Power Electronics Reliability: State of the Art and Outlook

Huai Wang^{id}, *Senior Member, IEEE*, and Frede Blaabjerg^{id}, *Fellow, IEEE*

Abstract—This article aims to provide an update of the reliability aspects of research on power electronic components and hardware systems. It introduces the latest advances in the understanding of failure mechanisms, testing methods, accumulated damage modeling, and mission-profile-based reliability prediction. Component-level examples (e.g., Si IGBT modules, SiC MOSFETs, GaN devices, capacitors, and magnetic components) are used for illustration purposes in addition to system-level studies. The limitations and associated open questions are discussed to identify future research opportunities in power electronics reliability.

Index Terms—Accelerated degradation testing, condition monitoring, control, failure mechanism, physics-of-degradation, power electronics, reliability prediction.

I. INTRODUCTION

EFFICIENCY and power density have been at the heart of the power electronics community over the course of the last five decades. The improvements in efficiency and power density are heavily driven by power semiconductor technologies, circuit topologies, and control methods. Fig. 1 shows the historical development of power semiconductors, power electronics, and reliability engineering. With the increasing demands of application-driven research, reliability has become a considerable practical challenge in power electronics, among others listed in Fig. 1. Reliability is an important performance factor that is considered during the design, manufacturing, and field operation of power electronic converters. Over the past decade, the business model in the industry has been transitioning from product suppliers to holistic service providers. This demands life-cycle-cost reduction and operation optimization of power electronic converters through innovative design, in-depth understanding of failure mechanisms and mission profiles, and predictive maintenance.

In 2013–2014, the authors reviewed the three aspects of research in power electronics reliability in [1] and [2]. In May 2015, the IEEE TRANSACTIONS ON POWER ELECTRONICS published a Special Issue on Robust Design and

Reliability of Power Electronics. In the same year, an edited book on the reliability of power electronic converter systems was published by IET [3]. Research activities and outcomes worldwide have increased significantly in the last decade. Many of the results are reviewed in [4]–[13]. In [4], the research activities in the power cycling tests of power modules between 1994 and 2015 are summarized, which show the varieties in packaging technologies, control strategies, failure mechanisms of interest, and failure analysis methods. In [5]–[7], the methods for estimating the junction temperature and health condition of power modules are reviewed. Following the adoption of wide bandgap devices in commercial applications, new packaging technologies are discussed in [8] and [9]. The chip- and packaging-level failure mechanisms, testing, and condition monitoring health precursors of SiC devices are summarized in [10]. The failure mechanisms of GaN devices are discussed in [11]. In addition to active components, capacitor reliability and condition monitoring methods are discussed in [12] and [13], respectively. These overview articles provide a foundation to understand the state-of-the-art research on power electronics reliability.

This article focuses on updating the power electronics reliability aspects of research, which are less addressed in [1]–[13]. Most of the references that will be discussed in this article are from the last five years. For a more comprehensive list of references and discussions, please refer to [1]–[13]. It should be noted that this article limits its scopes in the following.

- 1) The component failure mechanisms are mainly on the short circuit of SiC MOSFETs and GaN devices and the wear-out of magnetic components. The failure mechanisms of Si IGBT modules and capacitors and the degradation of SiC MOSFETs and GaN devices are discussed in detail in [10]–[12].
- 2) The discussed stressors are limited to the electrothermal stresses and humidity. Other stressors (e.g., vibration and environmental contaminants) and related failure mechanisms are not included.
- 3) A comprehensive reliability prediction procedure for power electronic converters is not included. Instead, the references that give detailed discussions of this topic are introduced. In addition, reliability prediction methods are only briefly presented. For more details, please refer to [2].

This article starts with a description of the relevance of component-level failure mechanisms in power electronic applications. Next, component degradation curves, lifetime model

Manuscript received April 30, 2020; revised October 8, 2020; accepted October 20, 2020. Date of publication November 10, 2020; date of current version December 1, 2021. Fig. 1. Historical development of power semiconductors, power electronics, and reliability engineering.

limitations, and time constraints of accelerated testing are discussed. Mission-profile-based reliability prediction and its challenges in thermal model simplification and accumulated damage modeling are also presented. Finally, a specific outlook of power electronics reliability research is provided.

II. FAILURE IN POWER ELECTRONIC COMPONENTS AND SYSTEMS

In reliability engineering, failure is typically classified into sudden failure and degraded failure. Degradation in time may ultimately cause a sudden failure if no corrective action is taken. Sudden failure is caused by design defects, manufacturing issues, single-event effects, overstress, or misuse. In contrast, degraded failure is caused by long-term degradation. For a power electronic system, failure can come from both hardware and software due to intrinsic and extrinsic factors. This article focuses on hardware failures; consequently, software reliability [14] and human reliability analysis [15] are not included. Nevertheless, they are essential to a complete system-level reliability design and analysis.

Theoretically, multiple failure mechanisms exist for a single power electronic component [10]–[12], [16]. At the application level, it might not be realistic to consider all of the reported failure mechanisms. A more effective method is to address a few dominant failure mechanisms that are relevant in field

operation. However, the problem here is that the dominant failure mechanisms may vary with the design criteria and environmental and operational conditions of different applications.

A. Examples of Field Experiences

An example of field experiences in photovoltaic (PV) applications is presented in [17], which is based on three data reports (primarily for central inverters). Report 1 includes more than 3500 service tickets (i.e., abnormal states of PV systems) that were requested during 2010–2012 with a total operation of 2800 inverter years [18]. Report 2 is from an older set of PV systems monitored during 2008–2010 with a total of 1650 inverter years. Report 3 is based on about 400 service tickets. According to [17, Fig. 1], inverters account for 43%–70% of PV plant service requests. Inverter component failure breakdown based on the three data sources is analyzed in [17, Fig. 3]. Control software failure stands out in all three reports. This specific failure area may be the consequence of hardware malfunction, besides software or firmware issues. The inverters may resume normal operation upon a manual restart [18]. Although the importance of the widely studied hardware components (e.g., IGBTs and capacitors) remains in terms of their failure percentage as a single type of component, other failure areas, including control card PCB boards, fans, and fuses, also rank high. However, in-depth failure analyses

are unavailable, and the causes of failure and the dominant stressors are still open to question. In particular, it would be interesting to study humidity-related failure mechanisms due to the condensation effect of frequent cold starts in the intermittent operation of PV inverters.

In [19], an example of wind power converter failure analysis is given. The phase modules are one area of failure, including IGBT modules, gate driver boards, dc-link capacitors, and bus-bars. The database used for this analysis includes 2734 wind turbines that were commissioned between 1997 and 2015, operating in 23 countries from 11 suppliers. As shown in [19, Fig. 3], most wind turbines are either in the early or middle operation phase when considering a typical service life of 25 years. According to [19, Fig. 5], except for other unknown failure sources, phase modules are responsible for the largest fraction of power converter failures (i.e., 22%), which is followed by the cooling system, control board, and the main circuit breaker. On average, 0.16 phase-module failure per year per turbine is observed for these turbines. The detailed results question the widespread assumption that thermal-related wear-out is the dominant failure mechanism of these phase modules. Instead, it indicates that there is a correlation between the failure rate and the absolute humidity level with seasonal change, which suggests that humidity and condensation may be the main stressors causing failure. These observations are consistent with the findings in [20].

