Sensitivity Analysis of Inductive Power Transfer Systems with Voltage-Fed Compensation Topologies

Jianghua Lu, Student Member, IEEE, Guorong Zhu, Senior Member, IEEE, Huai Wang, Senior Member, IEEE, Fei Lu, Member, IEEE, Jin Jiang, Fellow, IEEE, and Chunting Chris Mi, Fellow, IEEE

Abstract—The output characteristics and the transfer efficiencies of Inductive Power Transfer (IPT) systems are affected by the variation of parameters such as, but not limited to, variable load, misalignment between the primary and secondary coils, and resonance frequency detuning. This paper first analyzes the resonant conditions of all voltage-fed compensation topologies in IPT systems to achieve the load-independent voltage transfer characteristic at load-independent Zero Phase Angle (ZPA) frequency. With these conditions, the parameters sensitivity to the key performance factors of the S-SP, LCC-S, LCC-P, and double-sided LCC compensated IPT systems are systematically investigated when considering the losses in coils and compensation networks. Comparisons of the quantitative sensitivity analysis and experimental results for all IPT systems are made in terms of the voltage transfer ratio and efficiency. These analyses can provide guidance for the selection of superior compensation networks to minimize the additional converter effort and simplify the control algorithm of closed-loop IPT systems.

Index Terms—Compensation topology, constant voltage, inductive power transfer, parametric uncertainty, sensitivity, Zero Phase Angle (ZPA).

I. INTRODUCTION

INDUCTIVE power transfer (IPT) technology [1], [2] using magnetic coupling can transfer power from several milliwatts to hundreds of kilowatts with transfer distances from a few millimeters to several meters. The IPT technology has gained its wide acceptance across a range of applications such as electronic devices, wearable/implantable electronics, home appliances, and electric vehicles (EVs).

In IPT applications, several compensation networks in both primary (transmitter) and secondary (receiver) sides have been proposed and are usually used to achieve and/or improve the following one or more characteristics:

1) Near zero input reactive power. It is desirable for the primary inverter in IPT system to have Zero Phase Angle (ZPA) operating condition between the inverter output voltage and current. In such case, there is no reactive power circulating in the loop, which can minimize the Volt-Ampere (VA) rating of the power supply, increase the transfer power to the load, and make it easy to ensure Zero Voltage Switching (ZVS) [3], [4]. For example, ZPA operation is achieved for the series-series (S-S) compensation topology when the primary and secondary compensation capacitors are used to resonant with the self-inductance of the primary and secondary coils respectively [5].

2) Constant current and/or constant voltage output. A constant charging current for LED (Light Emitting Diode) application and a charging profile with constant current/constant voltage for EV and electric bicycle charger, regardless of the value of the load resistance, are the most important characteristics for IPT system. Among the approaches for achieving load-independent current output and/or load-independent voltage output, the method of designing special tuning conditions for compensation topology [4], [6] has the advantages of higher efficiency and lower cost compared with a back-end DC/DC converter [7] and is free from frequency bifurcation phenomenon and wireless data communication link between secondary and primary sides for the variable frequency control method [8]. The load-independent current output feature has been analyzed for the S-S [4], [9]-[12], series-parallel (S-P) [12], LCC-parallel (LCC-P) [4], and double-sided LCC [4], [6], [13], [14] compensation topologies by designing special tuning methods. And the load-independent voltage transfer characteristic is investigated for the S-S [4], [9], [15], [16], S-P [5], [16], S-SP [4], [17], LCC-series (LCC-S) [4], S-CLC [18], and double-sided LCC topologies [13], [14]. In [19], a general method that models a resonant circuit as gyrators in series is proposed. This method can be used to analyze the load-independent current output or voltage output characteristic of any compensation topologies in IPT system. Further, under the condition of achieving load-independent current output characteristic, input ZPA operations are analyzed for S-S [4], [5], [9], [10].
for an open-loop IPT system, what we desire to accomplish is not only minimize the output voltage and/or current fluctuation, but also achieve higher and steady efficiency under taking into account the variations of the input voltage, resonant frequency, coupling, and load. In this case, a closed-loop IPT systems with minimizing the additional converter effort and simplifying the control algorithm can easily be designed over the entire range of charging profile. So it is necessary to systematically investigate the parametric uncertainty to the key performance factors and compare the robust of the different compensation topologies.

