits in time linear in their size. We report on experimental results showing the successful compilation, and efficient inference, on relational Bayesian networks whose PRIMULA–generated propositional instances have thousands of variables, and whose jointrees have clusters with hundreds of variables.

1 Introduction

Relational probabilistic models extend Bayesian network models by representing objects, their attributes and their relations with other objects. The standard approach for inference with a relational model is based on the generation of a propositional instance of the model in the form of a classical Bayesian network, and then using classical algorithms, such as the jointree (Jensen et al., 1990), to compute answers to queries.

The propositional instance of a relational model includes one Boolean random variable for each ground relational atom. For example, if we have \( n \) objects \( o_1, \ldots, o_n \) in the domain, and a binary relation \( R(\ldots) \), we will generate a propositional variable for each instance of the relation: \( R(o_1, o_1), R(o_1, o_2), \ldots, R(o_n, o_n) \). The first task in making Bayesian networks over these random variables tractable for inference is to ensure that the size of the Bayesian network representation does not show exponential growth in the number \( n \) of domain objects (as can easily happen due to nodes whose in-degree grows as a function of \( n \)). This can often be achieved by decomposing nodes with high in-degree into suitable, sparsely connected subnetworks using a number of new, auxiliary nodes. This approach is systematically employed in the PRIMULA system. Even when a reasonably compact Bayesian network representation (i.e. polynomial in the number of objects) has been constructed for a propositional instance, this model will often be inaccessible to standard algorithms for exact inference, because its global structure does not lead to tractable jointrees.

Even though the constructed networks may lack the global structure that would make them accessible to standard inference techniques, they may very well exhibit abundant local structure in the form of determinism and context–specific independence (Boutilier et al., 1996). The objective of this paper is to describe a system for inference with propositional instances of relational models which can exploit this local structure, allowing us to reason very efficiently with relational models whose propositional instances may look quite formidable at first. Specifically, we will employ the approach proposed by (Darwiche, 2003) to compile propositional instances of relational models into arithmetic circuits, and then perform online inference by simply evaluating and differentiating the compiled circuits in time linear in their size. As our experimental results illustrate, this approach efficiently handles relational models whose PRIMULA–generated propositional instances are quite massive.\(^1\)

\(^1\)Some may recall the technique of zero–compression which can be used to exploit determinism in the jointree framework (Jensen and Andersen, 1990). This technique, however, requires that one do inference on the original jointree before it is zero–compressed, making almost all of our data sets inaccessible to this method.
This paper is structured as follows. We start in Section 2 with a review of relational models in general and the specific formalization used in this paper. We then discuss in Section 3 the PRIMULA system, which implements this formalization together with a method for generating propositional instances in the form of Bayesian networks. Section 4 is then dedicated to our proposed approach for compiling relational models. We then provide experimental results in Section 5, and finally close with some concluding remarks in Section 6.

2 Relational Models

Relational or first–order probabilistic models extend propositional modeling supported by Bayesian networks by allowing one to represent objects explicitly, and to define relations over these objects. Most of the early work on such generic models, which has been subsumed under the title knowledge-based model construction (see e.g. (Breese et al., 1994)), combines elements of logic–programming with Bayesian networks. Today one can distinguish several distinct representation paradigms for relational and first–order models: (inductive) logic-programming based approaches (Sato, 1995; Muggleton, 1996; Kersting and de Raedt, 2001), network fragments (Laskey and Mahoney, 1997), frame–based representations (Koller and Pfeffer, 1998; Friedman et al., 1999), and probabilistic predicate logic formulas (Jaeger, 1997).

We will use in this paper the language of relational Bayesian networks (Jaeger, 1997) to represent relational models, as implemented in the PRIMULA system (http://www.cs.auc.dk/~jaeger/Primula). The formal semantics of the language is based on Random Relational Structure Models (RRSMs), which we define next.

**Definition 1** Given (1) a set of relational symbols $S$, called predefined relations; (2) a set of relational symbols $R$, called probabilistic relations; and (3) a finite set $D$, called the domain; we define an $S^D$-structure to be an interpretation of relations $S$ over domain $D$, that is, a function which maps every ground atom $s(d)$ ($s \in S$, $d \subseteq D$) to either true or false. We also define a Random Relational Structure Model (RRSM) as a partial function which takes an $S^D$-structure as input, and returns a probability distribution over all $R^D$-structures as output.

