ABSTRACT: Timber is a complex building material with properties which are highly variable both spatially and in time. In structural engineering, the important material properties are the strength and stiffness related properties of standard test specimen under given (standard) loading and climate conditions and the timber density. JCSS (Joint Committee of Structural Safety) has recently developed a probabilistic model code for timber properties for structural design, (JCSS 2006). This paper describes the main content of this probabilistic model code and gives a short example for possible application.

1 BACKGROUND

Typical problems in structural engineering such as design, assessment, inspection and maintenance planning are decision problems subject to a combination of inherent, modeling and statistical uncertainties. Recent developments in the field of structural reliability together with the formulation of probabilistic models for the structural response and for loads enable the structural engineer to quantify these uncertainties and establish his decisions on a consistent basis. The results of these advances are summarized in the Probabilistic Model Code (PMC) published by the Joint Committee on Structural Safety (JCSS 2006).

The PMC contains general guidelines for uncertainty modeling, reliability assessment and probabilistic models for loads and material resistance for building materials as concrete and steel. Lately, also a probabilistic model code for structural timber has been developed by an international group of researchers organized under the umbrella of the European COST action E24 ‘Reliability of Timber Structures’ (COST 2005).

2 INTRODUCTION

Timber is a rather complex building material. Its properties are highly variable, spatially and in time. In structural engineering, material properties of timber are defined as the stress and stiffness related properties of standard test specimen under given (standard) loading and climate conditions and the timber density. Timber is a graded material. Due to the grading process, the material properties are associated with some control scheme, whereas only the so-called reference material properties are considered explicitly. The so-called other material properties are only assessed implicitly. The distinction between reference properties and other properties is made as illustrated in Figure 1. The bending strength \( f_{\text{bend}} \), the bending modulus \( E \), and the timber density \( \rho \) are referred to as the reference material properties.

Figure 1. Reference material properties and other material properties.

When modeling timber material properties in a structure, i.e. at any generic point, in time and in space, several issues have to be taken into account. As illustrated in Figure 2 the cornerstone of the modeling of...
timber material properties is constituted by the reference material properties under test conditions. The material property of interest at any generic point may derive in terms of type ('other material properties'), of dimensions and size ('scale') and of specific loading and climate conditions ('time (load/moisture)').

3 PROBABILISTIC MODEL FOR TIMBER MATERIAL PROPERTIES

3.1 Definitions

The three reference material properties are defined in three different contexts; as illustrated in Table 1.

Table 1. Basic material properties in different context.

Properties of test specimen, size, climate and loading conditions are specified by test standards.1,2

Properties of cross sections, climate and loading conditions are specified by test standards.

Properties of cross sections under any climate and loading condition.

where Ex(s, α, ω, τ) is the exposure of the structure to loads s, humidity ω and temperature τ, in the time interval [0, T]; α(Ex(.)) is a strength modification function, in general defined for a particular set of exposures; δ(Ex(.)) is a stiffness modification function, in general defined for a particular set of exposures.

rm, moem and ρ, den are the bending moment capacity, the modulus of elasticity and the density of a cross section under test (climate and loading) conditions.

Other material properties are estimated based on the reference material properties.

Expressions for the expected values E[.] and the coefficient of variation COV[.] are given in Table 2. (Note that the capital letters in Table 2 indicate that the material properties are now represented as random variables, i.e. rm → Rm, moem → MOEm, ρ, den → P, den, etc.)

The relations are derived for standard test specimen properties tested under reference conditions. However, it is assumed that the relations can be used at any level, i.e. for components of any size and/or for other climate and load conditions.

3.2 Typical limit state functions

3.2.1 Ultimate limit states

The ultimate limit state equation for a cross section subjected to stress in one particular direction is given as:

\[ g = z_i R X_M - \Sigma S_j \]  

where \( z_i \) is a design variable, e.g. cross-sectional area, \( R \) is the resistance, e.g. tension strength, \( \Sigma S_j \) is the sum of all possible load effects, e.g. axial stresses, \( X_M \) is the model uncertainty.

Ultimate limit state equations for cross sections subjected to combined stresses can be formulated similarly.

\[ g = 1 - \left( \Sigma S_i / (z_i R_i) + \Sigma S_{1,j} / (z_{1,j} R_{1,j}) \right) X_M \]
A proposal for the quantification of probabilistic uncertainty.