This paper mainly focuses on the comprehensive evaluation of the voltage-fed S-S, S-P, S-SP, LCC-S, LCC-P, and double-sided LCC compensation topologies in IPT system. When the parasitic resistances of the compensation components are neglected, all compensation networks are modeled as cascade combinations of multistages T-circuit to investigate the load-independent voltage transfer characteristics and load-independent ZPA operating conditions. Under these conditions, the influences of the variations of the coupling, load, and frequency on the output voltage and transfer efficiency are analyzed when the coils and compensation networks have the parasitic resistances. Finally, prototypes of 3-kW S-SP, LCC-S, LCC-P, and double-sided LCC compensated IPT systems are implemented to verify the sensitivity analyses.

The remainder of the paper is organized as follows. Section II investigates the equivalent circuits and resonant conditions of the S-S, S-P, S-SP, LCC-S, LCC-P, and double-sided LCC compensation topologies for achieving load-independent voltage outputs with ZPA conditions. Based on the analysis in Section II, the system parameters are designed in Section III, additionally, the sensitivity of the variations of the coupling, load, and frequency on the output voltage and efficiency for all IPT systems are investigated when the resonant components of the system have parasitic resistances. Section IV presents the experimental results of 3-kW IPT systems, followed by the conclusion in Section V.

II. LOAD-INDEPENDENT VOLTAGE TRANSFER CHARACTERISTIC WITH LOAD-INDEPENDENT ZPA

A general IPT system is shown in Fig. 1, which is composed of a full-bridge inverter, a high-order resonant tank network, a rectifier with capacitor (or inductor) filter, and the load. The resonant tank is composed of compensation networks in both primary and secondary sides and a loosely coupled transformer (LCT). \( L_p \) (and/or \( C_p \)) and \( L_s \) (and/or \( C_s \)) represent the compensation inductors (capacitors) in primary and secondary sides respectively. \( L_{PS} \) and \( L_{SS} \) are the self-inductances of the primary and secondary coils, and \( M \) is the mutual inductance between the two coils. \( V_{ab} \) and \( I_{ab} \) represent the phasor forms of the input voltage and current of the resonant tank and \( V_{ab} \) and \( I_{ab} \) are its output voltage and current. The equivalent circuits referred to the primary side for some widely-used voltage-fed compensation topologies (S-S, S-P, S-SP, LCC-S, LCC-P, and double-sided LCC) are shown in Fig. 2(a) to 2(f). It should be pointed out that the parallel-parallel (P-P), the parallel-series (P-S), and the PS-S compensation topologies are not analyzed in this paper because the voltage of the primary parallel compensation capacitor rises to source voltage immediately when the voltage polarity changes, causing instant large current and impairing capacitor lifespan. As shown in Fig. 2, a frequency-domain equivalent circuit is adopted.
This article has been accepted for publication in a future issue of this journal, but has not been fully edited. Content may change prior to final publication. Citation information: DOI 10.1109/TVT.2019.2903565, IEEE Transactions on Vehicular Technology

