Abstract—Technologies such as RFID and Bluetooth have received considerable attention for tracking indoor moving objects. In a time-critical indoor tracking scenario such as airport baggage handling, a bag has to move through a sequence of locations until it is loaded into the aircraft. Inefficiency or inaccuracy at any step can make the bag risky, i.e., the bag may be delayed at the airport or sent to a wrong airport. In this paper, we propose a novel probabilistic approach for predicting the risk of an indoor moving object in real-time. We propose a probabilistic flow graph (PFG) and an aggregated probabilistic flow graph (APFG) that capture the historical object transitions and the durations of the transitions. In the graphs, the probabilistic information is stored in a set of histograms. Then we use the flow graphs for obtaining a risk score of an online object and use it for predicting its riskiness. The paper reports a comprehensive experimental study with multiple synthetic data sets and a real baggage tracking data set. The experimental results show that the proposed method can identify the risky objects very accurately when they approach the bottleneck locations on their paths and can significantly reduce the operation cost.

I. INTRODUCTION

Technologies such as RFID and Bluetooth enable a variety of indoor, outdoor, and mixed indoor-outdoor tracking applications. Examples of such applications include tracking people’s movement in large indoor spaces (e.g., airport, office building, and shopping malls), airport baggage tracking, item movement tracking in supply chains, and package tracking in logistics systems. During the movement of the objects, these tracking applications record the symbolic locations of the objects at different time points. For example, consider an RFID baggage tracking application where RFID readers are deployed at the different baggage handling locations such as check-in, screening, sorter, etc. Each reader has a very limited tracking range that covers a small portion of the location. If an object containing an RFID tag moves from the check-in to the sorter, this produces two consecutive tracking records of the object location in different places. Due to the limitations in indoor positioning technologies, the locations between these two records are not obtained. We call this type of tracking Symbolic Location Tracking (SLT). An SLT system can generate a massive volume of tracking data. This massive tracking data can be very useful for analyses such as finding risk factors, problem discovery, and decision-making. For example, in an airport baggage handling system, a bag can be left behind in the airport (i.e., failed to catch the intended flight) or can be sent to a wrong airport. In the baggage tracking system, the baggage tracking data can be used to extract interesting patterns and find the reasons for baggage mishandling. In a supply chain system, the item tracking data can be used for finding the factors that lead to an item being returned or get rotten. Some work has been carried out for the efficient management of such tracking data and to analyze them in the offline scenario [8], [13]. However, using such data for time-critical online applications, such as online bags risk prediction in the airports can be very useful for getting real-time notifications for immediate handling of the risky bags. Moreover, online items risk discovery in supply chain and production systems, online item risk prediction in logistics systems, traffic jam prediction, etc., can also benefit from the insights obtained from analyzing the online data. An example of a real-time analysis request can be: "notify the baggage management team whenever a bag becomes risky during its processing time at Aalborg airport". Another request can be: "which are the 5 current bags with the highest risk of not reaching their plane on time?".

The paper makes several contributions. First, to the best of our knowledge, this is the first paper to propose a method for online risk prediction for indoor moving objects. Second, we propose the concepts of least duration probability (LDP), aggregated LDP (ALDP), LDP histogram (LDPH), and ALDP histogram (ALDPH) where the histograms store probabilistic information about the transition times of the historical objects. We propose a probabilistic flow graph (PFG) and aggregated PFG (APFG) that capture the flows of objects from one symbolic location to another and the edges of the graphs contain corresponding LDPH and ALDPH, respectively. Third, an online risk prediction (ORP) algorithm is proposed that uses the PFG and APFG for obtaining a risk score for an online indoor moving object. The risk score is used for predicting the riskiness of the object during its processing. Fourth, as the total available processing time of an object is an important factor, we propose an approach for normalizing the available processing time (e.g., available processing time for a bag before its flight) with the stay durations of objects at different locations for obtaining a better risk score. Fifth, we present a cost model for obtaining the best risk score threshold that can maximize the overall benefit of identifying and removing the risky objects. Sixth, the paper reports a comprehensive experimental study with several synthetic data sets following different data distributions and a real baggage tracking data set. The results show that the proposed method can produce a very accurate risk score and identify the risky objects very precisely in different types of data distributions.

The remainder of the paper is organized as follows. Sec-
II. PRELIMINARIES

SLT Systems. In an SLT system, tracking devices are strategically deployed at different fixed symbolic locations, such as different doors in an office space, between sections in an airport, different locations in airport baggage management, etc. The objects contain tags or devices that can be tracked by the tracking devices. For example, in the case of RFID technology, RFID readers and RFID tags are used; in the case of Bluetooth systems, Bluetooth access points and Bluetooth devices are used. After deployment of the tracking devices, the positions are recorded in the database.

Fig. 1 shows an example of airport baggage tracking scenario. The upper part of the figure shows the path of a bag that travels from Aalborg Airport (AAL) to Brussels Airport (BRU) via Copenhagen Airport (CPH). The bag has to go through several baggage processing steps inside each airport. The bottom part of the figure shows the baggage processing stages inside AAL. The circles represent the baggage tracking locations where RFID readers are deployed for baggage tracking. Before handing over a bag into the system, an RFID tag with some encoded information about the bag and the route is attached to the bag. Suppose the bag is intended for Flight1 and the preplanned path for the bag is: "Check-in→Screening→Sorter1→Gateway1→BeltLoader1".

Mismangement or inefficiency at any one of these transitions may result in the bag being mishandled, i.e., the bag might miss the flight due to delay, or the bag might be sent to a wrong flight. While passing through the different locations, the bag enters the activation range of an RFID reader, it is continuously detected by the reader with a sampling rate, and it generates raw reading records with the form: \((Obj, Loc, t)\). It means that a reader placed at location \(Loc\) detects a moving object \(Obj\) in its activation range at time \(t\). An example set of raw reading records in an SLT system is shown in Table I.

