Abstract—In this paper, we propose a null-space-based preemptive scheduling framework for cross-objective optimization to always guarantee robust URLLC performance, while extracting the maximum possible eMBB capacity. The proposed scheduler perpetually grants incoming URLLC traffic a higher priority for instant scheduling. In case that radio resources are not immediately schedulable, proposed scheduler forcibly enforces an artificial spatial user separation, for the URLLC traffic to get instantly scheduled over shared resources with ongoing eMBB transmissions. A pre-defined reference spatial subspace is constructed for which scheduler instantly picks the active eMBB user whose precoder is the closest possible. Then, it projects the eMBB precoder on-the-go onto the reference subspace, in order for its paired URLLC user to orient its decoder matrix into one possible null space of the reference subspace. Hence, a robust decoding ability is always preserved at the URLLC user, while cross-maximizing the ergodic capacity. Compared to the state-of-the-art proposals from industry and academia, proposed scheduler shows extreme URLLC latency robustness with significantly improved overall spectral efficiency. Analytical analysis and extensive system level simulations are presented to support paper conclusions.

Index Terms—URLLC; eMBB; Null space; MU-MIMO; 5G; Preemptive; Puncture scheduling.

I. INTRODUCTION

Emerging fifth generation (5G) systems are envisioned to support two major service classes: ultra-reliable low-latency communications (URLLC) and enhanced mobile broadband (eMBB) [1]. URLLC refer to the future services that demand extremely reliable and low latency data communication, i.e., one-way latency up to 1 ms with $10^{-5}$ outage probability [2]. That is, the quality of service (QoS) of the URLLC-type applications is infringed if more than one packet out of $10^3$ packets are not successfully decoded within the 1 ms deadline. This URLLC QoS is immensely different from that of the current long term evolution (LTE) technology [3], where the overall spectral efficiency (SE) is the prime objective.

To satisfy such stringent latency requirements, the system should be always engineered so that blocking a URLLC packet is a very rare event. Therefore, URLLC services must satisfy their individual outage capacity, instead of the ergodic capacity. That is, by setting an ultra-tight target block error rate (BLER) to always ensure a sufficient URLLC decoding ability. This way, it leads to a significant loss of the network SE due to the fundamental tradeoff between reliability, latency and the achievable SE [4].

In the recent literature, diverse 5G scheduling contributions have been introduced. User-centric scheduling with variable transmission time intervals (TTIs) [5] is essential to minimize the URLLC frame alignment and queuing delays. Furthermore, URLLC spatial diversity techniques are vital to preserve a sufficient URLLC signal-to-interference-noise-ratio (SINR). For example, the work in [6] demonstrates that a $4 \times 4$ multi-input multi-output (MIMO) microscopic diversity and two orders of macroscopic diversity are required to reach the URLLC outage SINR level. A recent study [7] further extends the usage of the spatial diversity for URLLC by flexibly allocating coded segments of the URLLC payload message to different interfaces. Thus, a better latency-reliability tradeoff can be achieved by reducing the original payload transmission time. Additionally, URLLC punctured scheduling (PS) [8] is a state-of-the-art scheme to further minimize the queuing delay of the URLLC traffic, where sporadic URLLC traffic is instantly scheduled by overwriting part of the radio resources, monopolized by ongoing eMBB transmissions.

However, the majority of the URLLC scheduling studies consider a monotonic optimization structure of the URLLC outage capacity. Therefore, URLLC requirements can be proportionally satisfied only with the size of the URLLC granted resources or received SINR levels. However, when joint eMBB and URLLC traffic coexists on the same radio spectrum, this approach fails to reach a proper system ergodic capacity.

In this work, a null-space-based preemptive scheduling (NSBPS) for joint eMBB and URLLC traffic is proposed. Proposed scheduler seeks to dynamically fulfill a jointly constrained objective, for which the URLLC QoS is guaranteed, while achieving the best possible eMBB capacity. If the available radio resources are not sufficient to accommodate the URLLC payload, NSBPS forcibly fits the URLLC traffic within an ongoing eMBB transmission in an instant, controlled, semi-transparent and biased multi-user MIMO (MU-MIMO) transmission. The proposed NSBPS instantly selects an active eMBB user whose transmission is most aligned within an arbitrary reference subspace. It spatially projects the selected eMBB transmission onto the reference subspace for which its paired URLLC user de-orients its decoding matrix into one possible null-space. Accordingly, a robust SINR level is preserved at the URLLC user side. Compared to the state-of-the-art studies, proposed NSBPS shows extreme robustness of the URLLC QoS with significantly improved ergodic capacity.