and only the fundamental component is considered here for simplicity, and the LCT is modeled as its T-model. The first-order RMS value of the input voltage can be expressed as $V_{AB} = 2\sqrt{2}V_{dc}/\pi$ and the equivalent ac resistance for the rectifier with capacitor (or inductor) output filter is given by $R_{ac} = 8R_L/\pi^2$ (or $R_{ac} = \pi^2R_L/8$) [28]. The rectifier with inductor filter should be selected for the S-P, S-SP, and LCC-P topologies. However, the S-S, LCC-S, and double-sided LCC topologies apply the rectifier with capacitor filter. $L_{spL}$ and $L_{sL}$ are the leakage inductance of the primary and secondary coils, and $L_{m}$ represents magnetizing inductance. Here and in the later section, the apostrophe symbol “ ’ ” indicates the corresponding variables of the secondary side converted to primary side. In addition, the unified nomenclature of the compensation components is presented in here. $C_{psx}$ (the first subscript “p” represents primary side, the “s” represents series connection, and subscript “x” represents the different topologies) is the series compensation capacitor at the primary side. And $L_{ssx}$ represents the series compensation inductor at the secondary side.

A. Load-independent voltage transfer ratio

In this paper, we focus on the sensitivity of the output voltages for all voltage-fed compensation topologies in IPT system to the variable parameters. In [14], a general modeling method for an arbitrary high-order resonant network is proposed, in which the resonant network is modeled as multiple T-circuits in series to analyze its load-independent voltage transfer characteristic. We can see that all compensation topologies shown in Fig. 2 are inherently high-order resonant networks. So the proposed method in [14] can be applied to analyze the load-independent voltage transfer characteristics of all compensation topologies. Among all compensation topologies, the double-sided LCC compensation topology shown in Fig. 2(f) has the highest degree of freedom. Thus, it is taken as an example to analyze the load-independent voltage transfer characteristic in detail. The analyses of other compensation topologies will be followed.

For constructing resonant T-circuit to analyze the load-independent voltage transfer characteristic, the series-connected capacitor and inductor branches of the double-sided LCC compensation topology shown in Fig. 2(f), i.e., $C_{psDLCC}$ and $L_{pL}$, are expressed by using $L_{opDLCC}$ and $C_{epDLCC}$. In addition, $L_{sL}$ and $C_{ssDLCC}$ are equivalent to $C_{esDLCC}$ and $L_{esDLCC}$. Then, the double-sided LCC compensation topology can be equivalent to Fig. 3, which is composed of three-stage
This article has been accepted for publication in a future issue of this journal, but has not been fully edited. Content may change prior to final publication. Citation information: DOI 10.1109/TVT.2019.2903565, IEEE Transactions on Vehicular Technology

The double-sided LCC compensation topology to achieve load-independent voltage transfer characteristics of the equivalent T-circuit in [14], the resonant conditions of the double-sided LCC resonant tank.

According to the analysis of achieving load-independent voltage transfer characteristic for the T-circuit in [14], the resonant conditions of the equivalent T-circuit of the double-sided LCC compensation topology to achieve load-independent voltage transfer ratio are expressed as

$$\omega_{DLCC}^2 L_{qDLCC} + \frac{1}{C_{pDLCC}} = \omega_{DLCC}^2 L_{qDLCC} + \frac{1}{C_{sDLCC}}$$

$$\omega_{DLCC}^2 L_{eDLCC} + \frac{1}{C_{sDLCC}} = \omega_{DLCC}^2 L_{eDLCC} + \frac{1}{C_{eDLCC}}$$

where, $\omega_{DLCC}$ represents the resonant angular frequency of the double-sided LCC resonant tank.

According to the analysis of achieving load-independent voltage transfer characteristic for the T-circuit in [14], the resonant conditions of the equivalent T-circuit of the double-sided LCC compensation topology to achieve load-independent voltage transfer ratio are expressed as

$$\frac{\omega_{DLCC}^2}{L_{qDLCC} + \frac{1}{C_{pDLCC}}} = \frac{1}{L_{m} (C_{qDLCC} + C_{eDLCC})}$$

$$\frac{\omega_{DLCC}^2}{L_{eDLCC} + \frac{1}{C_{sDLCC}}} = \frac{L_{eDLCC}}{L_{eDLCC} + \frac{1}{C_{eDLCC}} + \frac{1}{C_{qDLCC} + C_{eDLCC}}}$$

The constant $V_{abDLCC}$ can be achieved when the double-sided LCC compensation topology is driven by a constant voltage supply. And $V_{abDLCC}$ lags $V_{AB}$ by 180 degrees.

