Optimal Calculation of Residuals for ARMAX Models with Application to Model Verification

T KNUDSEN*

22nd April 1997

Abstract
Residual tests for sufficient model orders are based on the assumption that prediction errors are white when the model is correct. If an ARMAX system has zeros in the MA part which are close to the unit circle, then the standard predictor can have large transients. Even when the correct model is used there will be large correlations in the transient phase. In this case the standard residual tests are therefore not suitable. A new method based on backforecasting is therefore developed. Simulation and analysis shows that the new method gives the right answer where the standard method is misleading.

1 Introduction
Model verification is an important part of system identification. Statistical methods exist to test if the model is correct or not. The standard tests are based on asymptotic properties which of course are not true for all samples. The transient nature of the prediction errors has of course consequences for the well known prediction error method.

2 ARMAX models and the one step predictor
The ARMAX model can be formulated as (1)–(2) where ID(0, σ²) is short for independent distributed with mean 0 and variance σ². Notice that A(q) and C(q) are monic and that a unit time delay from u to y is assumed for simplicity. Assume also that C(q) is stable.

\[ A(q)y(t) = B(q)u(t) + C(q)e(t) , \quad e(t) \in ID(0, \sigma^2) \]  
\[ A(q) = 1 + a_1 q^{-1} + \cdots + a_n q^{-n_a} \]  
\[ B(q) = b_1 q^{-1} + \cdots + b_n q^{-n_b} \]  
\[ C(q) = 1 + c_1 q^{-1} + \cdots + c_n q^{-n_c} \]

The approach is to first take a closer look at the predictor in order to analyze the statistical properties of the prediction error. This will enable us to specify the problem in more detail. Some different solutions are discussed. The standard formulas for predicting the output from an ARMAX system, the prediction error are in general not white when the model is initialized by (8).

\[ \hat{\theta} = (a_1, a_2, \ldots, a_n, b_1, b_2, \ldots, b_n, c_1, c_2, \ldots, c_n)^T \]  
\[ \varphi(t) = (-y(t-1), \ldots, -y(t-n_a), u(t-1), \ldots, u(t-n_b), e(t-1), \ldots, e(t-n_c))^T \]  
\[ \epsilon(t) = y(t) - \hat{y}(t) \]  
\[ \hat{y}(t) = \varphi(t)^T \hat{\theta} \]  

Let us define the time for the first measurement as 1. Then the predictor can be calculated by (6)–(7) for \( t \geq t_s \) , \( t_s = \max(n_a, n_b) + 1 \) , when it is initialized by (8).

\[ \varphi(t_s) = (-y(t_s - 1), \ldots, -y(t_s - n_a), u(t_s - 1), \ldots, u(t_s - n_b), 0, \ldots, 0)^T \Rightarrow \epsilon(t_s - 1) = \cdots = \epsilon(t_s - n_c) = 0 \]

The idea behind this reasonable procedure is not to start predicting until the measurements of u, y needed in \( \varphi \) are

---

*Institute of Electronic Systems, Department of Control Engineering, Aalborg University, Fredrik Bajers Vej 7, DK-9220 Aalborg, Denmark
available and at that time to set the missing prediction errors to the unconditional mean for \( e \) i.e. zero. This initialization procedure is also suggested by [9, p 491] and [7, p 277], and it will be called the direct start (DS).

### 3 Autocovariance function for the prediction error when using the direct start

Now it is possible to make a theoretical calculation of the autocovariance function for the prediction error. To do this we need a stochastic model for \( e \), that is to say, a model with \( u \) and \( e \) as inputs.

\[
\begin{align*}
\epsilon(t) &= y(t) - \hat{y}(t) \\
&= y(t) - [(1 - A(q))y(t) + B(q)u(t)] \\
&+(C(q) - 1)e(t) \\
&= A(q)y(t) - B(q)u(t) + (1 - C(q))e(t) \\
&= C(q)e(t) + (1 - C(q))e(t) \Rightarrow \\
C(q)e(t) &= C(q)e(t) , t \geq t_s \tag{10}
\end{align*}
\]

The first prediction error (11) has the variance (12).

\[
\begin{align*}
\epsilon(t_s) &= C(q)e(t_s) = \sum_{i=0}^{n_c} c_i e(t_s - i) \Rightarrow \\
V(\epsilon(t_s)) &= \sigma^2 \sum_{i=0}^{n_c} c_i^2 
\tag{11} \tag{12}
\end{align*}
\]

At this point we notice that:

- All statistical properties for \( \epsilon(t) \) are specified by \( C \) and \( \sigma \).
- \( \epsilon(t) \to \epsilon(t) \) as \( t \to \infty \).
- The variance for the first prediction error will in general grow with the degree of \( C(q) \). For a first order system \( V(\epsilon(t_s)) = \sigma^2(1 + c_i^2) \leq 2\sigma^2 \).