III. PROBLEM FORMULATION

We consider an application scenario where an object can be processed in a single system or multiple subsystems throughout its journey from the origin to the final destination. In the case of subsystems, when an object is registered in its origin, its identifier and the global route are shared within all the subsystems for further processing. Depending on the application scenario, an online risk prediction system can monitor the object throughout its entire journey from origin to final destination or it can monitor the object individually within each subsystem between its entry and exit times within that subsystem. For example, in Fig. 1, the global path of the object is \(AAL→CPH→BRU\). The overall processing of the bag should be processed by the three subsystems, i.e., first at AAL, second at CPH, and third at BRU. Whenever the bag is first registered at AAL, its identifier, route and flight information is shared to CPH and BRU, so that they can recognize the bag when it appears to their systems. In this context, each subsystem has its separate online risk prediction system. Whenever the bag is first detected by an RFID reader at AAL, the bag becomes online to the local risk prediction system which starts monitoring the bag until it exits AAL, or...
until it is confirmed that the bag misses its flight. Similarly, when the bag is detected at CPH, it becomes online at CPH and so on.

**Definition 1. Online Object.** An object is considered as an online object to a system/subsystem at time $t$, if $t$ falls in the time interval $[t_{enter}, t_{exit}]$, where $t_{enter}$ is the first time the object is tracked in a tracking device in the system/subsystem and $t_{exit}$ is the last time the object is tracked by the last tracking device in the system/subsystem or the time within which the object is expected to exit the system/subsystem.

**Problem Statement.** Given a set of stay records $R$ and a set of online moving objects $O$, we are interested in building a predictive model from $R$ that can predict, as early as possible, whether an object $o_i \in O$ is at risk in real-time.

For example, in baggage tracking, the model should be able to predict whether a bag going through the baggage handling stages is at risk of being delayed at the airport and the prediction should be made as early as it sees the bag is being abnormally deferred compared to other bags.

**IV. Solution**

The overall outline of the data collection and risk prediction steps is shown in Fig. 2. The online object tracking data stream is passed into two sections. One of them stores the data offline for future analysis and model building purpose and another uses it during the online risk prediction (ORP) process. The offline/historical reading records are processed and converted into StayRecords. The StayRecords are used for building the probabilistic model. The model, raw data stream and the preplanned path of the objects are used by the ORP for deciding which objects are at risk. Finally, risky objects are notified by the ORP for special handling.

**Definition 2. Least Duration Probability (LDP).** A least duration probability (LDP) for a movement from $l_i$ to $l_j$ with threshold duration $d_k \in D_{i,j}$ is defined as,

$$LDP(l_i, l_j, d_k^2) = \frac{\text{Count}(l_i, l_j, d_k^2)}{\text{Count}(l_i, l_j)}$$ (1)

In Eq. (1), $\text{Count}(l_i, l_j, d_k^2)$ is the total number of objects that took at least $d_k$ duration from $l_i$ to $l_j$ and $\text{Count}(l_i, l_j)$ is the total number of objects that have a transition from $l_i$ to $l_j$.

**Definition 3. Least Duration Probability Histogram (LDPH).** A least duration probability histogram (LDPH) for transitions from $l_i$ to $l_j$ is a histogram with transition durations $D_{i,j}$ on the X-axis, and LDPs for the transitions on the Y-axis.

Table III shows an example summary of transitions for the path $l_1 \rightarrow l_2$ from the stay records in Table II. Fig 3 shows the different LDPHs for the transitions shown in Table III. In Fig. 3a, LDP=0.7 represents that the probability of transition from $l_1$ to $l_2$ with a duration $\geq 16$ is 0.7. The figure also shows that the LDP for duration 28 is very low (0.02).

Fig. 3: LDPHs for the transitions $l_1 \rightarrow l_2$ and $l_2 \rightarrow l_3$ in Table III

**Probabilistic Flow Graph (PFG).** We use a probabilistic flow graph (PFG) for modeling the movement of objects from one symbolic location to another. The PFG is formally defined as a labeled directed graph $G = (L, E, D, H, lb_E)$, where:
1) $L$ is the set of locations where each location is represented as a vertex in $G$.
2) $E$ is the set of directed edges: $E = \{(l_i, l_j) | l_i, l_j \in L\}$.
3) $D$ is the set of durations. $D_{i,j} \subseteq D$ represents the set of durations taken by objects for the transitions from $l_i$ to $l_j$.
4) $H$ is the set of LDPHs, where an $LDPH_{i,j} \in H$ is computed from the number of transitions from location $l_i$ to $l_j$ and the durations $D_{i,j} \subseteq D$.
5) $lb_E$ is a function $lb_E: E \rightarrow H$ that labels an edge by an LDPH, $h \in H$. An edge $(l_i, l_j) \in E$ is labeled by an LDPH $LDPH_{i,j} \in H$, where $LDPH_{i,j}$ is the LDPH from $l_i$ to $l_j$.