Similarly, the S-S and LCC-S compensation topologies can be equivalent to one or more T-circuit in series, which are shown in Fig. 4(a) and 4(d). The S-P, S-SP, and LCC-P compensation topologies are equivalent to cascade connections of one or more T-circuit with a parallel capacitor, which are shown in Fig. 4(c), 4(b), and 4(e), respectively. Here, it should be noted that the output parallel capacitor does not affect the output voltage. So, we only need to analyze the voltage transfer characteristics of the equivalent T-circuits of all compensation topologies.

From Fig. 4, the equivalent variables, resonant conditions for achieving load-independent voltage transfer characteristic, and corresponding mathematical models of the load-independent voltage transfer ratio of the S-S, S-P, S-SP, LCC-S and LCC-P compensation topologies can be presented in Tab. I. From the last column of Tab. I, it can be seen that the voltage transfer ratios of all compensation topologies ($G_{SS}$, $G_{SP}$, $G_{SSP}$, $G_{LCCS}$, and $G_{LCCP}$) are independent of the load. And the output voltages of the S-P, S-SP, and LCC-S topologies are expressed as

$$Z_{inDLCC} = \left( (R' + j\omega_{DLCC} L_{sDLCC}) \parallel \frac{1}{j\omega_{DLCC} C_{pDLCC}} \right) \parallel \frac{1}{j\omega_{DLCC} L_{eDLCC} + \frac{1}{j\omega_{DLCC} C_{eDLCC}}} \parallel j\omega_{DLCC} L_{m}$$

$$= \text{Re} (Z_{inDLCC}) + j \cdot \text{Im} (Z_{inDLCC})$$

$$\text{Im} (Z_{inDLCC}) = 0 \rightarrow$$

$$L_{spDLCC} L_{sDLCC} C_{pDLCC} \left( C_{qDLCC} + C'_{eDLCC} \right) = L_{spDLCC} L_{eDLCC} C_{pDLCC} C'_{eDLCC} + L_{sDLCC} L_{pDLCC} C_{pDLCC} C_{eDLCC}$$

$$\text{(5)}$$
VLC topology is also analyzed in detail. The double-sided LCC-S, LCC-P, and double-sided LCC topologies are analyzed in this section. Here, the double-sided load-independent ZPA operations under the conditions of achieving load-independent voltage transfer ratio and current and ensure ZVS for the MOSFET-based inverter. So, the resonant condition for achieving load-independent ZPA is given by (5), also shown at the bottom of the previous page. Under the conditions of (5), the purely resistive input impedance $R_{\text{inDLCC}}$ is given by

$$R_{\text{inDLCC}} = \text{Re} \left( Z_{\text{inDLCC}} \right) = \frac{R'_{ac} \left( L'_{\text{ppDLCC}} C'_{\text{ppDLCC}} L'_{\text{spDLCC}} \right)^2}{\left| G_{z} \right|^2} \quad (6)$$

Similarly, the load-independent input ZPA operating conditions for the S-P, S-SP, LCC-S, and LCC-P topologies are also calculated, which are tabulated in Tab. II. It can be observed that the input impedance of all compensation topologies are expressed regularly as $R'_{ac}/\left| G_{z} \right|^2$ (the voltage transfer ratio $G_{z}$ has been derived in Tab. I). Additionally, it should be pointed out that there is no ZPA condition for the S-S compensation topology in load-independent voltage output mode. This calculated result is compliance with the analysis in [9], [15]. So, the S-S topology is not listed in Tab. II and will not be analyzed in the next section.