Where $z_{d,A}$, $z_{d,M}$ are design variables, e.g., the cross sectional area and the section modulus, $R_{d0}$, $R_m$ are the tension strength and the bending moment capacity, $\Sigma S_i$, $\Sigma X_i$ are the sum of all possible load effects, e.g., axial stresses and bending stresses, $X_M$ is the model uncertainty.

Ultimate limit state equations for cross sections subjected to other combined stresses can be formulated similarly.

### 3.2.2 Serviceability limit states

E.g. when a deflection exceeds an allowable limit:

$$g(t) = \delta_t - W(t) \left(\Sigma S_i, MOE_{i,t}\right) X_M$$

where $\delta_t$ is an allowable deflection limit and $W(t)$ is the deflection at time $t$, depending on load effects $\Sigma S_i$ and modulus of elasticity and $X_M$ is the model uncertainty.

### 3.3 Formulation of prior models

A proposal for the quantification of probabilistic models is presented in this section. In general this information can be utilized for the formulation of prior models when new information, e.g., information of test data becomes available. However, the given specifications may also be seen as a common reference for e.g. code calibration procedures.

#### 3.3.1 Reference material properties

The distribution type and the recommended coefficient of variation (COV) of the basic material properties for European softwood are given in Table 3. Recommended distribution functions of other material properties are given in Table 4. The distribution parameters can be determined with the information given in Table 2 and 3. If additional information about the material property of interest of the considered population becomes available, e.g., inform of test data, this information should be integrated using a Bayesian updating scheme.

#### 3.3.2 Correlation matrix

The relations to other material properties are given in Table 2. Indicative values of the correlation coefficient matrix are given in Table 5.

#### 3.3.3 Strength and stiffness modification functions

Values for the strength modification function $\alpha(\cdot)$ are quantified for discrete exposures $Ex(s, w, t)$ as specified in Table 6. The particular sets of exposures are defined as in Eurocode (EC) 5 (EN 1995-1:2004); different load duration classes and different service classes (sc) depending on the expected moisture content (mc) of the timber (sc 1, 2, 3 is associated with mc <12%, <20%, <20%). The values for $\alpha(\cdot)$ are taken from EC 5.

Values for the stiffness modification function $\delta(\cdot)$ are quantified for discrete exposures $Ex(s, w, t)$ as specified in Table 7. The particular sets of exposures

4 REFINEMENTS OF THE PROBABILISTIC MODELS

4.1 Modeling the spatial variation of timber properties

4.1.1 Bending moment capacity

Following a model proposed by Isaksson (1999), the bending strength \( r_{m,i} \) at a particular point \( j \) in the component \( i \) of a structure can be modeled by:

\[
r_{m,i} = \exp \left( v + \sigma_j + X_j \right)
\]
The expected length of a section is 1 damage models with the general form: creep rupture and is modeled by so-called cumulative. Duration of load effect

\[ X(t) = \int_0^t h(s) \, ds \]

is assumed to be Poisson distributed, thus be constant within one section. The discrete section transition is illustrated in Figure 3. Figure 3. Section model for the longitudinal variation of bending strength.

where \( \nu \) is the unknown logarithm of the mean strength of all sections in all components (compare with Figure 3), \( \nu \) is normal distributed with mean value equal to zero and standard deviation \( \sigma_\nu \). \( \lambda \) is the difference between the strength weak section and the variable \( \nu \). \( \chi \) is normal distributed with mean value equal to zero and standard deviation \( \sigma_\chi \). \( \sigma_\nu \) and \( \chi \) are statistically independent. The bending strength \( R_{m,i} \) can be seen as the bending strength of a particular cross section \( R_{m,i} \) which is the lognormal distributed bending strength of a cross section.

It is assumed that the bending strength of a cross section \( R_{m,i} \) is related with the bending strength of a test specimen \( R_{m,s} \) as:

\[ R_{m,i} = \frac{R_{m,s}}{\nu_i} \]

where \( \nu \) is a constant depending on the applied bending test standard and the type of timber. The bending moment capacity \( R_{m,i} \) is assumed to be constant within one section. The discrete section transition is assumed to be Poisson distributed, thus the section length follows an exponential distribution with mean value \( 1/\lambda \). A realization of \( X, x_j \) is illustrated in Figure 3.

For Nordic spruce the following information basis can be given (Isaksson 1999): The variation of the logarithm of the bending capacity \( \ln (R_{m,i}) \) is related by 40% to the variable \( \nu \) and by 60% to the variable \( \chi \). The expected length of a section is \( 1/\lambda = 480 \text{ mm} \).