Intuitively, members of domain $D$ represent objects, and members of $S$ and $R$ represent relations that can hold on these objects. These relations can be unary in which case they are called object attributes. A user would typically define the relations in $S$ (by providing an $S^D$–structure), and then use an RRSM to induce a probability distribution over the possible definitions of relations in $R$ ($R^D$–structures). We note here that $S^D$–structures correspond to skeleton structures in (Friedman et al., 1999).

We now describe three RRSMs that will be used in our experiments. These models have been implemented in PRIMULA, which provides a syntax for specifying RRSMs, and can be obtained from http://www.cs.ucla.edu/~chavira/pgm04.

**Random Blocks.** This is a model for the random placement of blocks, which serve as obstacles, on the locations of a map, and the resulting accessibility relation among the locations. The input structures consist of a particular gridmap, and a set of blocks. This is represented using a set of predefined relations $S = \{\text{location, block, leftof, belowof}\}$ where location and block are attributes that partition the domain into the two types of objects, and leftof and belowof are binary relations that determine the spatial relationship among locations. Figure 1 shows an input $S^D$–structure.

One of the probabilistic relations in $R$ for this model is the binary relation $\text{blocks}(b, l)$ which represents the random placement of a block $b$ on some location $l$. Another is $\text{connected}(l_1, l_2)$ between pairs of locations which describes whether, after the placement of the blocks, there is an unblocked path between $l_1$ and $l_2$. A probabilistic query might be the probability that there is an unblocked path between two locations $l_1$ and $l_2$, given the observed locations of some blocks (but uncertainty about the placement of the remaining ones).

We will experiment with different versions of this relational model, blockmap–$l$–$b$, where $l$ is the number of locations and $b$ the number of blocks.

**Mastermind.** In the game of Mastermind, Player 1 arranges a hidden sequence of colored pegs. Player 2 guesses the exact sequence of colors by arranging guessed sequences of colored pegs. To each guessed sequence, Player 1 responds by stating
how many pegs in the guess match pegs in his hidden sequence both in color and position (white feedback), and how many pegs in the guess match pegs in the hidden sequence only in color (black feedback). This feedback is provided by placing white and black feedback pegs in a sequence. Player 2 wins if he guesses the hidden sequence within a certain number of rounds.

The game can be represented as an RRSM where the domain \( D \) consists of objects of types \( \text{peg}, \text{color}, \text{peg-color} \), and \( \text{round} \) specified by corresponding unary relations in \( S \), as well as binary relations \( \text{peg-ord} \) and \( \text{round-ord} \) in \( S \) that impose orders on the peg and round objects, respectively. The probabilistic relations \( R \) in the model represent the game configurations after a number of rounds: \( \text{true-color}(p,c) \) represents that \( c \) is the color of the hidden peg \( p \); \( \text{guessed-color}(p,c,r) \) represents that in round \( r \) color \( c \) was placed in position \( p \) in the guess. Similarly, the arrangement of the feedback pegs can be encoded. The probabilistic model specifies that all color sequences are equiprobable, but can also specify a distribution on the choice of hidden colors.

We will experiment with different versions of this model, mastermind–c–g–p, where \( c \) is the number of colors, \( g \) is the number of guesses, and \( p \) is the number of pegs.

Students and Professors. We refer the reader to http://www.cs.ucla.edu/~chavira/pgm04 for the definition of this last model used in our experiments, which is a variation on the model used by (Pasula and Russell, 2001) to investigate approximate inference for relational models.

3 The PRIMULA System

The RRSM is an abstraction of probabilistic relational models. For a practical system, one needs a specific syntax for specifying an RRSM. PRIMULA allows users to encode RRSMs using the language of relational Bayesian networks (Jaeger, 1997), and outputs the distribution on \( R^D \)–structures in the form of a standard Bayesian network.