</table>

(\(V_{\text{abSP}}\), \(V_{\text{abSSP}}\), and \(V_{\text{abLCCS}}\)) are in phase with the input voltage \(\left(V_{\text{AB}}\right)\), however, \(V_{\text{abSSP}}\) and \(V_{\text{abLCCP}}\) lag \(V_{\text{AB}}\) by 180 degrees. In addition, the voltage gain of the S-P topology \((G_{SP})\) is equal to the reciprocal of the coupling coefficient, that is \(G_{SP}=1/k\). So the S-P compensation network can be applied to achieve high voltage output application owing to the fact of low coupling coefficient in IPT system.

### B. Load-independent ZPA operating condition in CV mode

The ZPA operating condition between the input voltage and current of the resonant tank can minimize the reactive current and ensure ZVS for the MOSFET-based inverter. So, under the conditions of achieving load-independent voltage transfer characteristics, load-independent input ZPA operations of the S-S, S-P, S-SP, LCC-S, LCC-P, and double-sided LCC topologies are analyzed in this section. Here, the double-sided LCC topology is also analyzed in detail.

From Fig. 3, the input impedance of the double-sided LCC topology $Z_{\text{inDLCC}}$ is given by (4), shown at the bottom of the previous page. In (4), the “∥” represents “parallel circuits” sign. The ZPA condition is achieved when the imaginary component of the input impedance $\text{Im} \left(Z_{\text{inDLCC}}\right)$ equals zero. In this case, the resonant condition for achieving load-independent ZPA is given by (5), also shown at the bottom of the previous page. Under the conditions of (5), the purely resistive input impedance $R_{\text{inDLCC}}$ is given by

$$R_{\text{inDLCC}} = \text{Re} \left( Z_{\text{inDLCC}} \right) = \frac{R'_{ac} \left( L'_{\text{ppDLCC}} C'_{\text{spDLCC}} L'_{\text{plDLCC}} \right)^2}{\left| G_{z} \right|^2} \quad (6)$$
III. QUANTITATIVE SENSITIVITY ANALYSES OF PARAMETRIC UNCERTAINTY IN IPT SYSTEMS

According to the analysis in the last section, both the load-independent output voltages and load-independent ZPA operations for the S-P, S-SP, LCC-S, LCC-P, and double-sided LCC compensation networks are achieved when ignoring the ESR (Equivalent Series Resistance) of the compensation components. However, the variation of the load resistance has negative effect on the output voltage and input impedance when considering the ESRs. Furthermore, these features are also affected by the variations of the frequency and misalignment between the primary and secondary coils. This section first designs the system parameters of all topologies that achieve load-independent voltage output and load-independent ZPA operation simultaneously based on section II. Then, the parameters sensitivity to the key performance factors when considering the ESRs will be analyzed.

A. parameters design

The self-inductances of the primary and secondary coils for all topologies are designed to be equal to 120 μH and the coupling factor of the transformer without misalignment is 0.2. The system operating frequency is 85 kHz. The input DC voltage is equal to 200 V. And the rated voltage transfer ratio is designed to 1.5 to achieve output voltage of 300 V, which can be used to charge the EVs or the automated guided vehicles (AGVs). Then according to the analyses in section II-A and II-B, the system specifications of the S-SP, LCC-S, LCC-P, and double-sided LCC compensated IPT systems are designed and tabulated in Tab. III. For the S-P compensation topology, however, the voltage transfer ratio is always equal to the reciprocal of the coupling coefficient (G_{SP}=1/k) from

Transactions on Vehicular Technology

Fig. 6. Double-sided LCC compensation topology with resonant circuit losses included.

Tab. I. The designed coupling coefficient is 0.2. It means $G_{SP}$ is equal to 5. For the consistency of the study, so, the S-P topology will not be analyzed in the later section. However, it should be pointed out that the S-P compensation topology can be applied to achieve high output voltage owing to the small coupling coefficient in IPT systems.