Due to the complexity of the 5G new radio (NR) system model [1-3] and addressed problems therein, the performance of the proposed scheduler is validated by extensive system simulations (SLS), and supported by analytical analysis of
the major performance indicators. Those simulations are based on widely accepted models and calibrated against the 5G NR specifications to ensure highly reliable statistical results.

Notations: $(X)^T$, $(X)^H$ and $(X)^{-1}$ stand for the transpose, Hermitian, and inverse operations of $X$, $X \cdot Y$ is the dot product of $X$ and $Y$, while $\mathbb{E}$ and $\|X\|$ represent the mean and 2-norm of $X$. $\mathbb{C}_K$ indicates a complex Gaussian random variable with zero mean and variance $\sigma^2$, $\mathcal{K}_c \subseteq \{llc, mbb\}$ denotes the type of user $\mathcal{X}$, $\mathbb{E}\{\mathcal{X}\}$ and $\text{card}(\mathcal{X})$ are the statistical expectation and cardinality of $\mathcal{X}$.

The paper is organized as follows. Section II presents the system and signal models, respectively. Section III states the problem formulation and detailed description of the NSBPS scheduler. Extensive system level simulation results are introduced in Section IV, and paper results are concluded in Section V.

II. SYSTEM MODEL

We consider a 5G-NR downlink (DL) MU-MIMO system where there are $C$ cells, each equipped with $N_t$ transmit antennas, and $K$ uniformly distributed user equipment’s (UEs) per cell, each with $M_r$ receive antennas. Users are multiplexed by the orthogonal frequency division multiple access (OFDMA).

Two types of DL traffic are under assessment as: (a) URLLC bursty FTP3 traffic model with a finite B-byte payload and Poisson arrival process $\lambda$, and (b) eMBB full buffer traffic with infinite payload size. The total number of UEs per cell is: $K_{mbb} + K_{llc} = K$, where $K_{mbb}$ and $K_{llc}$ are the average numbers of eMBB and URLLC UEs per cell, respectively.

The agile 5G-NR frame structure is adopted [5], where the URLLC and eMBB UEs are scheduled with variable TTI periodicity. As depicted in Fig. 1, eMBB traffic is scheduled with a long TTI of 14-OFDM symbols for SE maximization while URLLC traffic with a shorter TTI of 2-OFDM symbols due to its latency budget. In the frequency domain, the smallest scheduling unit is the physical resource block (PRB), which is 12 sub-carriers and with 15 kHz sub-carrier spacing.

A maximal subset of MU co-scheduled URLLC-eMBB user pairs $g_c \in K_c$ is allowed over an arbitrary PRB in the $c^{th}$ cell, where $G_c = \text{card}(g_c)$, $G_c \leq N_t$ is the number of co-scheduled UEs and $K_c$ is the set of all active UEs in the $c^{th}$ cell. Since $N_t \leq K_M$, user selection on top of equal power allocation is assumed for MU pairing. The received DL signal at the $k^{th}$ user from the $c^{th}$ cell can be modeled as

$$y_{k,c}^c = H_{k,c}^c v_{k,c}^c s_{k,c}^c + \sum_{g \in g_c, g \neq k} H_{k,g}^c v_{g,k}^c s_{g,k}^c + n_{k,c},$$

where $H_{k,c}^c \in \mathbb{C}^{N_r \times N_t}, \forall k \in \{1, \ldots, K\}, \forall c \in \{1, \ldots, C\}$ is the wireless channel observed at the $k^{th}$ user from the $c^{th}$ cell, $v_{k,c}^c \in \mathbb{C}^{N_t \times 1}$ is the zero-forcing precoding vector, assuming a single layer transmission per user, where it is given as: $v_{k,c}^c = (H_{k,c}^c)^H (H_{k,c}^c H_{k,c}^c)^{-1}$. $s_{k,c}^c$ and $n_{k,c}$ denote the transmitted symbol and the additive white Gaussian noise at the $k^{th}$ user, respectively. The first and second summation terms represent the intra-cell-inter-user and inter-cell interference, generated from either the URLLC or eMBB traffic. In this work, the 3GPP 3D spatial channel model [9] is adopted, where the DL channel coefficient observed by the $m^{th}$ receive antenna from the $n^{th}$ transmit antenna is composed from $Q$ spatial clusters, each with $Z$ rays as

$$h_{m,n,k}^c = \frac{1}{\sqrt{Q}} \sum_{q=0}^{Q-1} \delta_k g_{q,k} r_{m,n,q,k},$$