4.2 Duration of load effect

The mechanism leading to strength reduction of a timber member under sustained load is referred to as creep rupture and is modeled by so-called cumulative damage models with the general form:

\[ \frac{d\mu_i}{dt} = h(x(t), r_i, \alpha_{D}, \theta) \quad \text{for} \quad 0 \leq \alpha_{D} \leq 1 \]

where \( t \) is time, \( \alpha_{D} \) is the damage state variable which commonly ranges from 0 (no damage) to 1 (failure), the function \( h(\cdot) \) contains parameters \( \theta \) that must be determined from experiment observations, \( s(t) \) is the applied stress and \( r \) is the failure stress under short term ramp loading.

The following long term limit state function is utilized:

\[ g = 1 - X_i \alpha_D \{ S(t) \} \]

where \( \alpha_D \) is the damage state variable at time \( t \) and \( X_i \) is the model uncertainty. More information about damage accumulation modeling can be found in the JCSS Probabilistic Model Code, section 3.5 (JCSS 2006).

4.3 Updating scheme for the basic properties

When information has been collected about the basic material properties the new knowledge implicit in that information might be applied to improve any previous (prior) estimate of the material property. For the type of information e.g. it can be differentiated between direct and indirect information; i.e. direct measurements of the material property and the measurement of some indicator of the property respectively.

In the proposed framework new information can be introduced at any stage of modeling. In the following the principle of considering new direct information e.g. in form of test results is presented. The utilization of new indirect information, e.g. information from grading indications, is illustrated with two different methods.

In the following updating is illustrated with three different methods based on Bayesian updating as described in JCSS Probabilistic Model Code (JCSS 2006), section 3.0.

4.3.1 Updating – direct information

The bending strength \( R_m \) and the bending modulus of elasticity \( E_m \) are modelled by lognormal distributed random variables which can be represented through the normal distributed random variables \( R_m = \ln (R_m) \) and \( E_m = \ln (E_m) \). All basic properties may be represented with the uncertain mean value \( M \) and standard deviation \( \Sigma \) as illustrated by:

\[ R_m = \exp (R'_m) \sim N (M, \Sigma) \]

\[ E_m = \exp (E'_m) \sim N (M, \Sigma) \]

\[ \rho_{\text{tri}} : N (M, \Sigma) \]

The parameters \( M \) and \( \Sigma \) of \( R'_m, E'_m \) and \( \rho_{\text{tri}} \) are quantified with a Normal-Inverse-Gamma-2 distribution with the parameters \( m, s, n, v \) which is equivalent to
the natural conjugate prior of a normal distribution with unknown mean and standard deviation. Given the parameters \(m, s, n, v\) the predictive distribution of \(R_m\), \(E_m^v\) and \(\rho_{\text{link}}\) can be derived as:

\[
F_{\text{dist}}(x|m,n,s,v) = T\left(\frac{x - m}{s}\sqrt{\frac{n}{n+1}}\right)
\]

(14)

where \(T(.)\) is the student-t-distribution with \(v\) degrees of freedom.

The prior predictive distribution can be quantified with parameters \((m, s, n, v) = (m', s', n', v')\).

New measurements on the material properties can be used for updating the parameters given above. For a sample of \(n\) observations \((x_1, x_2, \ldots, x_n)\), the posterior predictive distribution of \(X\) is obtained using the JCSS Probabilistic Model Code (JCSS 2006), section 3.0.

4.3.2 Indirect information I – machine grading

In this section a simple model for updating the statistical parameters of the Lognormal distribution for e.g. the bending strength of a given timber grade when new information becomes available in the form of machine grading results is described.

The Lognormal distributed strength parameter \(R\) is assumed to have a coefficient of variation \(\text{COV} \varepsilon\). The bending strength \(R\) is then Lognormal with expected value \(\mu'\) and standard deviation \(\sigma\).