State space models are convenient for analysis of time varying properties. Consequently we will rewrite (10) and (9) into state space form.

First define a new variable \( z \) by (13). Notice that \( z \) only depends on \( \epsilon(t) \) for \( t \in [t_s - n_c, t_s - 1] \). Therefore \( z(t), \epsilon(t) \) are uncorrelated when \( t \geq t_s \).

\[
\begin{align*}
z(t) &= \epsilon(t) - \epsilon(t) \\
&= z(t) \Rightarrow C(q)z(t) = 0 , t \geq t_s \tag{13} \tag{14}
\end{align*}
\]

The state vector \( x \) is defined by (14). And the state space models then become (15)–(16) with the initial conditions (17)–(18).

\[
\begin{align*}
x(t) &= (z(t), z(t - 1), \ldots, z(t - n_c - 1))^T \tag{14} \\
x(t) &= \Phi x(t - 1), t \geq t_s \tag{15} \\
\epsilon(t) &= \Gamma x(t) + \epsilon(t) , t \geq t_s \tag{16}
\end{align*}
\]

\[
\Phi = \begin{bmatrix}
-c_1 & -c_2 & -c_3 & \cdots & -c_{n_c} \\
1 & 0 & 0 & \cdots & 0 \\
0 & 1 & 0 & \cdots & 0 \\
\vdots & \vdots & \vdots & \ddots & \vdots \\
0 & \cdots & 0 & 1 & 0
\end{bmatrix}
\]

\[
\Gamma = (1, 0, \ldots, 0) \\
x(t_s - 1) = (z(t_s - 1), \ldots, z(t_s - n_c))^T \\
\epsilon(t) = -(e(t_s - 1), \ldots, e(t_s - n_c))^T \Rightarrow \\
\text{Cov}[\epsilon(t_s - 1)] = \sigma^2 I 
\tag{17} \tag{18}
\]

From above it follows that \( x(t_2) \) and \( \epsilon(t_1) \) are uncorrelated when \( t_2, t_1 \geq t_s \).

Using all this it is not difficult to find the autocovariance function for \( e \).

\[
\text{Cov}[\epsilon(t_2), \epsilon(t_1)] = E[\epsilon(t_2) \epsilon(t_1)] = E[\epsilon(t_2) \epsilon(t_1)](\Gamma x(t_1) + \epsilon(t_1))^T \\
= E[(\Gamma \Phi^t x(t_1) + \epsilon(t_2)) (\Gamma x(t_1) + \epsilon(t_1))] \\
= E[(\Gamma \Phi^t x(t_1) + \epsilon(t_2)) (\Gamma x(t_1) + \epsilon(t_1))] \\
= \sigma^2 \Gamma \Phi^t x(t_1) (\Gamma x(t_1) + \epsilon(t_1))^T + E[\epsilon(t_2) \epsilon(t_1)] \Rightarrow \\
\text{Cov}[\epsilon(t_2), \epsilon(t_1)] \\
= \begin{cases} 
\sigma^2 \Gamma \Phi^t x(t_1) (\Gamma x(t_1) + \epsilon(t_1))^T & , t_2 \neq t_1 \\
\sigma^2 \Gamma \Phi^t x(t_1) (\Gamma x(t_1) + \epsilon(t_1))^T + \sigma^2 & , t_2 = t_1
\end{cases}
\]

If a new time scale (19) is defined then \( \tau = 1 \Leftrightarrow t = t_s \) i.e. the time for the first prediction. This makes the formulas somewhat concise.

\[
\tau = t - (t_s - 1) \tag{19}
\]

The variance and autocovariance for the prediction error then becomes:

\[
\begin{align*}
V[\epsilon(\tau)] &= \sigma^2 (\Gamma \Phi^T \Phi^s T \Gamma^T + \Gamma^T) , \tau_1 \geq 1 \tag{20} \\
\text{Cov}[\epsilon(\tau_2), \epsilon(\tau_1)] \\
&= \begin{cases} 
\sigma^2 \Gamma \Phi^T \Phi^s T \Gamma^T & , \tau_2, \tau_1 \geq 1 , \tau_2 \neq \tau_1 \\
\sigma^2 \Gamma \Phi^T \Phi^s T \Gamma^T + \sigma^2 & , \tau_2 > \tau_1 \geq 1
\end{cases}
\tag{21}
\end{align*}
\]

Because (15)–(16) is a state space model for the transfer function model (10) the eigenvalues for \( \Phi \) equals the zeros for \( C(q) \). The eigenvalues are then inside the unit circle, thus \( \Phi^T \to 0 \) as \( \tau \to \infty \).