Fig. 4 shows the PFG constructed from the transition summary shown in Table III. Two LDPHs of Fig. 4 is shown in Fig 3. However, all the data for the rest of the LDPHs are available in the $LDP(tr, d_k^2)$ column of Table III.
V. ONLINE RISK PREDICTION (ORP)

In an SLT system, the movements of the mishandled objects are expected to differ from the usual movement. They can take a wrong transition or can stay longer between planned locations. As the PFG is learned from the historical data, we use it for obtaining a probability score of an online object and use the score for predicting the unusual movements. We consider a scenario, where the path of a given online object is predefined. For example, in the case of the baggage tracking, all the bags intended for a particular flight SKI23 should follow the same path sequence starting from the check-in desk up to the belt loader to the aircraft (e.g., \( l_1 \rightarrow l_2 \rightarrow l_3 \rightarrow l_5 \rightarrow l_7 \)). If the object does not follow its pre-planned path, it is triggered as risky. However, an object following its preplanned path, but taking a unusually longer duration for a transition can make the object risky. We use two different thresholds to decide the riskiness of an object. The method of finding the threshold is discussed at the end of this section. For each transition \( l_i \rightarrow l_j \) in the PFG, we use an LDP threshold \( LDP_{th}(l_i, l_j) \), that helps to get the maximum acceptable stay duration \( (Dur_{max}(l_i, l_j)) \) of an object between \( l_i \) and \( l_j \). If an object spends equal or more than \( Dur_{max}(l_i, l_j) \) between \( l_i \) and \( l_j \), the object is considered at risk. Another threshold is called risk score threshold \( (RS_{th}) \). After each transition of an object \( o \), its combined duration probability (CDP) for the so far traversed path is computed by multiplying the LDPs for the transitions as shown in Eq. (2).

In Eq. (2), \( n \) is the total number of transitions of \( o \) and \( LDP'_{th} \) is the LDP for the stay duration of \( o \) obtained from the LDPH for \( o \)'s \( t_{ij} \) transition. The value of CDP is converted into risk score \( (RS) \) by, \( RS = 1 - CDP \). If \( RS > RS_{th} \), we trigger that \( o \) is at risk. Maintaining the value of \( RS \) helps to find the top-k risky online objects in the system.

\[
CDP(o) = \prod_{i=1}^{n} LDP'_{th} \tag{2}
\]

Generally, when a PFG is learned from a large data set, the LDPHs should contain most of the possible stay durations for the upcoming new objects. However, if a new object \( o \) takes \( d \) duration for a transition \( l_i \rightarrow l_j \) and \( d \) is not directly available in LDPH \( l_i \rightarrow l_j \), the value of LDP \( l_i \rightarrow l_j, \) \( d \) is computed in one of the following ways:

- If \( d < d_{first} \) (the first entry of LDPH \( l_i \rightarrow l_j \)), then LDP \( l_i \rightarrow l_j, \) \( d \) is \( LDP(l_i, l_j, d_{first}) \).
- If \( d > d_{last} \) (the last entry of LDPH \( l_i \rightarrow l_j \)), then LDP \( l_i \rightarrow l_j, \) \( d \) is \( LDP(l_i, l_j, d_{last}) \).
- For the other cases we use linear interpolation to obtain the value of LDP \( l_i \rightarrow l_j, \) \( d \) from LDPH \( l_i \rightarrow l_j \).

Furthermore, as the new online object becomes part of the historical data after its operation, its new duration is included in the PFG next time when a new model is built. Now coming to the ORP, if \( LDP_{th}(l_i, l_j) \) is not directly available from LDPH \( l_i \rightarrow l_j \), we use linear interpolation for computing the duration (i.e., the value in X-axis) for that \( LDP_{th} \) and use it as the \( Dur_{max} \) for that transition.

For example, consider an object \( o \) following a path: \( l_1 \rightarrow l_2 \rightarrow l_3 \rightarrow l_5 \rightarrow l_7 \). The labels in the arrows represent the duration taken for the transitions. Let us consider that the object followed its preplanned path. As the LDPH \( l_1 \rightarrow l_2 \) has no entry for 17, its expected value by linear interpolation is, LDP \( l_1 \rightarrow l_2, 17 \) \( = 0.7(0.7-0.3)/(20-16) \times (17-16) = 0.6 \). The full CDP for the object is \( LDP(l_1, l_2, 17^9) \times LDP(l_2, l_3, 17^9) \times LDP(l_3, l_5, 60^9) \times LDP(l_5, l_7, 40^9) \) \( = 0.6 \times 0.05 \times 1 \times 1 = 0.03 \). Let us consider that \( RS_{th} = 0.8 \) and \( LDP_{th} \) for each of the transitions is 0.2. So, \( Dur_{max}(l_1, l_2) \) by linear interpolation \( = [20 + (0.3-0.2)/(0.3-0.02) \times (28-20)] = 23 \). Similarly, \( Dur_{max}(l_2, l_3) = 15 \). When \( o \) completes its first transition (i.e., \( l_1 \rightarrow l_2 \)), it passes both of the LDP and RS checks for that transition as the spent duration \( 17 < Dur_{max} = 23 \) and \( RS = 1 - CDP = 0.4 \). So, the bag is not risky until the current state. When \( o \) reaches at \( l_3 \), the spent duration \( 17 < Dur_{max} = 15 \). Furthermore, the CDP of \( o \) up to this location is 0.03 \((0.6 \times 0.05) \). So, \( RS = 1 - 0.03 = 0.97 \geq RS_{th} = 0.8 \). So, \( o \) is considered as a risky object after this transition in terms of both \( Dur_{max} \) and \( RS_{th} \).

![Fig. 5: Online risk prediction steps](image-url)
the first reading time of \( o_i \) at \( t_{curr} \) and \( t_{max} = t_{start} + Dur_{max} \). As mentioned earlier, the value of \( Dur_{max} \) is extracted from the corresponding LDPH. If \( o_i \) remains between \( t_{curr} \) and \( t_{p_{next}} \), until the clock time reaches \( t_{max} \), the time trigger \( TT_{oi} \) is raised and the trigger marks \( o_i \) as risky. Coming back to the starting point, if the new reading contains an old object, the process checks whether the object has changed its location. If it is in the same location, the process continues waiting for a new reading and a raise of a time trigger. However, if the object changes its location, its planned location is checked and based on that its further processing such as CDP computation, RS checking, time trigger update, etc., is performed. The time trigger allows a fast notification about a risky object as the process does not have to wait to complete the transition.