3.1 Specifying RRSMs using PRIMULA

We will now provide an example of specifying an RRSM using PRIMULA. Consider a relational version of the well known domain involving individuals, their alarms, neighbors (who can be pranksters), and whether they receive calls from these neighbors when their alarm is set off. The domain \( D \) contains individuals, and the set of predefined relations \( S \) contains a unary relation, \( \text{prankster} \), in addition to a binary relation \( \text{neighbor} \). There are four probabilistic relations in \( R \) for this domain. The first is \( \text{calls}(v,w) \): whether \( v \) calls \( w \) in order to warn \( w \) that his alarm went off. The probability of \( \text{calls}(v,w) \) is defined conditional on the predefined \( \text{neighbor} \) and \( \text{prankster} \) relations (it is 0 if \( v \) and \( w \) are not neighbors), and on the probabilistic \( \text{alarm}(v) \) relation: whether the alarm of \( v \) went off. We also have another probabilistic relation \( \text{alarmed}(v) \): whether \( v \) has been alarmed (called by at least one neighbor). The last probabilistic relation is \( \text{burglary}(v) \): whether \( v \)’s home has been burglarized.

This RRSM is specified in PRIMULA as given in Table 1, which provides the probability distribution on probabilistic relations using probability formulas. These formulas can be seen either as probabilistic analogues of predicate logic formulas, or as expressions in a functional programming language. A probability formula defines both the dependency structure between ground probabilistic atoms (which will depend on the predefined relations in the input structure), and the exact conditional probabilities, given the truth values of parent atoms.

| \( \text{burglary}(v) \) | 0.005 |
| \( \text{alarm}(v) \) | \( \text{burglary}(v):0.95,0.01 \) |
| \( \text{calls}(v,w) \) | \( \text{neighbor}(v,w) \) |
| (\( \text{prankster}(v) \)) | |
| (\( \text{alarm}(w):0.9,0.05 \)) |
| (\( \text{alarm}(w):0.9,0.0) \)) |
| \( \text{alarmed}(v) \) | \( \text{n-or}\{ \text{calls}(w,v)|w: \text{neighbor}(w,v) \} \) |

Table 1: Specifying an RRSM using PRIMULA.
3.2 From relational to propositional networks

To instantiate a generic relational model as in Table 1 in PRIMULA, one must provide a definition of an input \( S^D \)-structure. That is, one must define the set of individuals in domain \( D \), and then one must define who of these individuals are pranksters (by defining the attribute \textit{prankster}), and who are neighbors of whom (by defining the relation \textit{neighbor}). Given the above inputs, the distribution over probabilistic relations can be represented, as described in Section 1, using a standard Bayesian network with a node for each ground probabilistic atom. Our example also illustrates how the in-degree of a node can grow as a function of the number of domain objects: the node \texttt{alarmed(Holmes)}, for instance, will depend on \texttt{calls(w,Holmes)} for all of Holmes’s neighbors \( w \) (of which there might be arbitrarily many).

The PRIMULA system employs the general method described in (Jaeger, 2001) to decompose the dependency of a node on multiple parents. This method consists of an iterative algorithm that takes the probability formula defining the distribution of a node, decomposes it into its top-level subformulas—by introducing one new auxiliary node for each of these subformulas—and defines the probability of the original node conditional on the new auxiliary nodes. This method can be applied to any relational Bayesian network that only contains multilinear combination functions (which include \textit{noisy-or} and \textit{mean}), and then yields a Bayesian network in which the number of parents is bounded by 3 for all nodes.

Even when one succeeds in constructing a standard Bayesian network of a manageable representation size, inference in this network may be computationally very hard. It is a long-standing open problem in first-order and relational modeling whether one might not design inference techniques that avoid these complexities of inference in the ground propositional instances by performing inference directly on the level of the relational representation, perhaps employing techniques of first-order logical inference. Complexity results derived in (Jaeger, 2000) show that one cannot hope for a better worst-case performance with such inference techniques. This still leaves the possibility that they could often lead to substantial gains in practice.

A high-level inference technique that aims at achieving such gains in average-case performance has recently been described by Poole (Poole, 2003). The potential advantage of this and similar inference techniques seems to be restricted, however, to relational models where individual model instances are given by relatively unstructured input structures, i.e. input structures containing large numbers of indistinguishable objects. The potential of high-level inference techniques lies in their ability to deal with such sets of objects without explicitly naming each object individually. However, in the type of relational models we are here considering, the input structures consist of mostly unique objects (in Random Blocks, for instance, the block objects are indistinguishable, but all location objects have unique properties defined by the \textit{belowof} and \textit{leftof} relations). We can identify an input structure with the complete ground propositional theory that defines it (for the structure of Figure 1 this would be the theory \( \text{block}(B1) \land \neg \text{location}(B1) \land \ldots \land \text{leftof}(2,3) \land \ldots \land \neg \text{belowof}(5,5) \)), and, informally, characterize highly structured input structures as those for which this propositional theory admits no simple first-order abstraction.\footnote{Formally one would define the ‘structuredness’ of an input structure in terms of the number of its automorphisms.} When a relational model instance, now, is given by an input structure that cannot be succinctly encoded in an abstract, first-order style representation, chances are very small that probabilistic inference for this model instance can gain much efficiency by operating on a non-propositional level.