These examples represent two large databases for converter-specific failure analyses, which are rarely made publicly available in other power electronic applications. Both findings suggest the need for further investigation of humidity-related failure mechanisms for power electronic components [21], [22]. Nevertheless, they do not necessarily imply that the thermal-related wear-out failure mechanisms are irrelevant. Most of the analyzed wind turbines in [19] are still in the early-to-middle phase of their service life. A proper design and manufacturing process aims to prevent or, to a large extent, reduce wear-out failure. Thermal-related wear-out prediction can inform decisions in the design and operation phases to prevent the associated failure from becoming dominant during the service life.

B. Selected Failure Mechanisms

1) Short Circuit and Overstress Failure of SiC MOSFETs: The reliability performance of SiC MOSFETs is of significant consideration in power electronic applications. Extrinsic failures due to defectivity or high process variability and intrinsic failures due to material degradation are both relevant [23]. On the one hand, field experiences are limited by the early stage of technology adoption. On the other hand, unique reliability issues compared with Si devices give a lower cycling capability with conventional packaging and reduced short-circuit withstand time [24]. The power cycling capability of SiC MOSFETs has been reported to be lower than IGBTs with the same current rating and package technology by testing [25] and by simulation [26]. New packaging technologies [9] are likely to overcome the limitation in power cycling

capability. Nevertheless, the compromised short-circuit withstand time with the reduced SiC die size remains a challenge.

Much effort has been made in the short-circuit testing [27]–[34] of SiC MOSFETs and its protection in power converter design [34]–[38]. In [27], comparative testing of two types of 1.2-kV/24-A SiC MOSFETs with a Si counterpart is given. Only a gradual reduction of gate–source voltage is observed from the testing samples under short-circuit operation. This is caused by the gate leakage current triggered by excessive power dissipation, resulting in lower gate-oxide reliability due to a thinner gate thickness. In [28], 1.2-kV/36-A SiC devices are tested with short-pulse high voltage and long-pulse low voltage. Two different failure mechanisms are observed: first, thermal runaway due to high OFF-state drain leakage current; second, gate–source shorting due to breaking up of top layers. The observed failure mechanisms are consistent with [29] in the case studies of 1.2-kV/180-A and 1.2-kV/300-A SiC MOSFET modules. Under 600-V testing, the thermal runaway becomes dominant according to the switching waveforms shown in Fig. 2(a). The saturation current reaches about 18 times the nominal value. It then drops quickly before the switch is turned off, which indicates a significant increase in the chip temperature. A delayed failure occurs at 2 μ s after the turn-off due to excessive drain leakage current at high temperature. When the testing voltage increases to 800 V, gate–source shorting is observed. This is due to the increased gate leakage current triggered by high local temperatures close to the gate oxide. The corresponding switching waveforms are shown in Fig. 2(b). A safe operation area is proposed in terms of gate–source voltage and short-circuit current [29]. A case study of a 10-kV/10-A SiC MOSFET tested under 6 kV is presented in [30]. The testing results do not show signs of measurable thermally generated currents or degradation in the gate structure. The impact of thermal stress on short-circuit capability is studied in [31] and [32] based on the testing of 1.2-kV SiC MOSFETs under different case temperatures. This shows that the short-circuit critical energy and the withstand time slightly decrease with the case temperature. Moreover, the relationship between the number of repetitive short circuits to failure and the case temperature is presented [32]. The gate–source voltage drop from the initial value of 15 V at the time of 2 μ s in short-circuit operation is used as a failure criterion. This shows that with the increase in case temperature, the number of repetitive short circuits to failure increases. It is because that the energy dissipated during the short circuit operation decreases with the increase of temperature due to the negative temperature coefficient of the MOSFETs. The impact of degradation on the short-circuit withstanding capability of a 1.2 kV SiC MOSFET module has been investigated [33] based on comparisons between new samples and aged samples from power cycling test. This study shows that the gate-oxide degradation has a more significant impact on the short-circuit withstand time than the packaging-level degradation.

These studies give us a better understanding of the short-circuit failure mechanisms of SiC MOSFETs and mutual effects with chip-level and packaging-level degradation. It can

Fig. 2. Short-circuit testing of a 1.2-kV/300-A SiC MOSFET module under different dc voltages and case temperature of 25 °C. I_D : drain current; V_{GS} : gate–source voltage; and V_{DS} : drain–source voltage. Gate driver supply +20 V/–6V with an external gate resistance of 5 Ω [29]. (a) Short-circuit thermal runaway failure occurs at 600-V testing voltage. (b) Short-circuit gate breakdown failure occurs at 800-V testing voltage.

be noted that varieties still exist in testing conditions in terms of the dc supply voltage, gate driver voltage, and case temperature due to a lack of standardization. Moreover, the study of high-voltage or high-current devices is still limited due to the scarcity of the samples and higher demands on the testing facilities. With the increasing commercial applications of SiC devices, it is expected that more studies on short circuits will be needed. At the application level, fast and robust short-circuit protection [34]–[38] is essential to utilize the promising properties of SiC power devices without compromising the device-level design.

Overvoltage and overcurrent caused by parasitics and sustained oscillations are also important issues related to the reliability and EMI [39] in SiC applications. An excessive EMI may lead to a severe consequence of failing to fulfill the relevant standards and regulations. Advanced packaging technologies [9] and converter-level reduction of parasitics and couplings between the power loop and gate driver loop can help address this issue [39].

2) *Wear-Out and Short-Circuit Failure Mechanisms of GaN Devices:* Like SiC MOSFETs, both the extrinsic and intrinsic

failures of GaN devices need to be considered for power electronic applications. The level of extrinsic failures of GaN devices due to material defectivity still has not reached the level of the Si counterparts [40]. The internal GaN-specific degradation mechanisms during the OFF-state, switching-state, and ON-state are presented in [11] and [41]. In [41], a power cycling test is designed to exclude thermomechanical effects by setting temperature swings less than 25 °C. This work studies the threshold voltage shift and dynamic ON-state resistance change due to the trapping effect. Thermomechanical-related power cycling test is performed in [42]–[45] with temperature swings of 100 °C or above. The drain-to-source OFF-state leakage current (IDSS) failure is reported in [42] and [43]. The failure mechanism is identified in [44] by postfailure analysis tools and detailed FEM simulations. This reveals that the thermomechanical stresses induced by an acceptable temperature range can cause multilayer cracks in the die of the GaN device.

Short-circuit failure mechanisms are studied in [46]–[49]. The drain-to-source voltage distinguishes two failure modes of GaN devices. A case study on a 650-V p-GaN is given in [46] and [47]. The short-circuit withstand time is in the range of few μs or more when the testing voltage is below 350 V. This reduces to a few hundreds of ns when the voltage is above 350 V. The first failure mode is due to the temperature increase in the entire device (i.e., more than 1000 K), causing damage to the surface metal [48], [49]. The second failure mode is related to local thermal destruction in a relatively small region of the device [46], [48], [49]. Especially, it is observed that the right-hand side of the gate field plate is the most sensitive part of the testing samples [49]. It can be noted that destructive short circuits could happen within sub- μs under moderate-voltage stresses. Therefore, the design of an ultrafast overcurrent protection solution [50] is even more challenging than that for SiC MOSFETs. The drain-to-source voltage stress is a vital factor determining short-circuit capability and dominant failure mechanisms of both SiC MOSFETs and GaN devices.