Algorithm 1 shows the processing of the ORP. It takes a hash table, \( RS_{th} \), \( LDP_{th} \) list, and PFG as the input and updates the hash table as the result. The algorithm continuously waits for a new reading or a raise of a time trigger (lines 1-2). If a new reading arrives, based on the data in the new reading, it updates the hash table \( HT \). First, it checks whether the object \( o_i \) in the new reading is newly arrived in the system (line 5). If \( o_i \) is new, it is inserted in \( HT \) (line 6), and its preplanned path is checked (lines 6-9). If \( o_i \) is in the planned location, it is initialized to a safe object (lines 11-12). Based on the next planned location and \( LDP_{th} \), its \( Dur_{max} \) is extracted from the PFG (lines 13-14), maximum clock time threshold \( t_{max} \) is calculated (line 15), and a time trigger is registered for \( o_i \) (line 16). If \( o_i \) is not new, it is checked whether \( o_i \) has changed its location (line 17). If \( o_i \) has not changed its location, the algorithm continues waiting for a new reading or a raise in a time trigger. Conversely, if \( o_i \) changes its location in the new reading, its planned path is checked (lines 18-21). If it is in the planned path, \( o_i \)’s time trigger is updated with the new information (lines 22-25). After that, \( o_i \)’s stay duration for the transition is computed, CDP and RS are calculated, and the RS is checked with the \( RS_{th} \) (lines 26-31). Besides, if a time trigger is fired, the corresponding object is notified as risky (lines 33-35).

**Recovery Scenario.** The PFG cannot capture the possibility of a recovery of an object from its risky state. For example, an object might take a long duration between location \( l_1 \) to \( l_2 \) that makes it risky. However, it might be handled very quickly in its next transition \( l_2 \) to \( l_3 \) that recovers the object from being mishandled. To capture this, we modify the PFG into aggregate probability flow graph (APFG). Here, we additionally maintain an aggregate LDPH (ALDPH) for each path sequence \( S=l_1,l_1+1,l_1+2,...,l_n \), where \( l_i \) must be the first tracking location of at least one object in the data set and \( i<<n<=p \) (the length of the path sequence). An ALDPH (\( S \)) contains all the aggregate LDPs (ALDP) for \( S \). An ALDPH \( (S,d^p) \) represents the probability of taking at least a duration of \( d \) by an object for completing the path sequence \( S \). The value of an ALDPH for the path sequence \( S \) with a total duration \( d \) is computed by Eq. (3). In Eq. (3), \( Count(S,d^p) \) is the number of objects taking at least a \( d \) duration to complete the path sequence \( S \) and \( Count(S) \) is the number of objects traveling through path sequence \( S \). Table IV shows the ALDPs and data for ALDPHs for the path from \( l_1 \) to \( l_7 \) in our example scenario.

\[
ALDP(S,d^p) = \frac{Count(S,d^p)}{Count(S)} \tag{3}
\]

The processing of the ORP with the APFG is very similar to the algorithm discussed above with some additional conditions and operations. First, after each transition, in addition to the CDP computation, the ALDP for the traveled path is extracted from the corresponding ALDPH. If \( CDP<ALDP \), then CDP is updated with the value of ALDP to make the score less risky. Also note that for the first transition, the values of ALDP and LDP are the same. Second, instead of using \( LDP_{th} \) for each transition, we maintain an \( ALDP_{th}(s_i) \) for each path sequence \( s_i \) for each of the preplanned paths. In our example scenario, for the path from \( l_1 \) to \( l_7 \), there will be ALDP thresholds for each of the path sequences mentioned in Table IV.
the concept of \( \text{Dur}_\text{max}(l_i,l_j) \) is changed to \( \text{Dur}_\text{max}(s_i) \), where \( \text{Dur}_\text{max} \) represents the maximum allowable duration for an object to complete the path sequence \( s_i \). The value of \( \text{Dur}_\text{max}(s_i) \) can be extracted from the \( \text{ALDPH}(s_i) \) based on the \( \text{ALDP}(s_i) \). Fourth, the concept of the time trigger is updated with the concept of ALDP and its structure is changed to \( \text{TT}_{\text{oi}}(s_i, l_\text{prestart}, t_\text{start}, t_{\text{premax}}, k) \), where \( s_i \) is the so far completed path sequence by \( \text{oi} \), \( l_\text{prestart} \) is the next planned location, \( t_\text{start} \) is the timestamp when \( \text{oi} \) first tracked in the system, and \( t_{\text{premax}} = t_\text{start} + \text{Dur}_\text{max}(s_\text{premax}) \), where \( s_\text{premax} \) is the path sequence up to \( l_\text{premax} \) (i.e., \( s_i \rightarrow l_\text{premax} \)). Then the rest of the procedure is the same as the above algorithm.

Consider the example discussed above where an object \( o \) followed a path: \( l_1 \rightarrow l_2 \rightarrow l_3 \rightarrow l_4 \). In the above example, \( o \) was marked as risky when it completed the path up to \( l_3 \). From Table IV, the ALDP up to \( l_3 \) is 0.05 (as the total duration = 17 + 17 = 34). In terms of both LDP and ALDP, \( o \) is at risk at that point. After the next transition (i.e., up to \( l_4 \)), the ALDP is 0.41, thus \( RS = 0.59 \frac{1}{2} \times 0.41 = 0.09 \) (as total duration = 17 + 17 + 60 = 94). However, the value of CDP up to \( l_4 \) is 0.6 \times 0.05 \times 1 = 0.03. The value of CDP either decreases or remains same while multiplying new LDPs. The new score shows that the object recovered from its risky state as it was processed quickly between \( l_3 \) and \( l_4 \). So, we update the CDP with the value of ALDP and mark \( o \) as not risky. When \( o \) moves further, the time trigger for \( o \) is also updated based on the traversed path sequence, preplanned path, and ALDP at that transition.