It thus appears that at least for a fairly large class of interesting models more advantages might be gained by optimizing inference techniques for ground propositional models, than by non-propositional inference techniques.

Table 2 depicts the relational models we experimented with, together with the size of corresponding propositional Bayesian networks generated by PRIMULA’s decomposition method. The table also reports the size of largest cluster in the jointree constructed for these networks. Obviously, most of these networks are inaccessible to mainstream, structure-based algorithms for exact inference. Yet,
we will show later that all of these models can be handled efficiently using the compilation approach we propose in this paper.

4 Compiling Relational Models

We describe in this section the approach we use to perform exact inference on propositional instances of relational models, which is based on compiling Bayesian networks into arithmetic circuits (Darwiche, 2003). Inference can then be performed using a simple two–pass procedure in which the circuit is evaluated and differentiated given evidence.

4.1 Bayesian networks as polynomials

The compilation approach we adopt is based on viewing each Bayesian network as a very large polynomial (multi–linear function in particular), which may be compactly represented using an arithmetic circuit. The function itself contains two types of variables. For each value \( x \) of each variable \( X \) in the network, we have a variable \( \lambda_x \) called an evidence indicator. For each instantiation \( x, u \) of each variable \( X \) and its parents \( U \) in the network, we have a variable \( \theta_{x|u} \) called a network parameter. The multi–linear function has a term for each instantiation of the network variables, which is constructed by multiplying all evidence indicators and network parameters that are consistent with that instantiation. For example, the multi–linear function of the network in Figure 2 has 8 terms corresponding to the 8 instantiations of variables \( A, B, C \):

\[
f = \lambda_a \lambda_b \lambda_c \theta_{a|a} \theta_{b|a} \theta_{c|a} + \lambda_a \lambda_b \lambda_c \theta_{a|a} \theta_{b|a} \theta_{c|a} + \ldots + \]

\[ \theta_{b|a} = 0 \]
\[ \theta_{b|a} = 1 \]
\[ \theta_{b|a} = .7 \]
\[ \theta_{b|a} = .3 \]

Figure 2: A Bayesian net with one of its CPTs.

The ability to compute answers to probabilistic queries directly from the derivatives of \( f \) is interesting semantically, but one must realize that the size of function \( f \) is exponential in the number of network variables. Yet, one may be able to factor this function and represent it more compactly using an arithmetic circuit. An arithmetic circuit is a rooted DAG, in which each leaf represents a variable or constant and each internal node represents the product or sum of its children; see Figure 3. If we can represent the network polynomial efficiently using an arithmetic circuit, then inference can be done in time linear in the size of such circuits, since the (first) partial derivatives of an arithmetic circuit can all be computed simultaneously in time linear in the circuit size (Darwiche, 2003).

4.2 Compiling the network polynomial into an arithmetic circuit

We now turn to the approach for compiling/factoring network polynomials into arithmetic circuits, which is based on reducing the factoring problem to one of logical reasoning (Darwiche, 2002). This approach is based on three conceptual steps, as shown in Figure 3. First, the network polynomial is encoded using a propositional theory.
Next, the propositional theory is factored by converting it to a special logical form. Finally, an arithmetic circuit is extracted from the factored propositional theory.