Based on (20)–(21) we can now conclude:

- \( V[\epsilon(\tau)] \to \sigma^2 \) as \( \tau \to \infty \)

- \( \text{Cov}[\epsilon(\tau_2), \epsilon(\tau_1)] \to 0 \) as \( \tau_1 \text{ or } \tau_2 \text{ or } |\tau_2 - \tau_1| \to \infty , \tau_1 \neq \tau_2 \)

- The closer the zeros for \( C(q) \) are to the unit circle, the slower the convergence becomes. \( |\text{Cov}[\epsilon(\tau_2), \epsilon(\tau_1)]| \) and \( V[\epsilon(\tau)] \) will be larger than the stationary values at the beginning of the measurements.
4 Consequences for residual tests - DS start

In the previous section we saw that the statistical properties for the prediction error have a transient phase. The analysis also indicated that the transient is largest for system with \( C(q) \) of high order and with zeros close to the unit circle. A very important question to be answered now is: Do the transients have any significant impact on the residual tests for ordinary systems or are “pathological” cases needed to show an effect?

To answer this question we will look at three examples. These examples are used throughout the paper, and are therefore described in more detail than necessary at this point where only \( C \) and \( \sigma \) are needed. The output error structure (23) is chosen for the examples. This corresponds to the ARMAX structure (24) i.e. \( C(q) = A(q) \). In (22) \( \text{NID}(0, \sigma^2) \) is short for normal and independent distributed with mean 0 and variance \( \sigma^2 \).

\[
e(t) \in \text{NID}(0, \sigma^2) \ , \ \sigma = 0.1 \tag{22}
\]
\[
g(t) = \frac{B(q)}{A(q)} u(t) + e(t) \Rightarrow \tag{23}
\]
\[
A(q) g(t) = B(q) u(t) + A(q) e(t) \tag{24}
\]

The input is a PRBS signal switching between \( \pm 1 \). Notice however that the mean time step is five samples [9, Example 5.11]. The N/S ratio is approximately 10%. The first example is the discrete counterpart to a continuous time first order system with bandwidth \( \frac{1}{20} \) Hz. The second example is the discrete counterpart to a continuous time systems consisting of the series of a second order system with bandwidth \( \frac{1}{20} \) Hz and damping factor 0.5 and a first order system with bandwidth \( \frac{1}{20} \) Hz. The sampling time is 1, thus the sampling frequency is around 20 times the bandwidth. This is not at all an unusual system. The third example is similar to the second except for the damping factor which is 0.1 in order to illustrate the situation with zeros closer to the unit circle. Fig. 1 shows gain and poles for the examples, notice that the poles equals the zeros for \( C(q) \).

The variance and the autocovariance for the prediction errors are calculated by (20)–(21) and shown in Fig. 2–4 for the examples. It is evident that the transients becomes larger and longer as the zeros for \( C(q) \) approaches the unit circle. An important indicator of this is the maximum overshoot for the prediction error variance which are roughly 1.8, 100 and 260 for the first, second and third example respectively.

![Figure 2: Prediction error properties for the first order example (DS method).](image)

The autocorrelation test is based on an estimated autocorrelation function. As an example let us calculate the expectation of the estimated lag one autocorrelation for the prediction error.

\[
\hat{\rho}_1 = \frac{\hat{\text{Cov}}[\epsilon(\tau + 1), \epsilon(\tau)]}{\hat{V}[\epsilon(\tau)]}
\]
\[
\hat{\text{Cov}}[\epsilon(\tau + 1), \epsilon(\tau)] = \frac{1}{n} \sum_{t=1}^{n-1} \epsilon(t+1) \epsilon(t)
\]
\[
\hat{V}[\epsilon(\tau)] = \frac{1}{n} \sum_{t=1}^{n} \epsilon(t)^2
\]

The expectations for these estimates are:

\[
E[\hat{V}[\epsilon(\tau)]] = \frac{1}{n} \sum_{t=1}^{n} V[\epsilon(t)]
\]
\[
E[\hat{\text{Cov}}[\epsilon(\tau + 1), \epsilon(\tau)]] = \frac{1}{n} \sum_{t=1}^{n-1} \text{Cov}[\epsilon(t+1), \epsilon(t)]
\]
\[
E[\hat{\rho}_1] \sim \frac{E[\hat{\text{Cov}}[\epsilon(\tau + 1), \epsilon(\tau)]]}{E[\hat{V}[\epsilon(\tau)]]}
\]

The resulting expectations are shown in table 1. Rows 1 and 3 are based on the values shown in Fig. 2–3. The deviations from the stationary values are seen to be small for the first order system, but large for the third order system even when
using 500 samples. It is important to notice that the expected correlation estimate does not depend on the noise variance, but only on \( C(q) \).

Stationary values 0.01 0 0

Table 1: Expected values for estimates of the statistical properties for the prediction error when using the DS method.