3) *Reliability of Magnetic Components in Power Electronic Applications:* The transformers and inductors that are used in power electronic converters are generally recognized as having fewer failure issues than capacitors and power semiconductor switches. Nevertheless, design-to-limit could become a standard practice to meet the demand for cost reduction and power density increase. In these design scenarios, thermal-related failure and insulation-related wear-out become relevant within the service life of power electronic converters. Moreover, insulation degradation or sudden breakdown is further accelerated by thermal stress, moisture, and dust levels.

The reliability studies of medium- to high-frequency magnetic components for power electronic applications are rarely available. The first studies are presented in [51] and [52] on the degradation testing and lifetime modeling of planar transformers. Two groups of 12 samples are tested under 200 °C and 180 °C, respectively, for 3500 and 2500 h. The primary-side inductance reduces by 15%–40%. Two of the possible failure mechanisms are core material degradation and expansion of the glue between two cores.

Further investigations are needed to confirm the relevant failure mechanisms.

Understanding the relevant failure modes and failure mechanisms is the first step to prioritizing resources for reliability testing, lifetime and reliability prediction, and condition monitoring.

III. DEGRADATION AND LIFETIME OF POWER ELECTRONIC COMPONENTS

A. Component Degradation Curve and End-of-Life Criteria

The degradation of power electronic components typically occurs at the material or interconnection level, which needs advanced physics analysis tools [44] to identify the location and structure change. Alternatively, certain electrothermal parameters can be used as health precursors. The values of them change with the degradation level of materials and interconnects. For example, ON-state saturation voltage and thermal resistance between junction-to-case are widely used health precursors for IGBT modules, and they are applied for both accelerated degradation testing [53] and condition monitoring [6]. Capacitance, equivalent series resistance (ESR), dissipation factor, and insulation resistance are usually used for capacitors [12], [13].

Fig. 3 shows a generic degradation curve of a precursor corresponding to a specific failure mechanism. y is the value of the health precursor and Δy is its parameter shift. The y -axis shows the absolute percentage change of y to its initial value y_0 . The degradation curve has three possible distinctive stages: I, II, and III. These stages correspond to the time intervals in which the health precursor keeps constant, increases or decreases linearly, and increases or decreases with an accelerated pace.

It should be noted that Fig. 3 is given for illustration purposes only. Not all of the three stages necessarily appear for a specific precursor. A typical degradation curve is a combination of one or more of the three stages. The slope and percentage of each period vary for different failure precursors and stress conditions.

The time-to-failure of an individual component due to wear-out is determined by one or more defined end-of-life (EOL) criteria that are chosen by considering the component-level destruct limit, system-level specification, and a certain margin; as shown in Fig. 3. In practice, this is achieved in terms of the percentage of change of y to its initial value y_0 . It is reported in [4] that a 5% increase in ON-state saturation voltage or a 20% increase in junction-to-case thermal resistance is used as EOL in most of the analyzed 70 publications on power cycling. This is consistent with the recommendations by [53]. Nevertheless, 13% of the publications use a 20% increase in the ON-state saturation voltage as EOL. For electrolytic capacitors, 20% capacitance drop and two to three times increase in ESR or dissipation factor are commonly used [12]. The EOL in terms of capacitance drop for film capacitors is usually within the range of 2%–10%.

The varieties in EOL in terms of the percentage of change depend mainly on when the degradation accelerates and enters Stage III, as shown in Fig. 3. This does not usually correspond

Fig. 3. Three possible stages of a component degradation curve. Δy is the parameter shift of the health precursor y , and y_0 is the initial value of the parameter x before testing or in use.

to the time when the component destruct limit reaches or a system-level failure occurs. Therefore, the change rate of y plays an essential role in defining the EOL but not necessarily the absolute value of y . This implies that component- and system-level failures would occur soon if no action is taken at the EOL. Meanwhile, the EOL can also be decided according to the component parameter constraints considering system-level requirements.

B. (Percentile) Lifetime Definition

Lifetime is a widely used reliability metric for a population of items defined at a specific reliability level. For an individual item, time-to-failure is used corresponding to when the EOL is reached. Fig. 4 shows a Weibull plot [54] of an unreliability curve. The curve is plotted based on the time-to-failure data of a limited number of samples. The confidence intervals illustrate the uncertainties. The solid line and dashed line represent 50% and 95% confidence levels, respectively. B_X is used to define the percentile lifetime corresponding to when there is $X\%$ of accumulated failure. It can be noted that the obtained lifetime varies with $X\%$ and confidence level. $B_{0.1_95\%}$ implies 95% probability that 0.1% of the population of items will fail until the time. In other words, statistically, there is a 5% risk that more than 0.1% of the items fail until the time. $B_{10_50\%}$ implies 50% probability that 10% of the items fail until the time. Moreover, the plots shown in Fig. 4 are for specific stress conditions. Therefore, a comprehensive lifetime definition should include at least the following four aspects:

- 1) environmental and operational conditions;
- 2) EOL used for determining the time-to-failure;
- 3) corresponding percentage of accumulated failure ($X\%$);
- 4) confidence level.

Nevertheless, such comprehensive information is rarely provided in the literature when lifetime is stated, which means that we do not know the implication for failure and the associated risk. If any aspect of the information is missed, then the lifetime comparison would be in question. Moreover, the B_X lifetime with a certain confidence level is a single point in the unreliability curve. The same B_X lifetime for

Fig. 4. Illustration of percentile lifetime definition under different confidence levels for a specific wear-out failure mechanism based on time-to-failure data in a Weibull plot.

two different items does not imply equal reliability during the service life because the slope of their degradation curves could be different.

C. Limitations of Existing Lifetime Models

The most widely considered stressors in empirical lifetime models for power electronic components are temperature, temperature swing, and voltage. The capacitor lifetime model is given by (1) and a simplified version by (2) [11]. The lifetime model for the packaging related wear-out of power modules is given by (3). Relative humidity (RH) is an additional stressor, as described by [55]. The acceleration factor AF_{RH} is presented by (4)

$$L = L_{ref} \times \left(\frac{V}{V_{ref}} \right)^{-n_1} \times \exp \left[\left(\frac{E_a}{K_B} \right) \left(\frac{1}{T} - \frac{1}{T_{ref}} \right) \right] \times \text{other factors} \quad (1)$$

$$L = L_{ref} \times \left(\frac{V}{V_{ref}} \right)^{-n_1} \times 2^{\frac{T_{ref}-T}{n_2}} \times \text{other factors} \quad (2)$$

$$N = A \times (\Delta T)^{-\beta_1} \times \exp \left(\frac{E_a}{K_B T} \right) \times t_{on}^{\beta_2} \times \text{other factors} \quad (3)$$

$$AF_{RH} = \left(\frac{RH}{RH_{ref}} \right)^{-n_3} \quad (4)$$

where L is the predicted lifetime at the stress level of interest. N is the predicted cycle-to-failure at the stress level of interest. V is the voltage stress, T is the temperature, ΔT is the temperature variation, t_{on} is the heating time of the thermal cycle, E_a is the activation energy, K_B is Boltzmann's constant (8.62×10^{-5} eV/K), and RH is the relative humidity. L_{ref} is the lifetime at the referenced operation conditions of V_{ref} and T_{ref} . RH_{ref} is the referenced RH for the acceleration factor AF_{RH} . The parameters L_{ref} , A , E_a , n_1 , n_2 , n_3 , β_1 , and β_2 are constants obtained based on time-to-failure data. Other factors are not widely considered or unknown. For example,

a humidity derating factor, as shown in (4) is added to (2) in [55]. In [56], three other factors related to the power module design parameters are included.