Substituting the designed parameters into (3), (6), Tab. I, and Tab. II, the voltage transfer ratio and the phase angle of the input impedance $[\bar{P}_{inx} = \alpha = \frac{1}{\pi} \tan \{\frac{1}{\pi} \ln |Z_{inx}|\}]$ for the S-SP, LCC-S, LCC-P, and double-sided LCC topologies with different loading conditions can be plotted, which are shown in Fig. 5(a), 5(b), 5(c), and 5(d). It can be seen that load-independent voltage transfer ratio of 1.5 and load-independent ZPA operation are achieved for all compensation topologies when the IPT system operates at 85 kHz, which match well with the theoretical analysis.

B. Quantitative sensitivity analysis

Based on the designed parameters for the loosely coupled transformer and all compensation networks, the key performance factors versus the variation of the parameters are analyzed when considering the ESRs both of the inductors and capacitors. The double-sided LCC compensation topology is also taken as an example to analyze the sensitivity in detail, which is shown in Fig. 6. $R_{LpDLCC}, R_{CspDLCC}, R_{CpsDLCC}, R_{Lps}, R_{Lss}, R_{CspDLCC}, R_{CpsDLCC}$, and $R_{LsdDLCC}$ are the ESRs of the corresponding passive components. The input impedance $(Z_{inDLCC})$, the phasor form of the currents on primary and secondary coils (I_p and I_l), voltage transfer ratio ($G_{DLCC}$), and transfer efficiency $\eta_{DLCC}$ are calculated in (7), (9), (10), (11), and (12), respectively. In addition, the analysis for the S-SP, LCC-S, and LCC-P topologies are similar to that of the double-sided LCC topology and are therefore omitted.

\[
Z_{inDLCC} = \left(\frac{\omega_{DLCC} M}{Z_{L1} + Z_{Z1}} + Z_{p3}\right) \parallel Z_{p2} + Z_{p1} \tag{7}
\]

where

\[
\begin{align*}
Z_{p1} &= j\omega_{DLCC} L_{psDLCC} + \frac{\omega_{DLCC} L_{psDLCC}}{Q_L} + \frac{V_{AB} - V_{AB} Z_{psDLCC}}{Z_{p2}} Z_{p31}^2 \frac{D_F}{\omega_{DLCC} C_{psDLCC}} + \frac{V_{AB} - V_{AB} Z_{psDLCC}}{Z_{p2}} \frac{D_F}{\omega_{DLCC} C_{psDLCC}} \\
+ I_p \left(\frac{\omega_{DLCC} L_{ps}}{Q_L} + \frac{D_F}{\omega_{DLCC} C_{psDLCC}}\right) + I_l \left(\frac{1}{Z_{L2}} + \frac{1}{\omega_{DLCC} C_{psDLCC}}\right) \frac{D_F}{\omega_{DLCC} C_{psDLCC}} \tag{14}
\end{align*}
\]

In this paper, we consider the variations of the coupling, load, and frequency depending on the practical IPT application. The coupling coefficient $k$ of the transformer is usually changed from 0.1 to 0.3 [29]. The equivalent ac resistance $R_{ac}$ is roughly changed from 10 to 200 $\Omega$ [6] when the battery charging power was between 5% to 100% power. And
the frequency ranges from 81.38-90 kHz according to the SAE J2954. The measured quality factor of the compensation inductors ($Q_L$) without ferrite and aluminum shielding is approximately 500, however, that of the primary and secondary coils with PC40 ferrite core and aluminum shielding ($Q_{LCT}$) is about 200. Then the corresponding parasitic resistances of the compensation inductors can be calculated by $R_L = \omega L / Q$, as well as that of the primary and secondary coils. In addition, double sided metallized polypropylene film capacitors with a dissipation factor ($D_f$) of 1.5% are chosen. So, the ESR of the compensation capacitor can be given by $R_C = D_f / (\omega C)$.