The important conclusion to this section is the following. Assume we use the DS and the system parameters for the prediction. Then the variance and the lag one autocovariance for the prediction error has a transient which is significant for an ordinary third order system. The standard autocorrelation test is invalid in this situation, and the S/N ratio has no impact on the validity of the test. If the zeros for \( C(q) \) get closer to the unit circle and/or the order of \( C(q) \) increases then the transient will also increase. Even a first order system gives problems if the zero is sufficiently close to the unit circle.

5 Solutions

Before turning to specific solutions the problem is reviewed and two main approaches are discussed.

Given an ARMAX structure \( A(q), B(q), C(q) \) with \( C(q) \) zeros inside the unit circle, a parameter vector \( \theta \) and some measurements

\[
\begin{align*}
\mathbf{y}_n & = [y_1, \ldots, y_\nu]^T, \\
\mathbf{u}_n & = [u_1, \ldots, u_\nu]^T
\end{align*}
\]

The problem is to obtain the corresponding noise sequence \( e(t) \) to test it for white noise properties. Further assumptions are avoided to obtain a general solution.

The classical prediction error approach is based on the fact that one step prediction error equals \( e(t) \) in the stationary case i.e.

\[
e(t) = y(t) - \hat{y}(t|t-1) \rightarrow e(t) \quad \text{as} \quad t \to \infty
\]

The notation \( \hat{y}(t|t-1) \) emphasizes that \( \hat{y}(t) \) is based on past measurements \( \mathbf{z}_t \). Consequently \( e(t) \) is based on \( \mathbf{z}_t \) i.e. the measurements from the beginning to the present which are very few in the beginning.

In view of the problems with the transient it would be better to estimate \( e(t) \) using all data i.e. like \( E(e(t)|\mathbf{z}_t) \) because this is the best estimator in the MSE sense.
However, some prediction error based methods are discussed first.

5.1 Discarding the first part of the samples

Simply discard the transient phase from the prediction error sequence. Even though this principle is extremely simple it still require some of the calculations in section 3 to decide on the number of samples to discard. Anyway, this solution is far better than ignoring the problem. It can be recommended in cases with plenty of samples, but it is unsatisfactory with few samples.

5.2 Using a Kalman filter

The ARMAX model (1) can be represented in e.g. companion state space form as follows.

\[
x(t+1) = \Phi x(t) + \Gamma u(t) + \Pi e(t)
\]

\[
y(t) = H x(t) + \epsilon(t)
\]

\[
\Phi = \begin{bmatrix} -a_1 & 1 & 0 & \cdots & 0 \\ -a_2 & 0 & 1 & \cdots & 0 \\ \vdots & \vdots & \vdots & \ddots & \vdots \\ -a_n & 0 & 0 & \cdots & 0 \end{bmatrix}, \quad \Pi = \begin{bmatrix} b_1 \\ \vdots \\ b_n \end{bmatrix}
\]

\[
\Pi = \begin{bmatrix} c_1 - a_1 \\ \vdots \\ c_n - a_n \end{bmatrix}, \quad H = \begin{bmatrix} 1 & 0 & \cdots & 0 \end{bmatrix}
\]

Numerical minimization should be avoided if possible, thus 1 is not desirable. The success of 2 depends on the guess on \( \mu_x(0) \) and \( P_z(0) \) which will be quite arbitrary when no knowledge on \( u(t) \) previous to the measurements is available. If \( u(t) \) can be assumed to be a known stochastic process 3 can be used. This will however not always be the case and is therefore not assumed in this paper.

An alternative to the last approach would be to base the Kalman filter on the state space model for the MA(\( n_c \)) auxiliary process \( w(t) \) discussed in the next section. This would also avoid the dependence on the deterministic past and the prediction errors will be absolutely uncorrelated. Consequently this is a good solution for the residual test application.

However, the method in this paper is also intended for parameter estimation where simple calculations is very important [6] and where minimum MSE is more important than whiteness of the residuals. The fundamental drawback for the prediction error approach, including Kalman filtering, is that \( \epsilon(t) \) only is based on \( z_1^n \) i.e. part off the know data \( z_1^n \). Using all data will improve the estimate in the MSE sense and it turns out that this method only needs filtering which is much simpler than in the Kalman filter approach. Therefore the prediction error approaches will not be further pursued here.

5.3 Conditional expectation using all data

When all data are used to estimate the noise the term prediction error is not appropriate, therefore the more general term residual are used.