Physics-based lifetime models are also available for power modules, as given in [3, Ch.5]. These models provide insights into improving component design through physics analyses. They can verify the assumed failure mechanisms used for the empirical models. At the application level, empirical lifetime models, as given by (1)–(4), are commonly used due to their simple form and direct correlation with the electrothermal stresses and other stressors. They also give insights into lifetime extension by reducing the stresses through power converter design and control.

The following limitations of existing lifetime models are identified according to the literature and experience.

- 1) Limited information is available for EOL, B_X lifetime definition, and confidence level when a lifetime model is presented. In [55] and [57], comprehensive degradation data analyses are presented based on the testing of capacitors and power modules, respectively. This reveals that the obtained B_X values vary significantly with lifetime definitions and confidence levels.
- 2) Limited information is available for the associated failure mechanism when a lifetime model is presented. The power cycling tests are designed to trigger different failure mechanisms in bond wires and solder joints of power modules in [58] and [59]. For capacitors, lifetime models for different failure mechanisms [11] are unavailable, to the best of our knowledge.
- 3) The applicable stress ranges of a lifetime model are rarely investigated in reliability prediction. Fig. 5 illustrates the boundaries for the application of a specific lifetime model. S_L and S_H represent the lower and higher boundaries of the considered stressor. The underlying assumption of the models given in (1)–(3) is that the dominant failure mechanism remains the same within the predicted lifetime. L_1 and L_2 in Fig. 5 show the interval when the lifetime model is applicable. Consequently, if the predicted lifetime is longer than L_2 , the results should be interpreted cautiously. For example, in aluminum electrolytic capacitors, the lifetime model (2) is applied. In [60], it is stated that the lifetime model is applicable for up to 15 years (i.e., $L_2 = 15$ years). One reason for this is that a new failure mechanism (e.g., sealing rubber degradation) may become dominant after 15 years of operation, instead of the considered electrolyte evaporation and electrochemical reaction. It also indicates that the applicable range of the voltage stress in (2) is at the rated voltage or above for small-size capacitors. The voltage stress within the rated one has a negligible impact on their degradation. In [61], the applicable ranges of different factors are given for the IGBT power module lifetime model based on the testing conditions. Nevertheless, in many other studies in the literature, such information is unavailable. Therefore, further investigations of the specific boundaries shown in Fig. 5 are suggested.

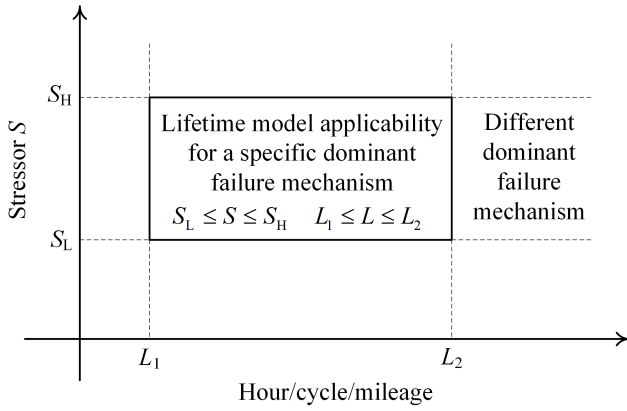

Fig. 5. Illustration of the lifetime model application boundaries in terms of stress level and service life. S_L and S_H are the lower and higher stress boundaries in which the lifetime model is valid; L_1 and L_2 are the lower and higher service life boundaries in which the specific failure mechanism described by the lifetime model is dominant.

- 4) Limited numbers of failure mechanisms are considered. The associated failure mechanisms of the models (1)–(3) represent a fraction. Failure during the early-to-middle service life could be responsible for a considerable percentage, as revealed by the field experiences in [19] and the discussions on power cycling test in [62]. Other factors may also play an important role, such as humidity or corrosive atmosphere. As discussed in Section II, these models are useful for designing power electronic systems to avoid the wear-out failure mechanisms becoming life-limiting factors. However, they are only part of the picture for the reliability prediction and reliability design. Other reliability tools are also widely applied, such as failure mode and effect analysis (FMEA), robustness design, protection, fault-tolerance, and burn-in testing.

D. Implications on Component-Level Accelerated Testing

Time and relevance are the two key considerations in component-level accelerated testing. On the one hand, for a given testing method and stressor S , the testing time can be reduced by increasing the stress. However, this may risk triggering new failure mechanisms that do not appear in normal operation if the stress level is above S_H shown in Fig. 5. On the other hand, testing under accelerated conditions close to normal operation is very time-consuming and not a preferable choice.

1) *Testing for Relevant Failure Mechanism and Stressor S* : Much effort is made to power cycling for triggering specific failure mechanisms individually, such as bond wire wear-out, chip solder fatigue, and baseplate solder fatigue. This is implemented by setting proper testing conditions in terms of junction temperature, temperature swing, and cycling period [4]. Besides component degradation curve analysis, the Weibull plot [54, Ch.5] can be used to verify if the time-to-failure data from accelerated testing are for a single failure mechanism or a mix of two or more. For a given failure mechanism, the slope of the unreliability curve (i.e., shaping factor) shown in Fig. 4 tends to be consistent. In [63], the Weibull plots based on the testing results under different temperature swings have a shaping factor of 37.5 and 14.8,

respectively. This corresponds to the dominant failure mechanism of chip solder fatigue and bond wire wear-out, respectively. Humidity-related failure mechanisms are investigated in [55], [64], and [65] for SiC MOSFET modules, Si IGBT modules, and film capacitors, respectively. As discussed in Section II on the field experiences, humidity-related failures are likely to be dominant over those caused by thermal stresses for the surveyed systems in the early-to-middle stage of service life. More studies are needed to confirm the associated failure mechanisms and design the relevant accelerated tests. Moreover, research to separate different failure mechanisms for capacitors and magnetic components in accelerated testing is still at an early stage.

2) *Testing With Conditions More Relevant to S_H and S_L* : As discussed in [4], since 1994, most studies on power cycling have focused on the stressors of junction temperature swing ΔT_j larger than 40 °C. In comparison, the impact of the heating time on the power cycling capability is less investigated. ΔT_j is usually less than 40 °C in the normal operation of a power converter. There are line frequency power cycles (i.e., 20 or 16.7 ms) and lower frequency cycles due to changes in load and ambient conditions.

Several studies have aimed to address these limitations [57], [66]–[71]. The power cycling is conducted with the heating time t_{on} as low as 70 ms, $\Delta T_j = 70$ °C, and the mean junction temperature $T_{jm} = 122$ °C for two types of IGBT modules in [68] and [69]. The impact of t_{on} on the cycling capability of aluminum (Al) wire bonds and chip solder joints within the range of 70 ms and 60 s is modeled separately. In [57], a type of transfer molded intelligent power modules (IPMs) is tested with t_{on} from 147.5 ms to 2.5 s, $\Delta T_j = 80.8$ °C, and $T_{jm} = 122$ °C. In [67], the tests are with t_{on} down to 10 ms, ΔT_j down to 23 °C, and $T_{jm} = 100$ °C. Fig. 6 shows that it lasts for more than 500 million cycles for the test with $t_{on} = 10$ ms. This study also reveals that the impact of t_{on} becomes insignificant when it is less than 40 ms. The results from other testing groups are shown in Fig. 6 with a different T_{jm} and current per bond wire foot I_{bf} normalized to $T_{jm} = 100$ °C and $I_{bf} = 5.87$ A [67]. When ΔT_j is between 23 °C and 27 °C, 10 °C reduction of T_{jm} would increase the cycling capability more than ten times. The high number of cycle-to-failure and distinct slope changes imply that it is near the elastic deformation range, where the resultant degradation due to ΔT_j is negligible. Instead, the absolute junction temperature plays a significant role in such a range. Power cycling tests with a combination of high ΔT_j and low ΔT_j are proposed in [70] and [71] to investigate the impact of low ΔT_j within a realistic testing period. ΔT_j is down to 32.8 °C with T_{jm} of 56 °C in three different testing stages. This reveals that the low ΔT_j has a minor impact on Stages I and II of the degradation curve shown in Fig. 3. This effect is manifested when the testing samples reach Stage III.