**Step 1: Encoding a multi-linear function using a propositional theory.** The purpose of this step is to specify the network polynomial using a propositional theory. To illustrate how a multi-linear function can be specified using a propositional theory, consider the following function \( f = ac + abc + c \) over real-valued variables \( a, b, c \). The basic idea is to specify this multi-linear function using a propositional theory that has exactly three models, where each model encodes one of the terms in the function. Specifically, suppose we have the Boolean variables \( V_a, V_b, V_c \). Then the propositional theory \( \Delta_f = (V_a \lor \neg V_b) \land V_c \) encodes the multi-linear function \( f \) as follows:

<table>
<thead>
<tr>
<th>Model</th>
<th>( V_a )</th>
<th>( V_b )</th>
<th>( V_c )</th>
<th>encoded term</th>
</tr>
</thead>
<tbody>
<tr>
<td>( \sigma_1 )</td>
<td>true</td>
<td>false</td>
<td>true</td>
<td>( ac )</td>
</tr>
<tr>
<td>( \sigma_2 )</td>
<td>true</td>
<td>true</td>
<td>true</td>
<td>( abc )</td>
</tr>
<tr>
<td>( \sigma_3 )</td>
<td>false</td>
<td>false</td>
<td>true</td>
<td>( c )</td>
</tr>
</tbody>
</table>

That is, if model \( \sigma_i \) encodes term \( t_i \), then \( \sigma_i \) sets Boolean variable \( V_j \) to true iff \( t_i \) contains the corresponding real-valued variable. This method of specifying network polynomials allows one to easily capture local structure; that is, to declare certain information about values of polynomial variables. For example, if we know that parameter \( a = 0 \), then we can exclude all terms that contain \( a \) by adjoining \( \neg V_a \) with our encoding.

**Step 2: Factoring the propositional encoding.** If we view the conversion of a network polynomial into an arithmetic circuit as a factoring process, then the purpose of this second step is to accomplish a similar task but at the logical level. Instead of starting with a polynomial (set of terms), we start with a propositional theory (set of models). And instead of building an arithmetic circuit, we build a Boolean circuit that satisfies certain properties. Specifically, the circuit must be in Negation Normal Form (NNF): a rooted DAG where leaves are labelled with literals, and where internal nodes are labelled with conjunctions or disjunctions; see Figure 3. The NNF must satisfy three properties: (1) conjuncts cannot share variables (decomposability), (2) disjuncts must be logically exclusive (determinism), and (3) disjuncts must be over the same variables (smoothness). The NNF in Figure 3 satisfies the above properties, and encodes the multi-linear function shown in the same figure. In our experimental results, we use a second generation compiler for converting CNFs to NNFs that are decomposable, deterministic and smooth (smooth d-DNNF) (Darwiche, 2004).

**Step 3: Extracting an arithmetic circuit.** The purpose of this last step is to extract an arithmetic circuit for the polynomial encoded by an NNF. If \( \Delta_f \) is an NNF that encodes a network polynomial \( f \), and if \( \Delta_f \) is a smooth d-DNNF, then an arithmetic circuit for the polynomial \( f \) can be obtained easily as follows. First, replace and–nodes in \( \Delta_f \) by multiplications; then replace or–nodes by additions; and finally, replace each leaf node labelled with \( V_x \) by \( x \) and each node labelled with \( \neg V_x \) by 1. The resulting arithmetic circuit is then guaranteed to correspond to polynomial \( f \) (Darwiche, 2002). Figure 3 depicts an NNF and its corresponding arithmetic circuit. Note that the generated arithmetic circuit is no larger than the NNF. Hence, if we attempt to minimize the size of NNF, we are also minimizing the size of generated arithmetic circuit.

### 4.3 Encoding PRIMULA’s networks

As mentioned earlier, the PRIMULA system generates propositional instances of relational models in the form of classical Bayesian networks. These networks, however, have a specific structure that we exploit when encoding the network polynomial as CNF; we do not use the exact encodings proposed in (Darwiche, 2002). In particular, the networks generated by PRIMULA will only have binary variables, and each node is restricted to have no more than 3 parents.