The relation between \( \epsilon(t) \) and the measurements is given by (34)–(35).

\[
A(q)y(t) - B(q)u(t) = C(q)\epsilon(t) \iff \quad w(t) = C(q)\epsilon(t), \quad w(t) = A(q)y(t) - B(q)u(t)
\]

In this contents the measurements can therefor be represented by the auxiliary sequence (36) which can be calculated exactly from \( z_1^n \).

\[
w^n_{ts} = [w(t_s) \ldots w(n)]^T
\]

The problem now is to find the conditional expectation (37) where the operator ‘\( \hat{\quad} \)’ is introduced for conveniences.

\[
\hat{\epsilon}(t) = E(\epsilon(t)|w^n_{ts})
\]

The solution is given below where the notation \( \{M\}_{ij} \) refers to the element in row \( i \) column \( j \) in matrix \( M \).

**Theorem 1.** Assume that the stochastic part of the ARMAX process is stationary and \( \epsilon(t) \in NID(0,\sigma^2) \), the conditional expectation for \( \epsilon \) is then given by

\[
e^n_{ts-n_c} = R_{ew}R^{-1}_w w^n_{ts}
\]

where

\[
\{R_{ew}\}_{ij} = \begin{cases} \sigma^2 c_{n_c+j-i} & \text{for } 0 \leq i-j \leq n_c \\ 0 & \text{otherwise} \end{cases}
\]

\[
\{R_w\}_{ij} = \begin{cases} r_w(i-j) & \text{for } |i-j| \leq n_c \\ 0 & \text{otherwise} \end{cases}
\]

\[
r_w(k) = \sigma^2 \sum_{i=0}^{n_c-|k|} c_i c_{i+|k|}
\]
Remark 1.1. No assumption on the zeros for \(C(q)\) is needed, they may be on or even outside the unit circle.

Remark 1.2. If \(e(t)\) is not normal distributed, \(\hat{e}^o_{t, n_c} (38)\) may not be the conditional expectation. Consequently, it may not be the best estimate in the mean square sense but it is the best linear estimate.

**Proof.** The dimension of the variables used are listed below.

\[
\begin{align*}
&\text{Dimension} & &v & &\left[ e^o_{t, n_c} w^n_{t, n_c} \right] \\
&\text{Variables} & &E(v) & &\left[ 0 \ldots 0 \ldots 0 \right]^T \\
& &\text{Cov}(v) & &\begin{bmatrix} R_e & R_{ew} \\ R_{ew} & R_{ew} \end{bmatrix} \\
& &R_e & = \text{Cov}(e^o_{t, n_c}) = \sigma^2 I \\
& &R_{ew} & = \text{Cov}(e^o_{t, n_c}, w^n_{t, n_c}) \\
& &e & = E(e(v) - \sigma^2 I) \\
& &\{R_{ew}\}_{ij} & = E(e(t - n_c + i - 1)w(t + j - 1)) \\
& & & = E(w(t)e(t - n_c + i - j)) \\
& & & = \sigma^2 c_{n_c+i-j} \\
& &R_w & = \text{Cov}(w^n_{t, n_c}) \\
& & & = E(w^n_{t, n_c}w^n_{t, n_c}^T) \\
& &\{R_w\}_{ij} & = E(w(t + i - 1)w(t + j - 1)) \\
& & & = E(w(t)w(j)) \\
& & & = r_w(i - j) \\
& &r_w(k) & = E(w(t)w(t + k)) = \sigma^2 \sum_{i=0}^{n_c - |k|} c_i c_{i+k} \\
\end{align*}
\]

The stationarity is used in (42) and (43).

According to the well known theorem proven in e.g. [1, sec. 7.3], the conditional expectation is given by

\[
\begin{align*} 
&e^o_{t, n_c} = E(e^o_{t, n_c}|w^n_{t, n_c}) \\
&= E(e^o_{t, n_c}) + R_{ew}R_{ew}^{-1}(w^n_{t, n_c} - E(w^n_{t, n_c})) \\
&= R_{ew}R_{ew}^{-1}w^n_{t, n_c}
\end{align*}
\]

and the estimation error has zero mean and covariance

\[
\begin{align*}
\text{Cov}(e^o_{t, n_c} - \hat{e}^o_{t, n_c}) & = R_e - R_{ew}R_{ew}^{-1}R_{ew}^T \\
\text{Finally, the covariance for the residuals is}
\end{align*}
\]

\[
\begin{align*}
\text{Cov}(\hat{e}^o_{t, n_c}) & = \text{Cov}(R_{ew}R_{ew}^{-1}w^n_{t, n_c}) \\
& = R_{ew}R_{ew}^{-1}\text{Cov}(w^n_{t, n_c})R_{ew}^{-1}R_{ew}^T
\end{align*}
\]

which completes the proof.

The method above gives the best estimate of \(e(t)\). However, it requires a huge amount of computation, especially the inversion of \(R_w\) is a problem.

5.4 The backforecasting method

The so called backforecasting (BC) method presented below is an computationally more suitable alternative to the method in theorem 1 because it only uses filtering.