where $\delta_k = \ell \rho_k \mu_k$, $\ell$ and $\mu_k$ are the propagation and shadow fading coefficients, respectively, and $\epsilon_k^m$ is the distance, with $\vartheta$ as the pathloss factor, and $g_{q,k} \sim \mathbb{C}_Q(0,1)$. The steering factor $r_{m,n,q,k}$ is given by

$$r_{m,n,q,k} = \sqrt{\frac{\xi}{Z} \sum_{z=0}^{Z-1} \left( \frac{\sqrt{2 \pi m_{n,q,k}(\theta_{\text{AoA}}, \varphi_{\text{EoD}})} e^{j(\rho T_f \vartheta_{\text{m,n,q,k}})}}{2 \pi m_{n,q,k}(\theta_{\text{AoA}}, \varphi_{\text{EoD}})} \right)^2 + \frac{\sqrt{2 \pi m_{n,q,k}(\theta_{\text{AoD}}, \varphi_{\text{TD}})} e^{j(\rho T_f \vartheta_{\text{m,n,q,k}})}}{2 \pi m_{n,q,k}(\theta_{\text{AoD}}, \varphi_{\text{TD}})}},$$

where $\xi$ and $\psi$ are the power and large-scale coefficients, $\mathbb{D}_{\text{BS}}$ and $\mathbb{D}_{\text{UE}}$ are the antenna patterns at the BS and UE, respectively, $n$ is the wave number, $\theta$ denotes the horizontal angle of arrival $\theta_{\text{AoA}}$ and departure $\theta_{\text{AoD}}$, while $\varphi$ denotes the elevation angle of arrival $\varphi_{\text{EoA}}$ and departure $\varphi_{\text{EoD}}$, respectively, $s$ is the speed of the $k^{th}$ user, $T_f = f_s \cos \vartheta_{\text{AoA}} \cos \varphi_{\text{EoD}}$ is the displacement vector of the uniform linear transmit array.

The received signal at the $k^{th}$ user is decimated by applying the antenna combining as: $(y_{k,c}^c)^* = (u_{k,c}^c)^* y_{k,c}^c$, where $u_{k,c}^c$ is designed by the linear minimum mean square error interference rejection combining (LMMSE-IRC) receiver [10]. The received SINR level at the $k^{th}$ user is then calculated as

$$\gamma_{k,c} = \frac{p_k^c \|H_{k,c}^c v_{k,c}^c\|^2}{1 + \sum_{g \in g_c, g \neq k} p_g^c \|H_{k,g}^c v_{g,k}^c\|^2 + \sum_{j=k}^N \sum_{g \in g_c, j \neq k} p_j^c \|H_{k,j}^c v_{j,k}^c\|^2},$$

where $p_k^c$ is the transmit power intended for the $k^{th}$ user. Then, the $k^{th}$ user received rate on a given PRB is given by

$$r_{k,r,b}^c = \log_2 \left( 1 + \frac{1}{G_{k,c}} T_{k,c}^c \right).$$

Accordingly, the user SINR levels across different $N_s$ sub-carriers are mapped into a single effective SINR using the effective exponential SNR mapping [11] as

$$\left( T_{k,c}^c \right)^{\text{eff}} = -\ln \left( \frac{1}{N_s} \sum_{i=1}^{N_s} e^{-\gamma_{k,c}^{(i)}} \right),$$

with $\partial$ as a calibration parameter.
III. PROPOSED NSBPS SCHEDULER

A. Problem Formulation

Under a 5G-NR system, there are user-centric, instead of network-centric, QoS utility functions. These are highly coupled and need to be reliably fulfilled, e.g., eMBB rate maximization and URLLC latency minimization as

\[ \forall k_{mbb} \in K_{mbb} : R_{mbb} = \arg \max \limits_{k_{mbb} \in K_{mbb}} \sum \beta_{k_{mbb}} R_{mbb}^{k_{mbb}}. \]

where \( R_{mbb} \) is the overall eMBB ergodic capacity, \( K_{mbb} \) and \( K_{llc} \) represent the active sets of eMBB and URLLC users, respectively; \( \beta_{k_{mbb}} \) and \( \beta_{k_{llc}} \) denote the granted set of PRBs and a priority factor of the \( k_{th} \) eMBB user. \( \psi_{k_{llc}} \) is the URLLC target one-way latency, which is expressed as

\[ \psi_{k_{llc}} = \lambda_q + \lambda_{bap} + \lambda_{bup} + \lambda_{tx} + \lambda_{uep}, \]