These specific properties of the generated networks allow one to use a tailored, efficient encoding of the network polynomial. Specifically, instead of using one propositional variable for each evidence indicator \( \lambda_x \)—which would be needed in general—we use one propositional variable \( I_X \) for each Bayesian network variable \( X \), where the positive literal \( I_X \) represents indicator \( \lambda_x \), and the negative literal \( \neg I_X \) represents indicator \( \lambda_x \). Not only does this cut the number of indicator variables by half, but it also relieves the need for clauses of
the form, $\lambda_x \lor \lambda_{\bar{x}}$ and $\neg \lambda_x \lor \neg \lambda_{\bar{x}}$ which would be needed to ensure that exactly one indicator for variable $X$ can appear in any polynomial term; see (Darwiche, 2002). The CNF encoding will also include one variable $P_{\theta_{x|u}}$ for each network parameter $\theta_{x|u}$ which is not equal to 0 or 1. Given these variables, the CNF will then only include the following clauses: If $\theta_{x|u_1,\ldots,u_n} = 0$, include clause $L_{U_1} \lor \ldots \lor L_{U_n}$, where $L_{U_i}$ is a literal over variable $I_{U_i}$ whose sign is opposite to the sign of $u_i$. If $\theta_{x|u_1,\ldots,u_n} \neq 0, \neq 1$, include clauses $L_{U_1} \lor \ldots \lor L_{U_n} \Rightarrow P_{\theta_{x|u_1,\ldots,u_n}}$, $P_{\theta_{x|u_1,\ldots,u_n}} \Rightarrow L_{U_1}$, $\ldots$, $P_{\theta_{x|u_1,\ldots,u_n}} \Rightarrow L_{U_n}$, where $L_{U_2}$ is a literal as defined earlier.

For example, the CPT for variable $B$ in Figure 2 will generate the following clauses: (1st row) $I_A \lor \neg I_B$, (3rd row) $\neg I_A \land I_B \Rightarrow P_{\theta_{b|a}}$, $P_{\theta_{b|a}} \Rightarrow \neg I_A$, $P_{\theta_{b|a}} \Rightarrow I_B$, (4th row) $\neg I_A \land \neg I_B \Rightarrow P_{\theta_{b|a}}$, $P_{\theta_{b|a}} \Rightarrow \neg I_A$, and $P_{\theta_{b|a}} \Rightarrow \neg I_B$.

Given that all network variables are binary, and given that each node has at most three parents, this encoding leads to a CNF whose size is linear in the number of network variables. Table 2 depicts the size of CNF encodings for the relational models we experimented with. The number of clauses for these encodings is usually smaller than the number of parameters in the corresponding Bayesian networks.

The special encoding used above calls for a slightly different decoding scheme for transforming a smooth d-DNNF into an arithmetic circuit. Specifically, literals $I_X$ and $\neg I_X$ are replaced with evidence indicators $\lambda_x$ and $\lambda_{\bar{x}}$, respectively. Moreover, literals $P_{\theta_{x|u}}$ and $\neg P_{\theta_{x|u}}$ are replaced by $\theta_{x|u}$ and 1, respectively. Finally, conjunctions and disjunctions are replaced by multiplications and additions.

5 Experimental Results

Our experimental results were obtained on a 1.6GHz Pentium M with 2GB of RAM. Table 2 lists for each relational model a number of instances, and for each instance, a number of findings. First is the size and connectivity of the Bayesian network that PRIMULA generated. Next is the size of CNF encoding in terms of the number of Boolean variables and clauses. Third, the table shows the size of the compiled arithmetic circuit in terms of both number of nodes and edges (count and log base 2). We also show the time it takes to evaluate and differentiate the circuit, averaged over 31 different pieces of evidence. Note that by evaluating and differentiating the circuit, one obtains the marginals over all network families, in addition to other probabilities discussed in (Darwiche, 2003).

The main points to observe are the efficiency of online inference on compiled circuits and the size of these circuits compared to the size and connectivity of the Bayesian networks. Table 2 also shows the time for jointree propagation using the SamIam inference engine (http://reasoning.cs.ucla.edu/samiam) on instances whose cluster size was manageable. One can see the big difference between online inference using the compiled AC and corresponding jointrees.

Table 2 finally shows the compile time to generate the arithmetic circuits. The compile times range from less than a minute to about 60 minutes for the largest model (blockmap-22-03). Yet note that the time for online inference ranges from milliseconds to about 13 seconds for these models. This clearly shows the benefit of offline compilation in this case, whose time can be amortized over online queries.

6 Conclusion

We described in this paper an inference system for relational Bayesian networks as defined by PRIMULA. The proposed inference approach is based on compiling propositional instances of these models into arithmetic circuits. The approach exploits local structure in relational models, allowing us to reason efficiently with relational models whose PRIMULA-generated propositional instances contain thousand of variables, and whose jointrees contain hundreds of variables. The described system appears to significantly expand the scale of PRIMULA–based relational models that can be handled efficiently by exact inference algorithms.