When machine grading is based on a measured indicator \(i_t\), typically related to the stiffness of a timber test specimen, the following relation between the indicator \(i\) and the strength \(R\) can be established for the bending strength of timber:

\[
i = b_0 + R^a \cdot \varepsilon
\]

(15)

where \(b_0\) and \(b_1\) are constants and \(\varepsilon\) is an error term which is assumed Lognormal distributed. \(\text{ln}(\varepsilon)\) is then Normal distributed and is assumed to have zero mean value and standard deviation \(\sigma_{\text{ln}(\varepsilon)}\). The parameters \(b_0\), \(b_1\) and \(\sigma_{\text{ln}(\varepsilon)}\) can be estimated from the tests using the Maximum Likelihood method.

\[
\ln \tilde{\varepsilon} = 1/n \sum_{i=1}^{n} \ln i
\]

(16)

Next, it is assumed that \(n\) new observations \(i_1, i_2, \ldots, i_n\) of the indicator is obtained from \(n\) specimens from a given timber grade. The mean value of these can be estimated as:

\[
\ln \tilde{\varepsilon}' = 1/n \sum_{i=1}^{n} \ln i'
\]

and the updated (predictive) distribution function for \(X = \ln R\) is then Normal with expected value \(\mu''\) and standard deviation \(\sigma''\):

\[
\begin{align*}
\mu'' &= \frac{n}{\ln b_0 + \mu_0\sigma_i^2}\frac{\ln \tilde{\varepsilon}'}{n\sigma_i^2 + \sigma_i^2}
\end{align*}
\]

(17)

The updated predictive distribution for the strength \(R\) is then Lognormal with expected value \(\mu'' = \exp(\mu'' - 0.5\sigma''^2)\) and standard deviation \(\sigma'' = \mu''\exp(\sigma''^2) - 1)^{0.5}\).

4.3.3 Updating – indirect information II – calibration of grading rules

The probabilistic model for bending strength described in this section can be used for machine graded timber and is based on the model described in Faber et al. (2004). The probabilistic model can be described by the following steps:

For a given geographic region and a given type of specie (e.g. Nordic Spruce) an initial (prior) distribution function \(F_{R_{ni}}(x)\) can be established for the bending strength \(R_{ni}\) for non-graded timber. The recommended distribution function is Lognormal. The statistical parameters in the distribution function can be obtained using e.g. the Maximum Likelihood method. For the identification of lower grades it is recommended to fit the initial (prior) distribution function \(F_{R_{ni}}(x)\) to the data in the lower end (e.g. 30% of the data with lowest strengths); in order to obtain good models in the lower tail of the distribution function for the graded timber strength. This can be done using the Maximum Likelihood method, see e.g. in Faber et al. (2004).

Machine grading is based on a measured indicator \(i_t\), typically related to the stiffness of a timber test specimen. For each grading technique the following linear relation with the bending strength is assumed:

\[
i(r) = a_0 + a_1 r + \varepsilon
\]

(18)

where \(a_0\) and \(a_1\) are constants and \(\varepsilon\) is the lack-of-fit quantity which is assumed Normal distributed with zero mean value and standard deviation \(\sigma_\varepsilon\). The parameters \(a_0\), \(a_1\) and \(\sigma_\varepsilon\) can be estimated using the Maximum Likelihood method which also gives the statistical uncertainty in form of standard deviations and correlation coefficients of the parameters \(a_0\), \(a_1\) and \(\sigma_\varepsilon\). It is noted that in Eq. (15) the logarithms are fitted with a Lognormal distributed lack-of-fit error, whereas in Eq. (18) a linear model with a Normal distributed lack-of-fit error is used.
After grading the updated (predictive) distribution function for the bending strength in grade no. \( j \) is obtained from:

\[
F_{L,j}^{U}(x) = P\left(R_j \leq x | b_{L,j} \leq U_j(x) \leq b_{U,j}\right)
\]

where \( b_{L,j} \) and \( b_{U,j} \) are lower and upper limits of the grading indicator \( i \) for grading no. \( j \). The updated distribution function \( F_{L,j}^{U}(x) \) can then be used in reliability analyses. A detailed description of the method can be found in Faber et al. 2004 and Köhler 2003.

5 EXAMPLE – RELIABILITY BASED CODE CALIBRATION

In Faber & Sørensen (2003) the principles of reliability based code calibration is demonstrated. In the following the approach followed there is illustrated along with an example on code calibration for a timber design code.

Reliability analysis of structures for the purpose of code calibration in general or for the reliability verification of specific structures requires that the relevant failure modes be represented in terms of limit state functions. The limit state functions define the realizations of resistance parameters, i.e. the material properties and the load variables resulting in structural failure.