For capacitors, the time for degradation testing is usually on the scale of thousands of hours [55], [60]. The acceleration factor is relatively lower compared with many tests designed for power semiconductor switches. In [60], the technical note finds that the lifetime model of aluminum electrolytic capacitors depends on the ranges of both temperature and

Fig. 6. Normalized lifetime of 1200-A IGBT modules with IHM-B package (140 mm × 190 mm) from manufacturer A and B with $t_{on} \leq 40$ ms (current per bond foot $I_{bf} = 5.87$ A and mean junction temperature at the beginning of the test $T_{jm} = 100^\circ\text{C}$, and Hartmann refers to the model in [66]) [67]. N_f : number of cycles to failure; ΔT_j : amplitude of junction temperature swing; and T_{jm} : mean junction temperature.

voltage. However, testing to verify the dependence is still not found in the literature.

3) *Testing With Relevant Control Strategy for Stressor S*: Empirical lifetime models (1)–(4) are usually derived from tests under two or more stress levels. The stress control strategies have an implication on how to apply the derived models. For power cycling of IGBT modules, the control strategy with a constant switching-ON duration of dc pulse current and constant switching-OFF duration is adopted by the standard IEC 60749-34 (2011) [72] and ECPE AQG324 guide [53]. T_{jm} and ΔT_j used for lifetime derivation are the values at the beginning of the testing. During the testing, they increase with possible parameter shifts due to degradation (e.g., thermal impedances of thermal interface materials, ON-state voltage, and thermal resistance of baseplate solder and chip solder). In addition to this standard control strategy, another three methods (i.e., constant minimum and maximum case temperature, constant power loss, and constant ΔT_j) are also discussed in [73]. The standard control strategy is most relevant to power electronic applications because parameter shifts can occur and result in higher thermal stresses during the service life of a power converter. Therefore, the impact of these degradation-dependent parameters does not need to be considered for the lifetime prediction in applications. If the lifetime model is obtained from a power cycling test based on the other three control strategies, then either part or all the parameter shifts need to be included in the thermal stress modeling for lifetime prediction. This would increase the application-level modeling complexity. In this regard, the passive thermal cycling of power modules without current stress ignores this degradation effect.

Capacitor testing can be implemented with or without ripple current. For the first category, a dc bias voltage, ac ripple current, and ambient temperature are kept constant. Similarly, the hot-spot temperature and peak voltage stress both increase during the test due to the changes in ESR and capacitance. The lifetime models (2) and (3) include the degradation effect

if this control strategy is applied. For the second category, the effect of degradation-dependent ESR and capacitance is not considered in the lifetime model.

The control strategy for accelerated stressors affects the obtained lifetime models and converter-level modeling methods. Compared with [73], the cycle-to-failure based on constant ΔT_j could be three times that of the standard power cycling control strategy.

4) *Testing With Appropriate Sample Size*: The sample size that is used for testing is closely related to the confidence interval. With the increase in sample size, the interval shown in Fig. 4 between the 95% confidence level and 50% confidence level becomes narrower. This implies a higher certainty level. Typically, six to ten samples for each testing run are recommended for a meaningful statistical analysis compromised with the required resources. For instance, ten and 12 samples are used for capacitor and planar transformer testing in [51] and [55], respectively. Nevertheless, it is reported that 86% of the power cycling tests have only one sample per test run based on the 70 publications discussed in [4]. This implies that meaningful lifetime information is unavailable in some cases even though a significant amount of resources are used. Consequently, more attention to the design of accelerated testing in terms of sample size is necessary.

5) *Testing With Superimposed Stress Conditions*: At the application level, another aspect is the correlation between the testing under static stress level and field operation with dynamic environmental and operational conditions. Two questions need to be raised here: how can the effect of two or more different stress levels be combined? and does the dominant failure mechanism remain the same under dynamic stress profiles?

The degradation curve shown in Fig. 3 represents a single stress level. The accumulated damage model is used to analyze the joint damage of two or multiple stress levels. The time-to-failure corresponds to when the accumulated damage

reaches one. The Palmgren–Miner rule that was presented in 1945 [74] is a linear accumulated damage model that is widely used for lifetime prediction. This rule assumes no interaction between stress levels in terms of amplitude, duration, and time sequence. Most of the wear-out failure predictions of active devices and passive components in power electronics under dynamic stress conditions are based on the Palmgren–Miner rule. The nonlinear accumulated damage models that are used in other areas in reliability engineering are summarized in [75]. The validity of the linear accumulated damage model is questioned in [76]–[78]. Simulations in [76] show that the numbers of cycle-to-failure of bond wires are similar between the linear and nonlinear models. In [77], power cycling tests under three sets of (ΔT_j , minimum junction temperature T_{jmin} , and t_{on}) are performed first as the reference numbers of cycle-to-failure. The conditions at the beginning of the tests are Test 1: (100 °C, 50 °C, and 2 s); Test 2: (50 °C, 100 °C, and 1 s); and Test 3: (100 °C, 50 °C, and 15 s). Each test has six samples. Test 4 runs for 50% of the referenced lifetime of Test 1 under the same condition and then for the rest of the time under the condition of Test 2 until the EOL reaches. Test 5 runs for 50% of the referenced lifetime of Test 3 under the same condition and then until EOL under the condition of Test 2. Test 6 runs periodically with 20% of the reference lifetime of Test 1 and Test 2, respectively, under the same conditions until failure. The results show an average of 9.9%, 18.6%, and 0.6% higher numbers of cycle-to-failure from Test 4, Test 5, and Test 6, respectively, to the values calculated based on the linear accumulated damage model. In [78], power cycling tests with superimposed stress levels are conducted with more frequent changes of the sequences than Test 6 in [77]. Bond wire wear-out is assumed as the dominant failure mechanism [77], [78]. The conclusions of both tests are consistent. A different conclusion may be drawn if the failure mechanism changes under different stress levels, such as the case studies in [63]. It is worthwhile further investigating the validity of the linear accumulated damage model given that the reported number of case studies and testing conditions are still limited. Furthermore, no conclusions are drawn to explain the observed results and the varieties in comparisons. In [79], a nonlinear damage model for aluminum electrolytic capacitors is applied for the lifetime prediction in a motor drive application.

Application-oriented testing under a representative mission profile can be used to check if the dominant failure mechanism remains the same with dynamic stress levels. In [80]–[82], power modules and capacitors are tested with a sequence of stress levels emulating PV applications. The daily profile of solar irradiance and ambient temperature is used [82] with a scaling factor to accelerate the test. The purpose of these tests is not to derive a lifetime model because the results are the joint effect of multiple stress levels in a single run. Instead, it is possible to verify the assumed failure mechanisms and lifetime prediction results. To support such a superimposed stress test, advanced mission profile emulators are necessary. For example, in [83]–[85], the emulators for motor drives and multilevel modular converters (MMCs) are proposed, respectively.