where \( \lambda_q \), \( \lambda_{bap} \), \( \lambda_{bup} \), \( \lambda_{tx} \), and \( \lambda_{uep} \) are the queuing, BS processing, frame alignment, transmission, and UE processing delays, respectively. \( \lambda_q \) is upper-bounded by the short TTI interval while \( \lambda_{bap} \) and \( \lambda_{bup} \) are bounded by 3-OFDM symbol duration [12], due to the enhanced processing capabilities with the 5G-NR. Hence, \( \lambda_{tx} \) and \( \lambda_q \) are the major impediment against achieving the hard URLLC latency budget. \( \lambda_{tx} \) depends on the outage SINR level as given by

\[ \lambda_{tx} = \frac{B}{\sum \psi_{k_{llc}} \log_2 \left( 1 + \frac{r_{mbb}}{r_{mbb}} \right)}. \]

with \( F \) is the outage gap between the expected and actual received SINR levels. The URLLC queuing delay \( \lambda_q \) can be modeled by the A/A/\( a \)/\( o \) queuing model [13], where the first \( A \) denotes a Poisson packet arrival, second \( A \) means exponential service times out of the queue, notation \( a \) represents the maximum number of the URLLC simultaneous transmissions, and notation \( o \) implies that an arriving URLLC packet will be dropped if there are \( o \) outstanding packets, worth of more than 1 ms in the queue. Thus, the probability of the URLLC reliability loss, i.e., \( \lambda_q \geq 1 \) ms, is given as

\[ \rho_{st} = \left( \rho_o \frac{n^a}{a!} \right) \rho^o, \]

where \( \rho_o \) is the probability of the queue being empty, and \( \rho = \left( \frac{\lambda_{tx}}{\lambda_{uep}} \right) \) with \( \frac{1}{\bar{s}} \) as the mean service time. Thus, to achieve the critical URLLC latency, the transmission and queuing delays should be always minimized to provide further allowance for the re-transmission delay. This can be achieved by guaranteeing a sufficient outage SINR level or allocating excessive PRBs to URLLC traffic in order to further minimize \( \rho_{st} \). In both cases, the eMBB utility function in (7) will be ill-optimized, leading to a severe degradation of the network SE.

B. Description of The Proposed NSBPS Scheduler

The proposed NSBPS scheduler seeks to simultaneously cross-optimize the joint objectives of the eMBB and URLLC traffic. Thus, the critical URLLC latency deadline is satisfied regardless of the system loading while reaching the best achievable eMBB performance. In the following sub-sections, we describe the proposed NSBPS scheduler in-detail.

At the BS side:

At an arbitrary TTI instance, if there are no newly incoming URLLC packets, NSBPS allocates single-user (SU) dedicated resources to the new/buffered eMBB traffic based on the standard proportional fair (PF) metric as

\[ \Theta \{ \text{PF}_{k_{mbb}} \} = \frac{r_{mbb}}{r_{mbb} + r_{mbb}}, \]

where \( r_{mbb} \) is the average delivered data rate of the \( k_{th} \) user. If sporadic DL URLLC packets arrive at the BS while sufficient radio resources are instantly available, the NSBPS scheduler immediately overpowers the eMBB traffic SU priority and assigns SU resources to incoming URLLC traffic based on the weighted PF (WPF) criteria instead as:

\[ \Theta \{ \text{WPF}_{k_{mbb}} \} = \frac{r_{mbb}^{\text{uep}}}{r_{mbb}^{\text{uep}} + r_{mbb}}; \beta_{k_{mbb}}, \]

where \( r_{mbb}^{\text{uep}} \) is the average data rate of the \( k_{th} \) user. When the critical URLLC latency deadline is satisfied, the scheduler enforces an instant, biased and controlled MU scheduling. If sporadic DL URLLC packets arrive at the BS while sufficient radio resources are instantly available, the NSBPS scheduler immediately overpowers the eMBB traffic SU priority and assigns SU resources to incoming URLLC traffic based on the weighted PF (WPF) criteria instead as:

\[ \Theta \{ \text{WPF}_{k_{mbb}} \} = \frac{r_{mbb}^{\text{uep}}}{r_{mbb}^{\text{uep}} + r_{mbb}}; \beta_{k_{mbb}}, \]

where \( r_{mbb}^{\text{uep}} \) is the average data rate of the \( k_{th} \) user. When the critical URLLC latency deadline is satisfied, the scheduler enforces an instant, biased and controlled MU scheduling. If sporadic DL URLLC packets arrive at the BS while sufficient radio resources are instantly available, the NSBPS scheduler immediately overpowers the eMBB traffic SU priority and assigns SU resources to incoming URLLC traffic based on the weighted PF (WPF) criteria instead as:

\[ \Theta \{ \text{WPF}_{k_{mbb}} \} = \frac{r_{mbb}^{\text{uep}}}{r_{mbb}^{\text{uep}} + r_{mbb}}; \beta_{k_{mbb}}, \]

where \( r_{mbb}^{\text{uep}} \) is the average data rate of the \( k_{th} \) user. When the critical URLLC latency deadline is satisfied, the scheduler enforces an instant, biased and controlled MU scheduling. If sporadic DL URLLC packets arrive at the BS while sufficient radio resources are instantly available, the NSBPS scheduler immediately overpowers the eMBB traffic SU priority and assigns SU resources to incoming URLLC traffic based on the weighted PF (WPF) criteria instead as:

\[ \Theta \{ \text{WPF}_{k_{mbb}} \} = \frac{r_{mbb}^{\text{uep}}}{r_{mbb}^{\text{uep}} + r_{mbb}}; \beta_{k_{mbb}}, \]

where \( r_{mbb}^{\text{uep}} \) is the average data rate of the \( k_{th} \) user. When the critical URLLC latency deadline is satisfied, the scheduler enforces an instant, biased and controlled MU scheduling. If sporadic DL URLLC packets arrive at the BS while sufficient radio resources are instantly available, the NSBPS scheduler immediately overpowers the eMBB traffic SU priority and assigns SU resources to incoming URLLC traffic based on the weighted PF (WPF) criteria instead as:

\[ \Theta \{ \text{WPF}_{k_{mbb}} \} = \frac{r_{mbb}^{\text{uep}}}{r_{mbb}^{\text{uep}} + r_{mbb}}; \beta_{k_{mbb}}, \]

where \( r_{mbb}^{\text{uep}} \) is the average data rate of the \( k_{th} \) user. When the critical URLLC latency deadline is satisfied, the scheduler enforces an instant, biased and controlled MU scheduling. If sporadic DL URLLC packets arrive at the BS while sufficient radio resources are instantly available, the NSBPS scheduler immediately overpowers the eMBB traffic SU priority and assigns SU resources to incoming URLLC traffic based on the weighted PF (WPF) criteria instead as:

\[ \Theta \{ \text{WPF}_{k_{mbb}} \} = \frac{r_{mbb}^{\text{uep}}}{r_{mbb}^{\text{uep}} + r_{mbb}}; \beta_{k_{mbb}}, \]

where \( r_{mbb}^{\text{uep}} \) is the average data rate of the \( k_{th} \) user. When the critical URLLC latency deadline is satisfied, the scheduler enforces an instant, biased and controlled MU scheduling. If sporadic DL URLLC packets arrive at the BS while sufficient radio resources are instantly available, the NSBPS scheduler immediately overpowers the eMBB traffic SU priority and assigns SU resources to incoming URLLC traffic based on the weighted PF (WPF) criteria instead as:

\[ \Theta \{ \text{WPF}_{k_{mbb}} \} = \frac{r_{mbb}^{\text{uep}}}{r_{mbb}^{\text{uep}} + r_{mbb}}; \beta_{k_{mbb}}, \]
an arbitrary discrete Fourier transform spatial subspace \( \mathbf{v}_{\text{ref}}(\theta) \), pointing towards angle \( \theta \), is constructed by

\[
\mathbf{v}_{\text{ref}}(\theta) = \left( \frac{1}{\sqrt{N_t}} \left[ 1, e^{-j2\pi \Delta \cos \theta}, \ldots, e^{-j2\pi \Delta (N_t-1) \cos \theta} \right]^T \right),
\]

where \( \Delta \) is the absolute antenna spacing. Next, the NSBPS searches for one active eMBB user whose precoder is closest pointing towards angle \( \theta \) within an arbitrary discrete Fourier transform spatial subspace \( \mathbf{v} \).

Then, scheduler instantly projects the precoder vector of the selected eMBB user \( \mathbf{v}_{\text{mbb}}^\dagger \) onto \( \mathbf{v}_{\text{ref}} \) as given by

\[
 \left( \mathbf{v}_{\text{mbb}}^\dagger \right)' = \frac{\mathbf{v}_{\text{mbb}}^\dagger \cdot \mathbf{v}_{\text{ref}}}{\| \mathbf{v}_{\text{ref}} \|^2} \times \mathbf{v}_{\text{ref}},
\]

where \( \left( \mathbf{v}_{\text{mbb}}^\dagger \right)' \) is the updated eMBB user precoder. The NSBPS scheduler then instantly schedules the incoming URLLC traffic over shared resources with the impacted eMBB user. Since the instant precoder projection is transparent to the victim eMBB user, it exhibits a SE projection loss. However, eMBB loss is constrained minimum, especially under high eMBB user load, e.g., NSBPS scheduler has a higher probability to find an eMBB user whose precoder is originally aligned within \( \mathbf{v}_{\text{ref}} \), such that the instant projection process would not greatly impact its achievable capacity. Finally, the BS acknowledges the URLLC user by a single-bit Co-scheduling indication \( \alpha = 1 \), to be instantly transmitted in the user-centric control channel.