The BC method has been used on ARMA models by Box and Jenkins [3]. Unfortunately this particular method can only be directly applied to ARMAX models if the input \(u(t)\) is known back in time, which is not usually the case. Therefore a method for ARMAX models based on the same principles is presented below.

**Theorem 2.** Assume that \(C(q)\) in an ARMAX system has all zeros inside the unit circle and that \(e(t) \in ID(0, \sigma^2)\) then \(\hat{e}(t)\) calculated by algorithm 1 is an approximation for \(\hat{e}(t) = E(e(t)|w^n_{t, n_c})\) with the property

\[
\hat{e}(t) \to e(t) \quad \text{as} \quad n \to \infty \quad \forall t \in [t_s - n_c, n]
\]

**Algorithm 1** (Backforecasting).

1. Calculate \(w(t)\) for \(t = t_s, t_s + 1, \ldots, n\).

\[
w(t) = A(q)y(t) - B(q)u(t)
\]

2. Calculate \(\hat{e}_b(t)\) backwards for \(t = n, n - 1, \ldots, t_s\), initialize with \(\hat{e}_b(n + 1), \ldots, \hat{e}_b(n + n_c) = (0, \ldots, 0)\).

\[
\hat{e}_b(t) = w(t) - c_1\hat{e}_b(t + 1) - \cdots - c_{n_c}\hat{e}_b(t + n_c)
\]

3. Multi step backforecasting of \(w(t)\) for \(t = t_s - 1, t_s - 2, \ldots, t_s - n_c\), using \(\hat{e}_b(t) = 0 \forall t \leq t_s - 1\).

\[
\hat{w}(t) = \hat{e}_b(t) + \cdots + c_n\hat{e}_b(t + n_c)
\]

4. Calculate \(\hat{e}(t)\) for \(t = t_s - n_c, t_s - n_c + 1, \ldots, t_s - 1\), using \(\hat{e}(t) = 0 \forall t \leq t_s - 1\).

\[
\hat{e}(t) = \hat{w}(t) - c_1\hat{e}(t + 1) - \cdots - c_{n_c}\hat{e}(t - n_c)
\]

5. Calculate the remaining part of \(\hat{e}(t)\) i.e. for \(t = t_s, t_s + 1, \ldots, n\) either by

(a) the filter in step 4 with \(\hat{w}(t) = w(t) \forall t \geq t_s\)

or

(b) use \(\hat{e}(t - 1), \ldots, \hat{e}(t - n_c)\) for the missing initial conditions \((\hat{e}(t - 1), \ldots, \hat{e}(t - n_c))\) in the usual prediction error formulas (6)–(7), then \(e(t)\) will equal \(\hat{e}(t)\).

**Remark 2.1.** Notice that only simple filtering involving the ARMAX polynomials is required in the algorithm.

**Remark 2.2.** Using the filter in step 4 for all data makes step five unnecessary. The motivation for step 5 is to show that the algorithm can be separated in step 1–4 which calculates the initial conditions for the first prediction \(\hat{y}(t_s)\) and step 5(b) which based on these initial conditions calculates the residuals in the usual prediction error way.
Proof. The key points in this proof are that the sequence \( w(t) \) with the forward model (44) is a MA(\( n_c \)) process which equally well can be modeled by the backward model (45). The backward model is developed further to show the notation used. Notice also that \( e(t) \) and \( e_0(t) \) are different sequences.

\[
w(t) = C(q)e(t), e(t) \in ID(0, \sigma^2) \tag{44}
\]

\[
w(t) = C(q^{-1})e_0(t), e_0(t) \in ID(0, \sigma^2) \Leftrightarrow \tag{45}
\]

\[
w(t) = (1 + c_1 q + \cdots + c_{n_c} q^{n_c}) \rho(t) = e_0(t) + c_1 e_0(t + 1) + \cdots + c_{n_c} e_0(t + n_c) \tag{46}
\]

Taking conditional expectation on both sides of (46) yields (47). Notice that \( \hat{\rho} \) denotes conditional expectation with respect to \( w^n_0 \) in general.

\[
\hat{\rho}(t) = C(q)\hat{e}(t) \Rightarrow \tag{47}
\]

\[
\hat{e}(t) = \hat{\rho}(t) - c_1 \hat{e}(t-1) - \cdots - c_{n_c} \hat{e}(t-n_c) \tag{48}
\]

It follows from (44), i.e. \( w(t) \) being an MA(\( n_c \)) process, that \( \hat{\rho}(t-k), w(t) \) are independent for \( k \geq n_c + 1 \) and that \( w(t+k), \hat{\rho}(t) \) are independent for \( |k| \geq n_c + 1 \) which implies (48) and (49) respectively:

\[
\hat{e}(t) = E(e(t)|w^n_0) = E(e(t)) = 0 \ \forall \ t \leq t_s - n_c - 1 \tag{48}
\]

\[
\hat{w}(t) = E(w(t)|w^n_0) = E(w(t)) = 0 \ \forall \ t \leq t_s - n_c - 1 \tag{49}
\]