IV. MISSION-PROFILE-BASED RELIABILITY PREDICTION

In [1] and [2], the methods for reliability prediction are reviewed. System-level reliability modeling methods, such as reliability block diagram (RBD), fault tree analysis (FTA), and Markov analysis (MA), are compared in [2]. Much progress has been made toward reliability prediction based on long-term environmental and operational conditions (i.e., mission profile). The methods and modeling procedures demonstrated in [86] and [87] represent the state of the art for case studies on PV inverter and MMC, respectively.

A mission-profile-based reliability prediction tool is developed in [88]. This tool is based on six modeling steps starting from system-level mission profile to component-level reliability modeling and system-level reliability modeling. This tool features a modular design with flexible input levels of mission profiles. As shown in Fig. 7, mission profiles along the modeling process are divided into four levels. Level 1 is system level (e.g., drive cycles of a car, ambient temperature, and humidity). Level 2 is the power electronic converter level, which can be directly measured or obtained from the system-level mission profile modeling shown as Step 2 in Fig. 7 (e.g., derive the output power, frequency, and voltage of a drive from the drive cycles, and motor models). Level 3 is down to the component stresses of interest (e.g., the local ambient temperature, voltage, and current of a capacitor). Level 4 is for stresses that are the variables in the lifetime models or failure rate models used for component-level reliability modeling. For dynamic thermal profiles, Rainflow counting [89] is widely used to extract the periodic temperature swings for the packaging-related wear-out of power semiconductor switches. The use of Rainflow counting is discussed in detail in [86] and [87]. Depending on the available mission profile information, the tool runs part or all of the six steps. For instance, if all the required information at Level 3 mission profile is available, then the first three steps can be excluded, and the software tool starts directly from Step 4. Fig. 8 shows a capture of the graphic user interface (GUI) of the software tool customized for motor drive applications. The user can select the available mission profile levels, configure the motor and drive, and select the component, assembly, or system of interest for reliability analysis.

The details of mission-profile-based reliability prediction methods and the corresponding software tools can be found in [86]–[88]. A few additional aspects are discussed in the following.

A. Mission Profile Data

The mission profile represents all of the relevant stresses that the item of interest withstands during the whole service life, including stresses during manufacturing, burn-in-test, transportation, installation, and field operation. Lifetime and reliability prediction often uses limited information that is compromised by the available data and complexity. The limitations come from both the considered stressors and the time span of the analyzed data. Predictions based on data for the whole service life and models for all kinds of failure mechanisms are rarely feasible. In the PV inverter case studies,

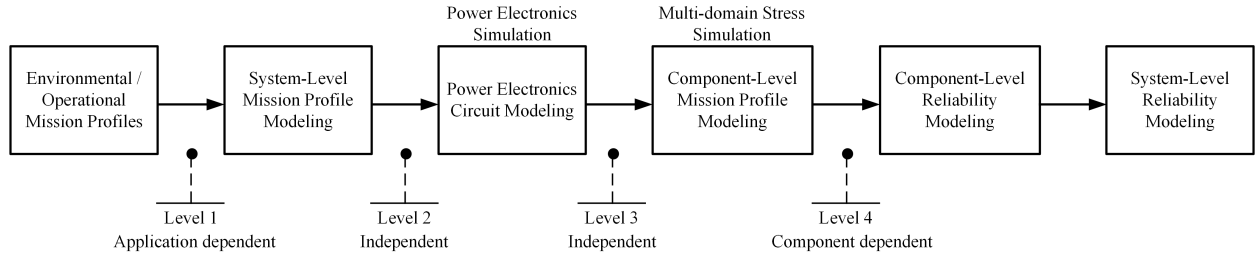

Fig. 7. Six-step mission-profile-based reliability prediction method for power electronic systems [88].

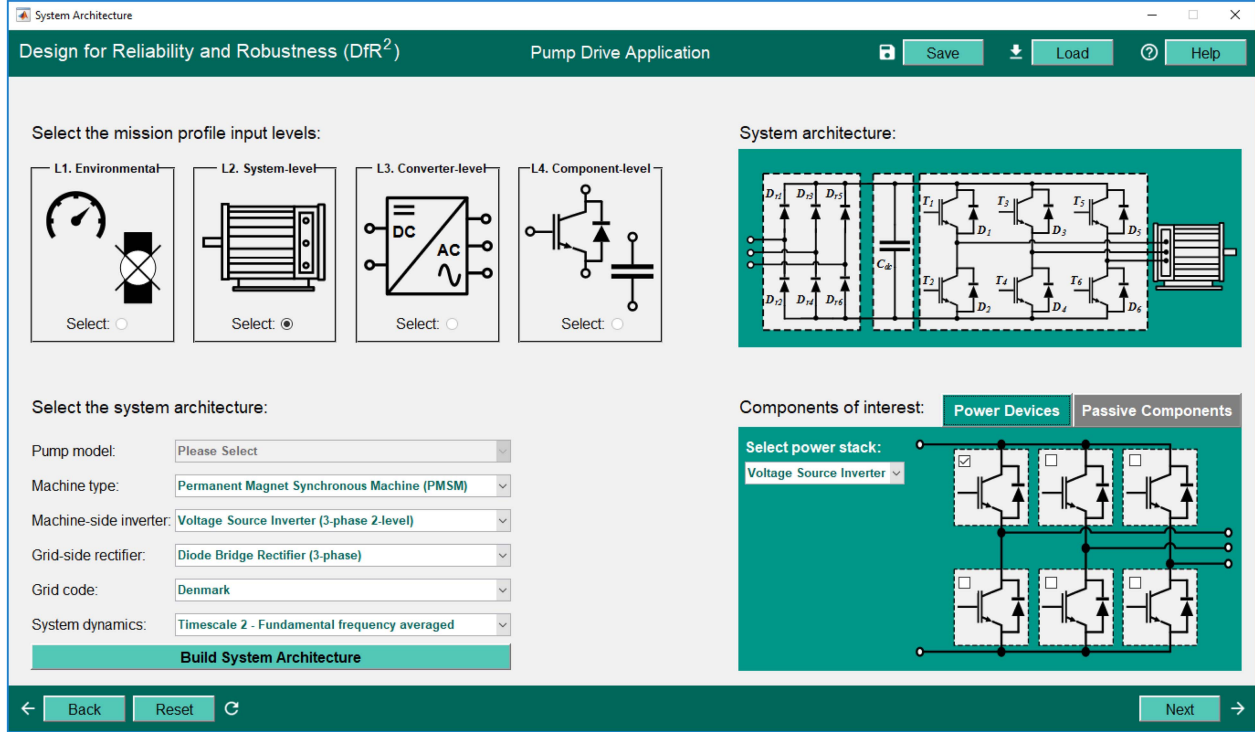

Fig. 8. GUI of the developed software tool customized for motor drive application with the six-step modeling method [88].

annual solar irradiance and ambient temperature profiles are used [86], [91]. In addition to the time span, the sampling frequency is also critical, and this is relevant to the failure mechanisms with different timescales. As studied in [92], the sampling frequency reveals significant variances in the predicted lifetime based on wind speed data with different sampling frequencies for an offshore wind application. Nevertheless, guidelines on the appropriate mission profile resolution are unavailable.