The voltage transfer ratio comparisons between S-SP, LCC-S, LCC-P, and double-sided LCC topologies in respect to the load, normalized frequency (the ratio of resonant frequency to operating frequency), and coupling factor are shown in Fig. 7(a), 7(b), and 7(c) respectively. Overall, the voltage transfer ratio of the double-sided LCC topology is the least sensitive to the variation of the load, frequency, and coupling, and followed by the S-SP topology. It means that the double-sided LCC topology are more suitable for achieving constant output voltage with independent of variation of all possible parameters in a closed-loop IPT system with a back-end DC/DC converter. Because higher efficiency, lower cost, and simple control algorithm can be achieved for a DC/DC converter with narrow output voltage range. In addition, the closer voltage transfer ratios of all topologies are to the ideal value ($G_z=1.5$) at light loads from Fig. 7(a).

Voltage transfer ratio of the S-SP, LCC-S, LCC-P, and double-sided LCC topologies versus (a) loading condition at 85 kHz and the coupling coefficient of 0.2, (b) normalized frequency at the load of 30 $\Omega$ and the coupling of 0.2, and (c) coupling coefficient at 85 kHz and the load of 30 $\Omega$.

Fig. 8. Transfer efficiency of the S-SP, LCC-S, LCC-P, and double-sided LCC resonant tank circuits versus (a) loading condition at 85 kHz and the coupling coefficient of 0.2, (b) normalized frequency at the load of 30 $\Omega$ and the coupling of 0.2, and (c) coupling coefficient at 85 kHz and the load of 30 $\Omega$.

Fig. 9. (a) Loosely coupled transformer and (b) experiment prototype of the S-SP compensated IPT system.
Fig. 10. Experimental results of the (a) S-SP, (b) LCC-S, (c) LCC-P, and (d) double-sided LCC compensated IPT systems at \( k = 0.2 \) and \( R_L = 30 \Omega \).

The simulated AC-AC efficiencies of the S-SP, LCC-S, LCC-P, and double-sided LCC compensation topologies are shown in Fig. 8. It can be seen that the efficiency of the S-SP compensation network is almost superior over a wide range of load (except at the very light load condition) and over the entire of coupling and frequency. In addition, from Fig. 8(c), the larger the coupling coefficient is, the higher the efficiencies for all topologies are achieved. The light load efficiency is a very important figure of merit (FoM) in wireless EV (electric vehicle) charging application. As is seen in Fig. 8(a), the LCC-P architecture has higher and steady light-load performance.

IV. EXPERIMENTAL EVALUATION

To verify the theoretical analysis, 3-kW S-SP, LCC-S, LCC-P, and double-sided LCC compensated IPT prototypes are implemented. In which, unipolar coils with the shape of square are used for both primary and secondary sides and shown in Fig. 9(a). The air gap between the primary and secondary coils is approximately 80 mm. And the designed geometric parameters of the coils are shown in Fig. 9(a). The photograph of the S-SP compensated IPT system is shown in Fig. 9(b). The LCC-S, LCC-P, and double-sided LCC prototypes are similar to that of the S-SP compensated IPT system and are therefore omitted. Here, it should be pointed out that the capacitors bank are obtained by connecting combinations of multiple capacitors in series and parallel, which will make the difference between the equivalent theoretical value shown in Tab. III and the experimental value less than 0.5 \( \mu \)F and increase the equivalent value of permissible voltage of the capacitor group. In addition, the primary side power MOSFETs are IPW65R041CFD. And the antiparallel diode of the MOSFET and secondary side diode of the rectifier use IDP30E65D2.

Fig. 11. Experimental results of the voltage transfer ratio for the S-SP, LCC-S, LCC-P, and double-sided LCC compensated IPT systems at the coupling coefficient of 0.2 and the operation frequency of 85 kHz.