**Time Constrained ORP.** Generally, a slow processing of an object at a location makes the object risky. This slow processing could also result in a dense location or traffic jam that could hamper the processing of the upcoming objects. However, there are many applications where an object has to reach a particular location within a given timestamp. For example, in the baggage tracking, a bag has to be loaded in the aircraft before the scheduled flight departure. So, the available duration before the flight departure is an important factor for baggage risk prediction. If a bag starts its processing well in advance before the flight departure, it is less risky, even if it stays longer for a transition. Conversely, a bag having a short duration before the flight makes it risky, even it is processed relatively quickly in its transitions. So, the stay duration should be normalized with the available processing time and use the normalized duration for taking the corresponding ALDP to reflect the actual riskiness of the object.

Let us consider, \( t_\text{enter} \) be the first time an object \( o \) detected in the system and \( t_\text{final} \) be the maximum timestamp when \( o \) should reach its final reading point/location. So, the total available duration for \( o \) is \( d_a = t_\text{final} - t_\text{enter} \). The expected average duration of travel of an object is extracted from the \( \text{ALDP} \) for the full preplanned path of the object. Let \( d_c \) be that expected duration extracted from the \( \text{ALDP} \) with \( \text{ALDP} = 0.5 \). After each transition of \( o \), its normalized total stay duration for the so far traversed path is computed by Eq. (4), where \( \text{dur}_i \) is the stay duration of \( o \) for its \( i_{th} \) transition. In the equation, the value of \( \text{offset} \) is computed initially by subtracting the value of \( d_a \) from \( d_c \). Then, after the \( k_{th} \) transition of \( o \), its total travel time up to that transition is added to the offset for obtaining the normalized duration. So, instead of taking the ALDP directly for the total duration \( d_a \), we take the ALDP for \( d_n \). Depending on the value of \( d_a \) and \( d_c \), the value of \( \text{offset} \) as well as \( d_n \) can be negative. As discussed earlier about picking the LDP from an LDPH for a given duration, the value of ALDP for \( d_n \) is also taken in the same way from the corresponding \( \text{ALDPH} \).

\[
    d_n(o) = \text{Offset} + \sum_{i=1}^{k} \text{dur}_i, \text{where offset} = (d_c - d_a) \quad (4)
\]

For example, consider an object \( o_1 \) following its preplanned path and the stay durations for the transitions are: \( l_1 \rightarrow l_2 \rightarrow l_3 \rightarrow l_5 \rightarrow l_7 \). \( o_1 \) has a total of 200 seconds to reach \( l_7 \) from \( l_1 \). So, \( d_a = 200 \) sec. From Table IV, \( d_c = 134 \) (as ALDP for 134 is 0.51). So, \( \text{offset} = 134 - 200 = -66 \). Now, for the first transition \( l_1 \rightarrow l_2 \), \( d_n = -66 + 17 = -49 \). So, from Table III, the value of ALDP or LDP for the transition is 1. It shows that instead of taking the actual LDP for duration 17 (which was 0.6 as computed earlier), we take the LDP for normalized duration. As \( o \) has plenty of time to reach \( l_7 \), the normalization makes the object less risky. After the next transition to \( l_3, d_n = -66 + 17 + 17 = -32 \). So, the ALDP after normalization is 1. Before the normalization, the ALDP was 0.05. However, after normalization the score says that the object is completely safe until that transition. Similarly, when \( o_1 \) reaches at \( l_7 \), the total stay duration is 178 and the normalized duration is 112. Thus, without normalization the ALDP is 0.02 and with normalization ALDP is 1. It shows that, even \( o_1 \) takes long for its transitions, the normalization marks it as a safe object as it has a long available time to reach its destination.

**Adjusting \( \text{Dur}_{\text{max}} \) and Time Trigger.** During processing of the ORP, \( \text{Dur}_{\text{max}}(s_i) \) is adjusted to the concept of normalization. The normalized maximum allowable duration of an object \( o \) for completing its path sequence \( s_i \) is computed by, \( \text{Dur}_{\text{max}}(s_i, o) = \text{Dur}_{\text{max}}(s_i) - \text{offset} \). As seen, if the value of \( \text{offset} \) is negative, then \( \text{Dur}_{\text{max}}(s_i, o) \) allows more time to

---

$o$. Besides, the higher value of $\text{offset}$ will reduce the value of $\text{Dur}_{\text{maxN}}$ for adjusting the riskiness of $o$. Finally, $t_{\text{e}_{\text{max}}} \text{ in the corresponding time trigger is computed by, } t_{\text{e}_{\text{max}}} = t_{\text{start}} + \text{Dur}_{\text{maxN}}$ and is used for the risk prediction.

**Finding the best thresholds.** The optimal threshold depends on the particular goal of the system. We consider mishandled as a positive class for classification. A prediction system, giving too many false positives (FP) (i.e., predicting correctly handled objects as the mishandled objects) or false negatives (FN) (i.e., predicting mishandled objects as the correctly handled objects) can make the system useless or not interesting. So, there should be a defined acceptable metric for deciding the optimal operational threshold. We define a benefit function based on the operation cost, where the costs for the different kinds of errors are used for finding the threshold that maximizes the benefit. For example, In the case of baggage tracking, if a bag is predicted as mishandled, it requires a special manual handling so that the bag can reach the airport before the flight. If an FP occurs, there will be a waste in the human resource cost for the mistake. However, if an FN occurs, there will be a significant cost to deliver the bag to the passenger’s address and insurance and other operating costs are involved for such mistakes as well. So, in the baggage tracking scenario, the cost for an FN is much more compared to that for an FP. During model building and testing (discussed further in Section VI), we use Eq. (5) for obtaining the total benefit for each of the generated thresholds and use the threshold that provides the maximum benefit. In Eq. (5), $x=$ cost for handling a mishandled object (i.e., positive case (P)), $y=$ cost for handling a predicted mishandled object (i.e., TP and FP), and $\#P$ is the total number of positive cases in the data set. So, Eq. (5) can provide an idea how much money can be saved by using the ORP system.