A mission profile logger is developed in [90] to collect operational and environmental data from field operations. The prototype is shown in Fig. 9(a). This measures the raw data of voltages and currents of a phase-leg and climatic conditions. The data can be preprocessed, stored locally, and collected by wireless networks. Fig. 9(b) shows an example of the measured climatic data inside and outside of the enclosure of a 60-kW PV inverter.

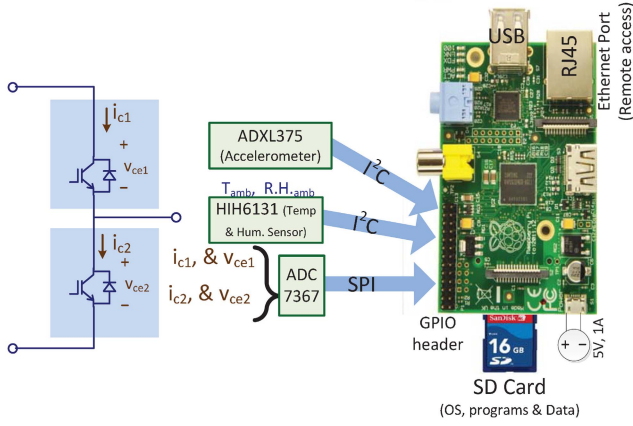

While the mission profile enables more realistic reliability prediction, it increases the complexity and computational burden, especially considering the dynamic thermal profile modeling [86], [87]. Consequently, it could be more feasible to

simplify mission profiles by identifying representative profiles. Moreover, considering the varieties in thermal time constants and failure mechanisms of different components (e.g., IGBT modules and capacitors), the use of different data resolutions can reduce the computational burden. A simplified mission profile is usually sufficient because products are commonly designed for applications with a wide range of operating conditions. However, for benchmarking or warranty analysis of a specific application, a more detailed mission profile is preferred.

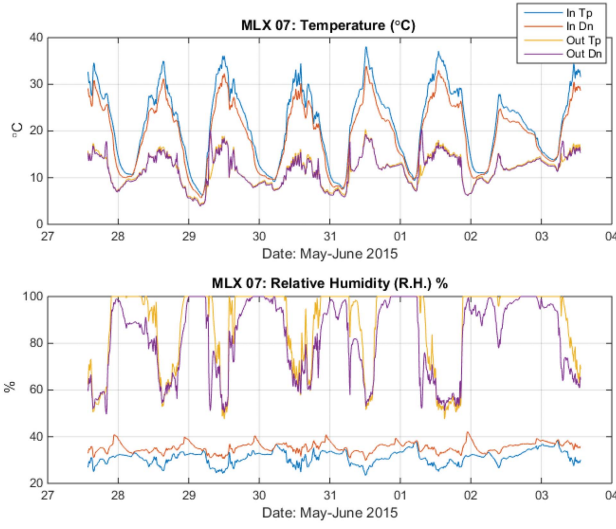

B. Simplified Electrothermal Modeling

Thermal modeling is a key step for thermal-related wear-out failure mechanisms. There are two significant challenges here.

- 1) The local ambient temperature in Level 3 mission profile shown in Fig. 7 is dependent on the cooling, layout, power loss, and thermal couplings of the converter of interest. Therefore, system-level electrothermal modeling is needed to obtain the component-level thermal stress. In the case study of [86], the thermal stresses of capacitors and MOSFETs mainly depend on their local

(a)

(b)

ambient temperatures (i.e., the enclosure temperature and the air temperature around the components). Fig. 10 shows that the enclosure temperature is more than 30 °C higher than the outside ambient temperature at heavy loads. The maximum rises of component internal temperatures due to self-heating are 5 °C and 15 °C, respectively, for the capacitor and MOSFETs. This implies that the accuracy of the enclosure temperature modeling is even more critical than that of the temperature rise due to self-heating in this example. In another case study of MMC in [87], there is a maximum of 17 °C difference in local ambient temperatures among the 24 submodules. The setup and measurements are shown in Fig. 11. This implies that there are likely to be life-limiting submodules in the MMC setup. In [86] and [87], converter-level finite element method (FEM) simulations are performed to obtain the system-level thermal models, including mutual coupling among the key heating sources. Moreover, system-level thermal

ΔT_{la} is the maximum ambient temperature difference.

modeling can identify hot-spots in the system. This provides insights into improving reliability by heat redistribution.

- 2) Thermal modeling with long-term dynamic profiles is time-consuming. Therefore, in applications where the ambient climatic conditions or loading conditions are highly intermittent and dynamic (e.g., wind power, PV, and e-mobility), it is necessary to consider the impact

of thermal capacitance. A frequency-domain thermal modeling method is proposed in [93]. This simplifies the modeling at different timescales by coordinating different thermal time constants and the frequencies of power loss profiles. In [94], a simplification method is proposed for thermal modeling with periodic power loss profiles. An analytical error model is derived for different degrees of simplifications. Because the ambient temperature change is relatively slow, IGBT module junction temperatures are assumed to change simultaneously with the ambient temperature in [93] and [94]. Nevertheless, the thermal time constants of capacitors or large heatsinks range from a few minutes to hours, which are comparable with ambient temperature dynamics. A modified thermal model is proposed to incorporate the effect of ambient temperature dynamics [95]. The snap-in aluminum electrolytic capacitor that is used for the case study is shown in Fig. 12(a). The comparative results with the experimental characterizations are shown in Fig. 12(b). With the application of SiC and GaN devices, new challenges come from the nonlinearity of thermal impedance in a wide range of temperature stresses [96], [97], as well as PCB board-level thermal modeling and optimization [98].

C. Limitations of Existing Mission-Profile-Based Reliability Prediction Methods

The limitations of the existing mission-profile-based reliability prediction methods are discussed in the following.

- 1) Limited failure mechanisms and failure sources are considered. The discussed hardware failure is mainly for the thermal-related wear-out. Other failures due to humidity, vibration, and contamination are not usually quantitatively analyzed. Sudden hardware failures and software failures are yet to be included. For example, single-event-burnout due to cosmic rays is relevant for electronic device applications at high elevations [99].
- 2) There is a lack of humidity aspect modeling. As discussed previously, humidity-related failure mechanisms [21] may become dominant, especially for applications with intermittent loading profiles and frequent shutdowns and start-ups. A transient hygrothermal modeling method is proposed in analogy with electrical domain models in [100]. It is, therefore, worthwhile investigating the application of such models in power electronic converters.
- 3) The linear accumulated damage model is dominantly used in wear-out failure prediction. To what extent it is a reasonable approximation is still open to question. Various nonlinear damage models are available, as discussed in [75]. However, the relevance and the necessity to use them are not yet known.
- 4) Failure interactions among components and external factors are not considered in the system-level reliability analysis. As shown in [86] and [87], the RBD method is applied to calculate the system-level reliability based on the component-level reliability and system redundancy