**At the URLLC user side:**

Upon reception of \( \alpha = 1 \), the URLLC user realizes that its granted resources, from the scheduling grant, are shared with an active eMBB user whose transmission is aligned within the reference subspace \( \mathbf{v}_{\text{ref}} \). Thus, the first-stage decoder matrix of the URLLC user is constructed by a standard LMMSE-IRC receiver to reject the inter-cell interference

\[
\begin{align*}
\mathbf{u}_{k}^{(1)} &= \left( \mathbf{H}_{k}^{\text{ref}} \mathbf{v}_{\text{ref}} \left( \mathbf{H}_{k}^{\text{ref}} \mathbf{v}_{\text{ref}} \right)^{H} + \mathbf{W} \right)^{-1} \mathbf{H}_{k}^{\text{ref}} \mathbf{v}_{\text{ref}},
\end{align*}
\]

where the interference covariance matrix is given by

\[
\mathbf{W} = \mathbb{E} \left\{ \mathbf{H}_{k}^{\text{ref}} \mathbf{v}_{\text{ref}} \left( \mathbf{H}_{k}^{\text{ref}} \mathbf{v}_{\text{ref}} \right)^{H} \right\} + \sigma^2 \mathbf{I}_{M_{r}},
\]

where \( \mathbf{I}_{M_{r}} \) is \( M_{r} \times M_{r} \) identity matrix. The IRC vector \( \mathbf{u}_{k}^{(1)} \) is then de-oriented to be aligned within one possible null space of the effective inter-user interference subspace \( \mathbf{H}_{k}^{\text{ref}} \mathbf{v}_{\text{ref}} \), as expressed by

\[
\begin{align*}
\mathbf{u}_{k}^{(2)} &= \mathbf{u}_{k}^{(1)} - \frac{\left( \mathbf{u}_{k}^{(1)} \right)^{H} \mathbf{H}_{k}^{\text{ref}} \mathbf{v}_{\text{ref}}}{\| \mathbf{H}_{k}^{\text{ref}} \mathbf{v}_{\text{ref}} \|^2} \times \mathbf{H}_{k}^{\text{ref}} \mathbf{v}_{\text{ref}},
\end{align*}
\]

This way, the final URLLC decoder vector \( \mathbf{u}_{k}^{(2)} \) exhibits no inter-user interference, providing the URLLC user with a robust decoding ability.

**C. Analytic Analysis Compared to State of The Art**

We compare the performance of the proposed NSBPS scheduler against the state-of-the-art schedulers as follows:

1. **Punctured scheduler (PS)** [8]: the URLLC traffic is always scheduled a higher scheduling priority. If radio resources are not available, PS scheduler instantly overwrites part of the ongoing eMBB transmissions, i.e., immediately stop an ongoing eMBB transmission, for instant URLLC scheduling. PS scheduler shows significant improvement of the URLLC latency performance at the expense of highly degraded SE.

2. **Multi-user punctured scheduler (MUPS)** [14]: in our past work, we considered a MU scheduler on top of the PS scheduler. MUPS first attempts to achieve a successful MU-MIMO transmission between a URLLC-eMBB user pair; however, it is a transparent, non-biased and non-controlled MU-MIMO. If the SDoFs are limited, MUPS scheduler rolls back to PS scheduler. MUPS has shown an improved performance tradeoff between system SE and URLLC latency; however, with a limited and non-robust gain, due to the non-controlled MU-MIMO and the SE-less efficient PS events.