$$\text{Benefit}(x, y) = x \times \#P - (x \times \#\text{FN} + y \times (\#\text{TP} + \#\text{FP})) \quad (5)$$

VI. EXPERIMENTAL EVALUATION

The PFG and APFG are implemented using a set of SQL statements and the prediction is implemented in C#. For all SQL queries, we use a leading RDBMS. The experiments are conducted on a laptop with an Intel Core i7 2.7 GHz processor with 8 GB RAM. The operating system is Windows 7 64 bit.

A. Data Sets Descriptions

We use both synthetic and real data for experimenting the different aspects of the proposed systems. The real data set reflects a specific scenario and contains a lot of erroneous readings, miss readings, and other anomalies. So, only experimenting with such real data cannot provide the other aspects of the prediction systems. Furthermore, synthetic data can be generated in different ways to see how the models perform with different ratios and distributions. During model building and prediction, it is assumed that the data set is cleaned.

**Synthetic data sets.** We generate 5 different data sets for the airport baggage tracking scenario, where bags follow the paths shown in the floor plan in Fig 1. There are two preplanned paths, $P1: l_1 \rightarrow l_2 \rightarrow l_3 \rightarrow l_4 \rightarrow l_5 \rightarrow l_6$, and $P2: l_1 \rightarrow l_2 \rightarrow l_3 \rightarrow l_6 \rightarrow l_7$. There are 20 flights a day and each flight departs after every 30 to 60 minutes. The first flight of the day starts at 8:00 am. In each of the data sets, there are a total of 5K flights carrying 100K bags. Each of the flights has 20 registered bags. Each data set contains approximately 450K stay records. Flight IDs and bag IDs are generated sequentially and the flight with even IDs are allocated to path P1 and others to P2. Bags are checked in at the earliest 3 hours and the latest 30 minutes before the flights. For each possible transition, bags follow a realistic range of duration with different distributions that will be discussed next. In our example scenario, the transitions $l_1 \rightarrow l_2$ and $l_2 \rightarrow l_3$ have less influence on baggage mishandling, whereas the sorters (i.e., $l_3 \rightarrow l_5$, $l_3 \rightarrow l_4$, and $l_4 \rightarrow l_6$) have higher influence. So, we put relatively smaller time intervals for those transitions.

The duration ranges (in seconds) for different paths are, $P1: l_1 \rightarrow l_2$ $25$-$60$, $l_2 \rightarrow l_3$ $50$-$300$, $l_4 \rightarrow l_5$ $120$-$900$, $l_5 \rightarrow l_6$ $400$-$500$, and for $P2: l_1 \rightarrow l_2$ $25$-$60$, $l_2 \rightarrow l_3$ $50$-$300$, $l_4 \rightarrow l_5$ $120$-$2500$, $l_5 \rightarrow l_6$ $400$-$500$.

Varying the distributions of the durations for the transitions and durations before the flights, we generate 5 different data sets (DS). Each data set is divided into a training set (TRS) and a test set (TSS) containing 70K and 30K bags, respectively. It is also made sure that the bags for the same flight are not be distributed between training and test set as it might give a biased estimation due to overfitting. We also use validation sets from the TRS for cross validation while finding the best model. The real data set contains 12% mishandled bags. The data sets are described below:

- **DS$_1$:** Transition durations and durations before flights are uniformly distributed. DS$_1$ contains 53% mishandled bags.
- **DS$_2$:** Transition durations follow a normal distribution and durations before flights follow uniform distribution. DS$_2$ can show the effect in the models when the transition durations are normally distributed compared to the uniform distribution of DS$_1$. DS$_2$ contains 54% mishandled bags.
- **DS$_3$:** Transition durations follow a log-normal distribution and durations before flights follow uniform distribution. As a log-normal distribution creates long tail, it generates less mishandled bags compared to DS$_1$ and DS$_2$. This distribution reflects a more realistic scenario of airport baggage tracking. The data set contains 12% mishandled bags.
- **DS$_4$:** Transition durations follow a log-normal distribution with different $\mu$ and $\sigma$ compared to DS$_3$ and durations before flights follow a normal distribution. The main intention is to reduce the mishandling rate to below 2%. It also can expose how good the models are when the mishandling rate is very low. DS$_4$ contains 1.42% mishandled bags.
- **DS$_5$:** The distributions of durations are similar to DS$_4$. However, the bags flow from the opposite direction. So, in DS$_5$, $P1 = l_7 \rightarrow l_5 \rightarrow l_3 \rightarrow l_2 \rightarrow l_4$, and $P2 = l_8 \rightarrow l_6 \rightarrow l_4 \rightarrow l_3 \rightarrow l_2 \rightarrow l_1$. As seen, the change in direction of the path brings the sorter in the earlier step. In the sorter bags generally spend most of its operational time and considered as the bottleneck of the system. The data set can show how bringing bottleneck
earlier in the path can affect the models. DS3 contains 1.53% mishandled bags.