In code based design formats such as the Eurocodes (EN 1990-1 2002), design equations are prescribed for the verification of the capacity of different types of structural components in regard to different modes of failure. The typical format for the verification of a structural timber component in Eurocode 5 (1990-1 2004) is given as a design equation in the following form:

\[
G = k_{mod} \sum_{i=1}^{n} \left( r_i / Y_i - \sum_{j=1}^{m} \psi_j J_{j,i} S_{j,i} \right) = 0
\]

where \( r_i \) is the characteristic value for the resistance, \( z_d \) is the design variable (e.g. the cross section of a timber beam), \( s_{j,k} \) are the characteristic values of load effects which are considered in the design, \( g_j \) and \( \gamma_j \) are partial safety factors for the resistance and the load effects respectively, and \( \psi_j \) are load combination factors. \( S_{j,i} \) are factors indicating relative frequency / importance of the different load parameters.

The following optimization problem can be formulated, (Faber & Sørensen 2003):

\[
\min W(\gamma) = \sum_{i=1}^{n} w_i (\beta(\gamma) - \beta_i)^2
\]

where \( \beta_i \) is the reliability index corresponding to the target reliability, \( \beta(\gamma) \) is the reliability index corresponding to a design performed with a set of partial safety factors \( \gamma \) and \( w_i, i = 1, 2, \ldots, L \) are factors indicating relative frequency / importance of the different design situations.

The code calibration procedure as described above is already included in the software package CodeCal, a MS EXCEL based software, which is provided as software by the JCSS (2006). In the following, the partial safety factors $\mathbf{\gamma} = (\gamma_M, \gamma_G, \gamma_Q)$ are calibrated using CodeCal. The calibration takes basis in Eqs. (22)–(23). The probabilistic model of the random variables of the problem are chosen as proposed in the JCSS PMC (JCSS 2006) and shown in Table 9.

$L = 10$ design situations are considered (see Eqs. (22), (eq23)). For a chosen target reliability index $\beta_t = 4.2$ (yearly, as recommended in the JCSS PMC (JCSS 2006)) the partial safety factors are calibrated by solving Eq.(24). The calibrated set of partial safety factors together with the partial safety factors prescribed in EC5 (2004) is given in Table 9.

In Figure 4 the reliability index $\beta$ is plotted over the different design situations represented by different values of $\alpha_i$. It shows how the set of partial safety factors prescribed in EC5 is not corresponding to the optimal set if all partial safety factors are subject to calibration. In load and resistance factor design (LRFD) formats as EC5, however, partial safety factors for load effects are in general similar and independent from the structural material which is utilized. Therefore, code calibration procedures should involve all possible building materials, i.e. calibrate partial safety factors considering all relevant design situations and materials. The software package CodeCal facilitates this option.

6 CONCLUSIONS, DISCUSSION AND OUTLOOK

A framework for probabilistic modeling of timber material properties is presented. The basic reference properties for timber strength parameters are described and some limit state equations are formulated. The recommended probabilistic model for the basic properties is presented and indicative numerical values for the parameters are given. Refinements related to updating of the probabilistic model given new information, spatial variation of strength and duration of load effects are described.

The proposal can be seen as a guideline and common reference for probability based code calibration of timber design codes as it is illustrated with an example. The parameters of the proposed models, however, need to be quantified on a broad and representative data base. Comprehensive experimental data concerning the basic timber phenomena already exist, especially resulting from research projects in North America, Europe and Australia. One major task for developing further the presented model code is to collect and assess existing experimental data. The timber research community is asked to contribute by making available experimental data for the quantification of model parameters for timber predominantly used for timber design.

The present version of the ‘JCSS – Timber Probabilistic Model Code’ does not cover all aspects of
the design of timber structures. An attempt to model the spatial variability of the timber bending strength is presented in this document. More experimental work should be performed or reviewed to quantify the parameters of the presented model. The description of size effects in regard to the modeling of other material properties has earned considerable recognition in the past research; no general consensus has been reached and future research should be directed in the development of a consistent framework for the description of size effects in structural timber elements. For timber structures, the structural performance depends to a considerable part on the connections between different timber structural members; connections can govern the overall strength, serviceability and fire resistance. Beside solid timber other timber materials are utilized in timber engineering. Glued laminated timber is an example of an interesting timber material, frequently used in high performance load carrying structures. It is of utmost importance to develop consistent probabilistic models for these timber materials and for timber connections, especially in the perspective of their potential competitiveness to other building materials such as steel and reinforced concrete.

The further development of the probabilistic model code for timber should constitute an important future task for the timber research community.