Accordingly, the aggregate eMBB user rate can be linearly calculated from the individual sub-carrier rates for simplicity, assuming OFDMA flat fading channels, as

\[
\mathbf{r}_{\text{mbb}} = \Xi_{\text{mbb}} \mathbf{r}_{\text{mbb}} + \mathbf{r}_{\text{rb}}.
\]

Then, the portion of the radio resources \( I_{\text{k mbb}}^\text{llc} \) allocated to the \( k^\text{th} \) eMBB user, and being altered by the sporadic URLLC traffic, can be expressed by a set of random variables, as

\[
\Gamma = \left\{ \mathbf{r}_{\text{mbb}} \mid k_{\text{mbb}} \in K_{\text{mbb}} \right\}.
\]

Since URLLC packets are of small payload size, it is reasonably to assume that \( I_{\text{k mbb}}^\text{llc} \leq \Xi_{\text{mbb}} \) is almost surely satisfied. Hence, the actual eMBB rate is formulated by the joint URLLC-eMBB rate allocation function, given by

\[
R_{\text{mbb}} = \mathcal{F} \left( \Xi_{\text{mbb}}, I_{\text{k mbb}}^\text{llc} \right).
\]

For an instance, if an eMBB user is allocated SU dedicated resources, then \( \mathcal{F} \left( \Xi_{\text{mbb}}, I_{\text{k mbb}}^\text{llc} \right) = \Xi_{\text{mbb}} \mathbf{r}_{\text{mbb}} + \mathbf{r}_{\text{rb}} \), with no capacity loss. However, due to the prioritized URLLC traffic, the actual eMBB user rate suffers a loss over a portion of the allocated resources, expressed by the rate loss function \( \Pi \) as

\[
\mathcal{F} \left( \Xi_{\text{mbb}}, I_{\text{k mbb}}^\text{llc} \right) = \Xi_{\text{mbb}} \mathbf{r}_{\text{mbb}} + \mathbf{r}_{\text{rb}} (1 - \Pi),
\]

where the rate loss function \( \Pi : [0, 1] \to [0, 1] \) indicates the effective portion of impacted PRBs of the \( k^\text{th} \) eMBB user. Under the proposed NSBPS scheduler, the gain of the updated eMBB effective channel is given as

\[
Q_{k}^\text{mbb} = \left[ \left( \mathbf{H}_{k}^{\text{ref}} \mathbf{v}_{k^{\dagger}} \right) \times \left( \mathbf{H}_{k}^{\text{ref}} \mathbf{v}_{k^{\dagger}} \right)^{H} \right]^{T},
\]

where \( Q_{k}^\text{mbb} \) is the achievable post-projection channel gain of the \( k^\text{th} \) eMBB user, and its magnitude can be rewritten in terms of the precoder projection loss, i.e., the on-the-fly eMBB precoder update from \( \mathbf{v}_{k^{\dagger}} \) to \( \mathbf{v}_{k^{\dagger}} \), as
where $\sin^2\left(\theta_{\text{mbb}}^{\text{transmitted}}(\vartheta_{\text{mbb}}^s)\right)$ introduces the eMBB projection loss over the shared resources with the URLLC traffic, with $\theta_{\text{mbb}}^{\text{transmitted}}(\vartheta_{\text{mbb}}^s)$ as the spatial angle deviation between its original and projected precoders. Thus, $\Pi$ can be expressed as

$$\Pi_{\text{NSBPS}} = \left(\frac{\gamma_{\text{mbb}}}{\gamma_{\text{kmbb}}^{\text{transmitted}}}\right) \times \sin^2\left(\theta_{\text{mbb}}^{\text{transmitted}}(\vartheta_{\text{mbb}}^s)\right).$$

Due to the constraints in (14) and (18), the projection loss is always guaranteed, i.e., $\sin^2\left(\theta_{\text{mbb}}^{\text{transmitted}}(\vartheta_{\text{mbb}}^s)\right) \ll 1$. For the PS scheduler, the rate loss function is expressed in terms of the entire URLLC resources inducing the resource allocation of the eMBB user, since the eMBB transmission is instantly stopped over these resources, as

$$\Pi_{\text{PS}} = \left(\frac{\gamma_{\text{kmbb}}^{\text{transmitted}}}{\gamma_{\text{mbb}}^{\text{transmitted}}}\right).$$

Finally, the MUPS scheduler exhibits an average eMBB capacity loss due to the persistent PS events, if the normal MU-MIMO scheduler fails; thus, the rate loss can be given as

$$\Pi_{\text{MUPS}} = \Phi\left(\frac{\gamma_{\text{mbb}}^{\text{transmitted}}}{\gamma_{\text{kmbb}}^{\text{transmitted}}}\right),$$

where $\Phi \leq 1$ is a fraction to indicate the probability density of rolling back to PS scheduler, under a specific cell loading. Hence, the average eMBB user rate can be calculated as

$$\bar{\gamma}_{\text{kmbb}} = \gamma_{\text{kmbb}}^{\text{transmitted}} \gamma_{\text{mbb}}^{\text{transmitted}} (1 - \mathbb{E}\{\Pi\}).$$

Based on (26) - (33), it can be concluded that the proposed NSBPS scheduler provides the best achievable eMBB and URLLC joint performance against state-of-the-art schedulers.

