Abstract: In this work we present some new results about the sub- T_g enthalpy relaxation in a hyperquenched glass, which is obtained from an oxide melt with extremely low glass-forming ability (GFA). The low GFA is reflected by a very sharp exothermic peak that occurs slightly above the glass transition temperature. We also show how the sub- T_g annealing affects crystallization during dynamic heating process. This study is conducted by using the differential scanning calorimetry (DSC) and x-ray diffraction. We have observed a non-monotonic trend of both the enthalpy recovered during the first DSC upscan and the isobaric heat capacity (C_p) measured during the second upscan with sub- T_g annealing time. By analyzing the relaxation patterns of the C_p curve, we confirm that both α - and β -relaxations are involved in the sub- T_g annealing. Furthermore, the crystallization peak of the samples annealed even for short time shifts to higher temperature compared to the as-hyperquenched glass. This implies that the atoms in local structural regions is rearranged as a consequence of annealing in the manner that more ordered domains appears, which makes nucleation more readily. In summary, the glass under study has a high degree of structural heterogeneity, and hence, to a strong tendency to crystallization.