It follows from (35) that \( w(t) \) is known for \( t \in [t_s, n] \) i.e.

\[
\hat{w}(t) = E(w(t)|w^n_0) = w(t) \ \forall \ t \in [t_s, n] \tag{50}
\]

To calculate \( \hat{\rho}(t) \) for \( t = t_s - n_c, \ldots, n \) by the filter (47) only \( \hat{w}(t) \) for \( t \in [t_s - n_c, t_s - 1] \) are missing because the rest of \( \hat{w}(t) \) is given by (50) and the initial conditions is given by (48).

The values \( \hat{w}(t) \) for \( t \in [t_s - n_c, t_s - 1] \) can be found by using the backward model (45) for backforecasting. Taking conditional expectation on both sides of (45) yields (51). Thus \( \hat{\rho}_b(t) \) can be calculated by (52) backwards i.e. for \( t = n, n-1, \ldots, t_s \),

\[
\hat{\rho}_b(t) = C(q^{-1})\hat{\rho}_b(t) \Rightarrow \tag{51}
\]

\[
\hat{\rho}_b(t) = w(t) - c_1 \hat{\rho}_b(t + 1) - \cdots - c_{n_c} \hat{\rho}_b(t + n_c) \tag{52}
\]

Starting this filter for \( t = n \) requires the initial conditions \( \hat{\rho}_b(n+1), \ldots, \hat{\rho}_b(n+n_c) \) which are unknown. If these are set to zero a slightly different sequence (53) is obtained which is called \( \hat{\rho}_b(t) \). The notation \( \hat{\rho}_b(t) \) are also used for other sequences which are affected by this approximation.

\[
\hat{\rho}_b(t) = w(t) - c_1 \hat{\rho}_b(t + 1) - \cdots - c_{n_c} \hat{\rho}_b(t + n_c) \tag{53}
\]

\[
(\hat{\rho}_b(n+1), \ldots, \hat{\rho}_b(n+n_c)) = (0, \ldots, 0) \tag{54}
\]

However, only the \( n_c \) first values \( \hat{\rho}_b(t_s), \ldots, \hat{\rho}_b(t_s + n_c - 1) \) are needed in the following and because all zeros for \( C(q) \) are assumed inside the unit circle the effect of initial conditions will vanish if the number of samples is much larger than the length of the impulse response for \( \frac{1}{C(q)} \) i.e.

\[
(\hat{\rho}_b(t_s), \ldots, \hat{\rho}_b(t_s + n_c - 1)) \Rightarrow (\hat{\rho}_b(t_s), \ldots, \hat{\rho}_b(t_s + n_c - 1)) \text{ as } n \to \infty \tag{55}
\]

Assume for a moment that \( \hat{\rho}_b(t) \) can be calculated. Because \( e_b(t) \in ID(0, \sigma^2) \) it follows that

\[
\hat{e}_b(t) = E[e_b(t)|w^n_0] = E[e_b(t)] = 0 \ \forall \ t \leq t_s - 1
\]

Now \( \hat{w}(t) \) for \( t = t_s - 1, \ldots, t_s - n_c \) can be calculated (back-forecasted) by (51). This first part of \( \hat{w}(t) \) together with the last part (50) and the initial conditions (48) are sufficient to calculate \( \hat{\rho}(t) \) by (47) for \( t = t_s - n_c, \ldots, n_c \) as needed.

When the approximation \( \hat{\rho}_b(t) \) is used corresponding approximations \( \hat{w}(t) \) \( \hat{e}(t) \) are obtained, however (55) implies that

\[
\hat{w}(t) \to \hat{w}(t) \text{ as } n \to \infty \ \forall \ t \in [t_s - n_c, t_s - 1] \Rightarrow \hat{e}(t) \to \hat{e}(t) \text{ as } n \to \infty \ \forall \ t \in [t_s - n_c, n]
\]

which completes the proof.

Theorem 2 above makes it possible to relax the distribution assumption in theorem 1 as follows.

**Theorem 3.** The results in theorem 1 holds asymptotically for \( n \to \infty \) for any distribution of \( e(t) \) when \( C(q) \) has all zeros inside the unit circle.

Proof. \( \hat{\rho}(t) \) is calculated by filtering only, therefore it will be a linear function of data. Then theorem 2 implies that the conditional expectation \( \hat{\rho}(t) \), which is the optimal estimate in the MSE sense, tends to a linear function, now \( \hat{\rho}_b^n \) is the optimal linear estimate, in the MSE sense, for any distribution of \( e(t) \) therefore it also is the conditional expectation in the limit.