The experimental waveforms of the S-SP, LCC-S, LCC-P, and double-sided LCC compensated IPT systems are shown in Fig. 10(a), 10(b), 10(c), and 10(d), respectively. It can be seen that the output voltage of the S-SP and LCC-S topologies, \( v_{abSSP}(t) \) and \( v_{abLCCS}(t) \), are nearly in phase with the input voltage, however, the \( v_{abLCCP}(t) \) and \( v_{abDLCC}(t) \) approximately lag the input voltage by 180 degrees, which match well with the analysis of (3) and Tab. I. In addition, the input currents of all topologies are almost in phase with the corresponding input voltages. It means that near ZPA conditions for all topologies are achieved. The little phase differences between the input current and voltage for all topologies are caused by the ESRs of the compensation components and harmonics of the input current. Last but not least, the output currents are in phase with the output voltages due to the diode rectifier action.
In this paper, the sensitivity of the inevitable variation of the parameters to the voltage transfer ratio and transfer efficiency for all voltage-fed compensation topologies in IPT system are investigated. The theoretical analysis and experimental results of the 3-kW S-S, S-P, S-SP, LCC-S, LCC-P, and double-sided LCC compensated IPT systems show that:

1) All voltage-fed compensation topologies in IPT system can be designed to achieve the load-independent voltage transfer ratio.

2) For the S-P resonant topology, the load-independent voltage transfer ratio is always equal to the reciprocal of the coupling coefficient. It means the S-P compensation topology can be applied to get high output voltage owing to the low coupling coefficient in wireless charging system.

3) Load-independent ZPA operation in CV mode can be achieved for the S-P, S-SP, LCC-S, LCC-P, and double-sided LCC compensation topologies, except the S-S topology. And the input impedance for all analyzed topologies are expressed as $R_{ac}^g = \frac{1}{G_x}$ (G_x represents the voltage transfer ratio of different compensation topologies).

4) When considering the ESRs, the following conclusions can be made based on the parameter sensitivity analysis: (a) The double-sided LCC is the most robust topology to obtain approximate constant voltage output and have the minimum voltage error between the experimental results and the designed value compared with other topologies. So double-sided LCC topology can be used to achieve constant voltage output in a closed-loop IPT system to minimize the power converter and control algorithm efforts. (b) The efficiency of the S-SP compensated IPT system is the least sensitive to changes over a wide load range and the full coupling coefficient range. (c) The larger the load resistance is, the higher the efficiency of the LCC-P compensated IPT system is achieved. (d) The efficiency increases as the coupling coefficient increases for all topologies.

V. CONCLUSION

## REFERENCES

Fei Lu (S’12-M’17) received the B.S. and M.S. degree from Harbin Institute of Technology, Harbin, China, in 2010 and 2012, respectively, and the PhD degree from University of Michigan, Ann Arbor, Michigan, USA, in 2017, all in electrical engineering.

He is currently an assistant professor in the Department of Electrical and Computer Engineering in Drexel University, Philadelphia, PA, USA. His research topic focuses on power electronics and the application of electric vehicle charging.
Jin Jiang (S’85-M’87-SM’94-F’17) received the Ph.D. degree in electrical engineering from the University of New Brunswick, Fredericton, NB, Canada, in 1989. Since 1991, he has been with the Department of Electrical and Computer Engineering, The University of Western Ontario, London, ON, Canada, where he is currently a Senior Industrial Research Chair Professor. His research interests include fault-tolerant control of safety-critical systems, advanced control of electrical power plants, and power systems involving renewable energy resources.

He is a Fellow of the Canadian Academy of Engineering. He is also a member of the International Electrotechnical Commission 45A subcommittee to develop industrial standards on instrumentation and control for nuclear facilities. He also works closely with the International Atomic Energy Agency on modern control and instrumentation for nuclear power plants.

Chunting Chris Mi (S’00-A’01-M’01-SM’03-F’12) received the B.S.E.E. and M.S.E.E. degrees in electrical engineering from Northwestern Polytechnical University, Xi’an, China, and the Ph.D. degree in electrical engineering from the University of Toronto, Toronto, Ontario, Canada, in 1985, 1988, and 2001, respectively.

He is a Professor and chair of electrical and computer engineering and the Director of the Department of Energy (DOE) -funded Graduate Automotive Technology Education (GATE) Center for Electric Drive Transportation, San Diego State University, San Diego, USA. Prior to joining SDSU, he was with University of Michigan, Dearborn from 2001 to 2015.