Real data sets (DSR). We use a small real RFID baggage tracking data set from the departure system of an airport A1. For the reason of confidentiality, the airports’ names are not disclosed. The bags are originated from A1 to the destination airport A2. In A1, there are 6 RFID readers deployed. Four of them are for departure system that includes Check-in, Sorter, Gateway1, and BeltLoader and 2 of them for arrival system. From the data set we derived three different preplanned paths, \( P_{r1} \): Check-in → Sorter → Gateway1 → BeltLoader, \( P_{r2} \): Check-in → Sorter → Gateway1, and \( P_{r3} \): Check-in → Sorter → BeltLoader. After removing many noisy records, we have a total of 20.4K bags for 2.5K different flights. There are only 75 mishandled (MH) bags which are only 0.35% of the total bags. The details for the training set are: total 15.9K, MH 29 (0.18%), \( P_{r1} \)-[total 1.5K, MH 27], \( P_{r2} \)-[total 10.1K, MH 4], \( P_{r3} \)-[4.3K, MH 18]. The test set details are: total 4.6K, MH 43, \( P_{r1} \)-[total 1.5K, MH 20], \( P_{r2} \)-[total 2.6K, MH 20], \( P_{r3} \)-[total 0.5K, MH 3].

B. Test Cases

We build PFGs and APFGs from all the mentioned data sets and tested them from various perspectives. The PFGs and APFGs are constructed from the combined records (i.e., containing all the paths in the data sets) called C-PFG, and C-APFG, respectively. We also separately build PFGs and APFGs with the records of each different path, e.g., P1-PFG, P1-APFG for P1 in synthetic data, \( P_{r1} \)-PFG, \( P_{r1} \)-APFG for \( P_{r1} \) in real data, etc. The PFGs and APFGs are tested on the test set for the relevant paths. We test them without normalizing (WON) and with normalizing (WN) the durations before flights.

We apply the PFGs and APFGs on all the bags of the TSS and for each bag, we obtain a risk score for each of its transitions based on their transition duration. For each of the generated risk scores \( r \), we compute the recall, where \( \text{recall}(r) = \frac{\# \text{ of mishandled bags}}{\# \text{ of bags having a risk score } \geq r} \). Conversely, for each \( r \), we also compute the precision, where \( \text{precision}(r) = \frac{\# \text{ of mishandled bags having a risk score } \geq r}{\# \text{ of mishandled bags}} \). In our scenario, a perfect precision score of 1 means that all the classified mishandled bags are actually mishandled. However, this precision score says nothing about whether all mishandled bags are predicted correctly. Conversely, a perfect recall score of 1 means that all the actually mishandled bags are classified as mishandled. However, this recall says nothing about how many correctly handled bags are wrongly predicted as mishandled. We draw precision-recall (PR) curves that represent how precision and recall changes with the risk scores. The perfect point in a PR curve is (1,1) that represents the predictions for the mishandled bags are perfect and any correctly handled bags are not predicted as mishandled.

We generate PR curves for the various test cases discussed above and report only the cases that are interesting to analyze. For all the test cases we analyze the PR curves for the different transition lengths, e.g., for path \( P_1 \) there are 4 different lengths of transitions \( l_1 \) to \( l_2 \) (Len1), \( l_1 \) to \( l_3 \) (Len2), ..., and \( l_1 \) to \( l_7 \) (Len4). Similarly, \( P_2 \) has 5 different lengths of transitions. For the real data, \( P_{r1} \) has 3 different transitions, \( P_{r2} \) and \( P_{r3} \) have 2 different lengths of transitions. The PR curves for the different test cases are reported in Fig. 6 and 7. The PR curves are analyzed from the different perspectives and explained next. The PR curves for DS2 and DS3 are not reported as they show the same behavior as others.

C. Analyzing the PR Curves

PFGs vs. APFGs. The PR curves for comparing the PFGs and APFGs are shown in Fig. 6a and 6b. Fig. 6a reports the PR curves generated by applying P1-PFG and P1-APFG on the TSS for \( P_1 \) in DS3. It reports the results for Len3 and Len4. PFG-Len3 can be compared with APFG-Len3 and so on. The results show that the APFGs always provide higher precision compared to the PFGs. As we found same type behavior for the other DSs, they are not reported due to space limitation. Fig. 6b shows the similar experiments with DS_R. For Len1 PFG and APFG provide the same score. So, the lines are overlapped. However, for Len2, the APFG provides relatively better results. Overall from the experimental results, it is clear that the APFGs can better capture the riskiness and recovery of the objects and better differentiate between the correctly and incorrectly handled bags. In rest of the experiments, we report only the results with APFG.

With and without normalization. The PR curves for comparing the results with and without normalizing the duration before flights are presented in Fig. 6c and 6d. In Fig. 6c, P2-APFG is applied on the records for \( P_2 \) in DS1. In Fig. 6d, we use the same APFG used for Fig. 6b. In all cases, the results show that the normalizing boosts the performance. In all the cases except WN-Len1 (Fig. 6d), we can get almost a perfect classification, i.e., close to full precision with 100% recall when normalizing. The results for WN-Len1 can be understood better in the next paragraph.
Influence of path length and location type. Fig. 7 reports the PR curves for showing the effect of path length on the classification performance. Overall, the results show that the performance gets better with increasing the path length. In the case of DS1 (Fig. 7a) and DS3 (Fig. 7b), Len1 and Len2 have less influence on a baggage mishandling. These transitions also take very short durations. As a result, the performance is poor up to those transitions. However, in the case of DS5, which contains the same distribution as DS1, with the direction of the path is reversed, the performances from Len2 and afterward are close to perfect classification. The main mishandling occurs in the sorting system as a bag takes longer for completing its sortation. So, it shows that the model can classify mishandled bags very accurately when they come in the bottleneck in their path and the result continues getting better as objects move forward. The result with DS5 also shows the similar behavior (Fig. 7d).

Combined model vs. specialized model for each path. Comparing the results of Fig. 6c with Fig. 7a shows that testing the bags with path P2 by the C-APFGs and P2-APFGs provides the same result. In all the experimental cases we found that testing the bags with combined model and specialized model provide the same results. However, it is also true that the ALDPHs of a C-APFG become specialized for the different paths when they start following different path sequences. In our generated data set, P1 and P2 have a common path from $l_1$ to $l_2$. After that, they follow different path sequences. So, it will be best to use only combined model, instead of building many models for different paths.