### IV. Simulation Results

In this section, we present the extensive SLS results of the NSBPS scheduler, following the 5G-NR specifications, where the main simulation parameters are listed in Table I.

Fig. 2 shows the URLLC average one-way latency $\Psi$ at the $10^{-5}$ outage probability, under proposed NSBPS, PS, MUPS, and WPF schedulers. On the top left, a close snap of the complementary cumulative distribution function (CCDF) of the URLLC latency distribution is further presented. We define the cell load setup by: $\Omega = (K_{\text{mbb}}, K_{\text{uc}})$. The proposed NSBPS scheduler clearly provides a significantly robust and steady URLLC latency against different cell load conditions, and hence, independently from the aggregate levels of interference. The overall performance gain of the NSBPS scheduler is due to: 1) the guaranteed instantaneous URLLC scheduling without queuing in a controlled (almost surely occurs), biased (for the sake of the URLLC user), and semi-transparent (URLLC user is aware of it) MU transmission, leading to no inter-user interference at the URLLC user, 2) the constrained-minimum eMBB user rate loss function, and 3) the enforced regularization of the inter-cell interference spatial distribution within a limited span, due to the fixed subspace projection, and hence, the linear MMSE-IRC receiver nulls the average inter-cell interference more efficiently and with improved SDoFs.

The PS scheduler shows an optimized URLLC latency in the low load region, at the expense of degraded eMBB performance. However, in the high load region when the inter-cell interference levels are extreme, PS scheduler provides a degraded URLLC latency performance due to the experienced re-transmissions and degraded capacity per PRB. The MUPS scheduler shows a fair tradeoff between URLLC latency and the eMBB SE, where the non-controlled URLLC-eMBB MU-MIMO transmissions reduce the URLLC decoding ability. Finally, the WPF scheduler exhibits the worst URLLC latency performance, where the URLLC packets are queued for multiple TTI's if the radio resources are not instantly schedulable.

As shown in Fig. 3, the empirical CDF (ECDF) of the average cell throughput in Mbps is presented. The NSBPS scheduler provides the best achievable cell throughput compared to other schedulers, due to the always constrained-

minimum rate loss function of the victim eMBB users. The PS scheduler exhibits severe loss of the network SE due to the punctured eMBB transmissions. However, the WPF scheduler achieves an improved capacity since no puncture-events are allowed; however, at the expense of the worst URLLC latency. Finally, the MUPS scheduler shows further improved capacity, due to the successful MU events; however, with limited MU gain since when a successful MU pairing is not possible, MUPS falls back to SE-less-efficient PS scheduler.

Examining the eMBB performance, Fig. 4. shows the average eMBB user throughput in Mbps, for all schedulers under evaluation, where similar conclusions can be clearly obtained. For instance, with \( \Omega = (5, 5) \), where the system SDoFs are limited by the small number of active eMBB users, i.e., \( K_{mbb} = 5 \), the proposed NSBPS shows a gain \( \approx 28.9\% \) in the eMBB user throughput than the MUPS scheduler. Under such SDoF-limited state, the MUPS scheduler is highly likely to roll back to PS scheduler, i.e., \( \Phi \approx 1 \), while the NSBPS forcibly enforces these missing SDoFs, sufficient enough to instantly fit the URLLC traffic within an eMBB transmission.

Finally, Table II presents the achievable MU throughput gain of the NSBPS and MUPS schedulers. The best achievable MU gain of the NSBPS over the MUPS scheduler is obtained when the system is originally SDoF-limited, i.e., \( \Omega = (5, 5) \). With SDoF-rich loading states such as \( \Omega = (20, 5) \), the MUPS scheduler rarely falls back to PS scheduler, i.e., \( \Phi \approx 0 \), and hence, an improved MU gain is achieved.

VI. CONCLUSION

A null space based preemptive scheduler (NSBPS) has been proposed for joint 5G URLLC and eMBB traffic. The proposed NSBPS scheduler aims to fulfill a constraint-coupled objective, for which the URLLC quality of service is almost surely guaranteed while achieving the maximum possible ergodic capacity. Extensive system level simulations and analytic gain analysis have been conducted for performance evaluation. Compared to the state-of-the-art scheduler proposals from academia and industry, the proposed NSBPS shows extreme robustness of the URLLC latency performance, i.e., regardless of the cell loading, and aggregate interference levels, while providing significantly improved eMBB performance. A comprehensive study on the performance of the proposed scheduler will be considered in a future work.