From an application point of view this section can be summarized as follows. If the impulse response for \( \frac{1}{C(q)} \) can be assumed to be shorter than the data sequence the computationally efficient BC algorithm should be used to calculate the residuals. If this is not the case e.g. if the zeros for \( C(q) \) is on the unit circle the BC method will not work but then the method in theorem 1 can be used. Finally, if the impulse response for \( \frac{1}{C(q)} \) is known to be negligible the DS can be used.

### 6 Consequences for residual tests - BC start

To compare the BC method with the DS method the results from the three examples described in section 4 are shown below.

The number of samples are chosen sufficiently large to apply the BC method. This method i.e. algorithm 1 is used to calculate the residuals in the second subplots in figure 5–7, clearly no transient are visible here. With the DS method the prediction errors could be calculated only from time \( t_s \) and forward but the BC method can also give the \( n_c \) values before \( t_s \) these are however not shown in the figures.

The statistical properties for the residuals is given (approximately) by theorem 1 and shown in the last two subplots where \( t_s \) is indicated by the first tick-mark and vertical dotted line. Clearly there are transients in the statistical properties but they are very small compared to the corresponding ones from the DS method. Larger deviations from the stationary values can only be observed for the first \( n_c \) samples which is the reason to exclude them from the calculated sequences.

Based on the above results the expected values for the important estimates can be calculated and are show in table 2. It can be concluded that the BC method succeeds to produce estimates with expected values with a negligible deviation from the theoretical ones. Comparing with table 1 it is seen that this is not at all the cases using the DS method.
7 Application to residual test

In this section the third order system with damping factor 0.5 is used to compare the BC procedure with the DS when the prediction errors are applied in residual tests. The number of observations used is 500. It is necessary to know the right parameters and to be able to control the assumptions. For these reasons the comparison is based on simulation. The software used is MATLAB.

As a reference the resid procedure from the System Identification Toolbox [8] is chosen. The reasons are that this procedure uses some kind of DS and it is written by Lennart Ljung, which gives us every reason to believe that it works well.

According to the analysis the first three white noise samples will specify the transient. A particular 500 sample sequence may or may not show a transient. Of course I have chosen a sequence which gives a transient. Actually the default initial values for the random generators in MATLAB are used.

All three sequences in Fig. 8 are calculated from the same single input/output sequence. The middle and bottom sequences are based on the correct system parameters and calculated by resid and the BC algorithm respectively. Clearly only the former gives a transient. The topmost sequence is also calculated by resid but now with parameters estimated by ARMAX, an parameter estimation procedure from the toolbox. In this case the transient has been reduced. The reason for this is that the ARMAX procedure searches for a minimum of the usual LS criterion which increases dramatically for parameters given a transient as e.g. the system parameters. The resulting estimate will then be biased because it is a compromise between minimizing the transient and the stationary part of the sequence [5].

To test if the model is large enough, the resid procedure graphs the auto- and crosscorrelation estimates with their 99% confidence limits. Figure 9 shows the three autocorrelation tests which correspond to the three sequences in Fig. 8. For the reasons explained the estimated parameters pass the test using the resid procedure. Using the resid procedure one would not accept the system parameters because the autocorrelations exceed the confidence limits for lag 1–7. Finally the BC based procedure gives no reason to reject the system parameters.
8 Conclusion

This paper concerns noise estimation and its application to model testing for ARMAX models. The focus is on problems that occur when the MA part has zeros close to the unit circle. It is shown that the prediction errors resulting from the optimal one step predictor, initialized in the ordinary way, gives large transients even for a quite ordinary third order system. Thus the stationary properties on which the tests are based are not true for all samples.

By analysis it is shown that this results in severe problems for the standard autocorrelation test when the order of the MA part is larger than around two depending on how close the zeros are to the unit circle, even a first order system can give problems. The prediction error transients will also cause problems for other applications as e.g. tests for too many parameters and parameter estimation.

A Kalman filter based on the stochastic part of the ARMAX process is a good solution if only residual test is of concern.

A more general solution to the problem is to use the measurements to estimate the missing initial condition. This will be optimal in the MSE sense and it nearly removes the transient. In this paper a method based upon the principle of backforecasting is developed, it only requires simple filtering.

Analysis shows that this method is superior to the ordinary method. By simulation this method is compared to the RESID procedure from the system identification toolbox for MATLAB. For the simulation experiment an ordinary third order system is used. Using the RESID procedure one could not accept the system parameters, but using the procedure developed here there was no reason to reject them.

The conclusion is therefore that when working with ARMAX models, especially with MA order larger than 2, one should be careful when using standard procedures to calculated residuals and perform model tests, because they can be misleading. It is better to use the procedure developed in this paper.