Effect of data distribution and mishandle ratio. In general, the data distributions do not change the overall behavior of the models. In DS1, the mishandling rate is balanced. So, it starts giving very good precision from Len1 (Fig. 7a) compared to the other cases where the mishandling rate is extremely low (Fig. 7b to 7d). However, the models built from all our different data set provide very good results. It also shows the proposed APFG with normalization can perform very well in an imbalanced class situation and does not get affected by the class imbalance problem.

Finding the best $RS_{th}$. We use $DS_1$ in this experiment. TRS of $DS_1$ is divided into 10 folds for the standard k-fold cross validation. Each fold contains 17.4K bags, where almost half of them belong to P1. It is also made sure that the bags from the same flight are not distributed to multiple folds. We do not use $DS_R$ to show this experiment as $DS_R$ is small and dividing it into multiple folds will make it even smaller for learning. Iteratively, we learn APFGs from 9 folds and use the 10th fold for testing. So, finally we have the test results for 10 APFGs. We use Eq. (5) with $w=x$=$96$ (according to [1]) and $y$=$15$ (salary of a baggage handler is app. $13/hour) for obtaining the benefit for the different RSs in the results. For optimizing the $RS_{th}$ for each path length, we take the average of the risk scores that provide the highest benefit in each of the 10 models. Then the average RS is used as the $RS_{th}$ for predicting the riskiness of the actual test bags. The test results are analyzed from two different perspectives. In scenario1 (SC1), the predicted mishandled bags are not removed from the system unless they automatically disappear when they are really mishandled. It can show the actual benefit at different path lengths. In scenario2 (SC2), at different path lengths, the predicted mishandled bags are removed from the system such that they cannot be seen in the subsequent locations in their path. It can show the total benefit if bags are saved whenever it is detected as mishandled. The selected $RS_{th}$,'s, benefits, confusion matrices, and how early the bags are saved before the flight (SBF) for the bags with preplanned path P2 are reported in Table V. As there are 286 mishandled bags, the total cost without using the ORP will be $27456. The benefits with SC1 shows that handling bags only at $L_4$ can save 82% of the total mishandling cost, whereas, in SC2 $\frac{168+1+1464+21141+12}{2464} \times 100 = 83%$ of the total cost can be saved. It also shows that 99% of the mishandled bags are predicted within Len4 and at least 25 minutes before the flights.

Scalability. We use $DS_1$ for building PFGs and APFGs for showing the scalability regarding their construction time and memory use. We use a set of SQL queries with some DDL and DML operations for building PFGs and APFGs and they are stored in the database tables. Before prediction, a C# program loads the PFG and APFG into main memory. The full PFG and APFG construction and loading times are reported in Fig. 8a. In the case of SQL query times, we clear the cache

after executing each operation. In all cases, we run the queries and code 3 times and report the rounded average time. In both cases, the results show that the construction time increases almost linearly with the number of bags. We also report the memory use of LDPHs and ALDPHs for the different numbers of bags. It shows that the size grows linearly with the number of bags. It also shows that the total size of ALDPHs is on average 84% higher than the total size of LDPHs. However, the total size of the ALDPHs is very small, only 194 KB for 70K bags. So, it is feasible even for a larger data set.

VII. RELATED WORK

Related work falls into two main categories. One is to pre-process raw indoor tracking data and another one is to perform data mining on such tracking data. The RFID data management challenges and solutions are discussed in [6], [15]. Data warehousing, mining, and workflow analysis are proposed for RFID-based item tracking in the supply chain systems in [8], [9]. The authors convert the raw RFID records into cleansed record containing the first and last reading times of an object under the readers activation range. In the present paper, we use stay records [2], as it can capture the total stay duration between locations. Graph-based model for indoor tracking is discussed in [3], [11]. In the present paper, we extend graph models for capturing the object flows with new probabilistic concepts such as LDP, ALDP, and histograms.

Data mining is performed on the tracking data for finding frequent spatio-temporal sequential patterns [5], [10], typical movements of objects in indoor space [14], frequent trajectory patterns for activity monitoring [12], and frequent walk in RFID-equipped warehouse [4]. Interesting spatio-temporal rule mining applications, techniques and issues are discussed in [7]. The present paper introduces a new perspective which is for risk prediction in indoor moving object. In [1], RFID baggage tracking data are analyzed for mining risk factors in the offline scenario. The present paper focuses on an online risk prediction scenario that require more fine grained features such as object transitions at the reader level and duration for each of the transitions. Further, this paper is more general as such as object transitions at the reader level and duration for risk prediction scenario that require more fine grained features.

The present paper focuses on an online indoor moving object. We converted the historical raw tracking records into stay records and used them for constructing the probabilistic flow graphs called PFG and APFG. The graphs capture the probabilistic information about the transition times by using histograms called least duration probability histogram LDPH and aggregated LDPH (ALDPH). The flow graphs are used for obtaining risk score of an online indoor moving object and for predicting risks. A comprehensive experiment with synthetic and real data showed that the proposed risk prediction method can differentiate risky objects from the correctly handled objects very accurately when the objects approach the bottleneck locations on their paths. We also proposed a cost model for object mishandling and the experiments showed that using APFG with the proposed normalization can significantly save the operation cost. The result also showed that the risky objects are predicted early enough such that they can be saved from being mishandled.

In future work, the proposed techniques can be expanded to more general scenarios such as mixed indoor-outdoor object tracking. Further, predicting risks for the objects in nondeterministic scenarios, where the paths of the objects are unknown in advance, can be another future direction.