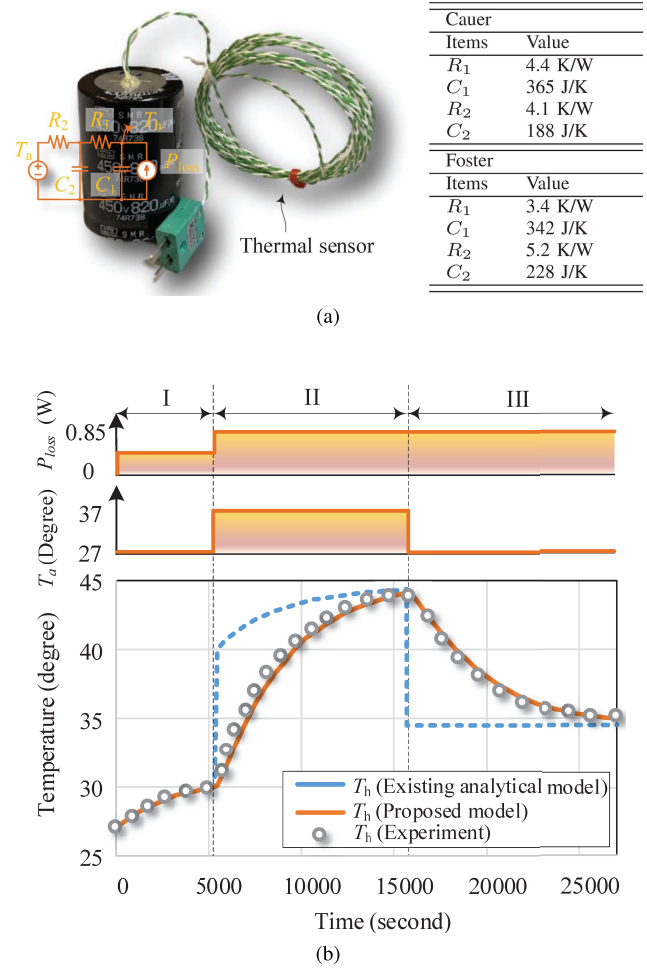

Fig. 12. Proposed thermal modeling method considering the dynamics of ambient temperature in [95]. (a) Capacitor testing sample and its thermal model parameters. R_1 , R_2 , C_1 , and C_2 are the thermal resistances and thermal capacitances, respectively. (b) Experimental verification of the model considering the impact of ambient temperature dynamics. T_h is the capacitor hot-spot temperature, T_a is the capacitor ambient temperature, and P_{loss} is the power loss in the capacitor.

level. In practice, failure causes could be mutually affected by multiple factors. The assumption of the isolated failure of each component needs to be rigorously justified [101]. In [102], a Markov reliability modeling method is applied for multiphase dc-dc converters to analyze different failure scenarios.

- 5) Activities in system-level reliability demonstrations are expanding but still limited in the literature. In [103] and [104], converter-level reliability testing is performed for motor drives and PV inverters, respectively. The system-level testing outcomes could identify the weakest links and demonstrate that the reliability is no less than the designed target.

V. OUTLOOK FOR POWER ELECTRONICS RELIABILITY RESEARCH

Power electronics reliability research has been booming in recent years, both at universities and in companies. Among others, design-margin reduction, predictive maintenance, cost of failure, and the increasing use of power electronic converters in critical applications are the main drivers. Life-cycle

performance optimization and cost reduction are of interest, as are the time-zero performance and design cost. The recognition of the importance of data also plays a significant role in reliability studies. This section will describe several future research opportunities.

A. Physics-of-Degradation and Condition Monitoring

The failure-free operation may become a requirement for power electronic converters as they are increasingly used in reliability-, availability-, or safety-critical applications. If failure is not an option, then the understanding and modeling of the degradation process become important. A degradation curve retains all the information from accelerated degradation testing, as shown in Fig. 3, while a lifetime model is based on a single data point (i.e., EOL) of the degradation curve of each testing sample. Understanding the physics-of-degradation enables identifying key features of the degradation process.

Condition monitoring is likely to become an even more important tool in reliability engineering if failure is not allowed within the service life. Degradation modeling is essential to predictive maintenance. The following two key challenges remain to be addressed.

- 1) Most condition monitoring methods are limited to a single type of component or an individual component [6], [7], [13], [105]. Nevertheless, at the application level, degradation could occur on multiple components concurrently. Different sources of parameter shifts happen simultaneously. However, the mutual effects cannot be verified based on the assumption that a single component degrades at a time. Moreover, a full converter or an assembly is usually replaced in the presence of component failure. It is, therefore, essential to monitor the health status of the entire converter or the assembly parts of interest. Converter-level health precursors and converter-level signal measurements are alternative solutions.
- 2) Robust and cost-effective condition monitoring methods are required. Even though a wide range of health precursors and implementations is proposed in the literature, they are rarely adopted in field operation. Complexity, cost, design constraint, accessibility, and effectiveness under field operation environment are of great concern. In [106] and [107], challenges in circuit parasitics and data analytics of a condition monitoring unit for IGBT power modules are addressed. A converter-level power device ON-state voltage measurement method is developed in [108], which reduces the design cost and provides a converter-level plug-and-play solution without the need to connect to the monitored power devices. Condition monitoring provides an ancillary service, which is critical to minimize the new risk brought by the added sensors, measurement circuits, and/or software algorithms. In addition, this service may only require an intermittent operation. It is needed most during Stage III of the degradation curve shown in Fig. 3. Anomaly detection from similar systems in operation, leverage

special operation state (e.g., startup transient [109]), and system-level health precursors (e.g., efficiency) are among the most promising methods. In [110], a digital-twin-based condition monitoring concept is proposed, representing a future direction of combining physical power electronic circuit models and data-driven approaches. A composite health precursor is proposed in [111] by an optimal weighting of multiple relevant parameters. This method expects to improve the sensitivity and reduce noise in the remaining useful lifetime prediction based on multiple sources of degradation data. Artificial intelligence (AI)-based condition monitoring methods [112] hold great potential with the continued digitization and increasing amounts of available data in power electronics applications.

B. Accumulated Damage Modeling

Fig. 13 illustrates the validity of the linear accumulated damage model under different types of degradation curves. For the sake of simplicity, Fig. 13(a) and (c) shows the degradation curves for two stress levels A and B, having only Stage II and Stage III illustrated in Fig. 3, respectively. More general cases could be a combination of the curves shown in Fig. 13(a) and (c). Even though the degradation curve at the beginning of testing may diverse, as shown in [78], it is negligible because it is usually a short period of the whole service life. Stress Levels A and B correspond to the referenced time-to-failure L_A and L_B , respectively. Three different scenarios of the nonlinear degradation curve under Stress Level B are considered in Fig. 13(c), namely: Scenario 1, Scenario 2, and Scenario 3. Fig. 13(b) and (d) shows the degradation curves with normalized hour/cycle/mileage to L_A and L_B . As shown in Fig. 13(b), the degradation curves overlap under the two stress levels due to the normalization of the x -axis. Scenario 1 in Fig. 13(c) corresponds to when the two degradation curves of Level A and Level B are the same. Scenario 2 and Scenario 3 represent the cases for two different degradation curves shown in Fig. 13(d). All the curves reach EOL criteria at 100% with testing under the individual level of stress conditions. At $x\%$ of the time-to-failure, the stress level changes from A to B.

With the linear degradation curves, the superimposed stress of Level A and Level B results in the same time-to-failure as predicted by the linear accumulated damage model, as shown in Fig. 13(b). With the nonlinear degradation curves, the health precursor's change at different intervals in the x -axis is different due to the nonlinearity. For instance, the testing under Level A stress condition at the very beginning causes a negligible change of Δy compared with a significant change in approaching the EOL L_A , as shown in Fig. 13(c). Nevertheless, this nonlinearity in the degradation curve is already considered in lifetime models, which does not necessarily imply that a nonlinear accumulated damage model is needed. In Scenario 1 for Stress Level B, its degradation curve is the same as that of Stress A in Fig. 13(d). The resultant changes of Δy under Stress Levels A and B are the same at $x\%$ of operation. The degradation curve ends at 100% under Stress

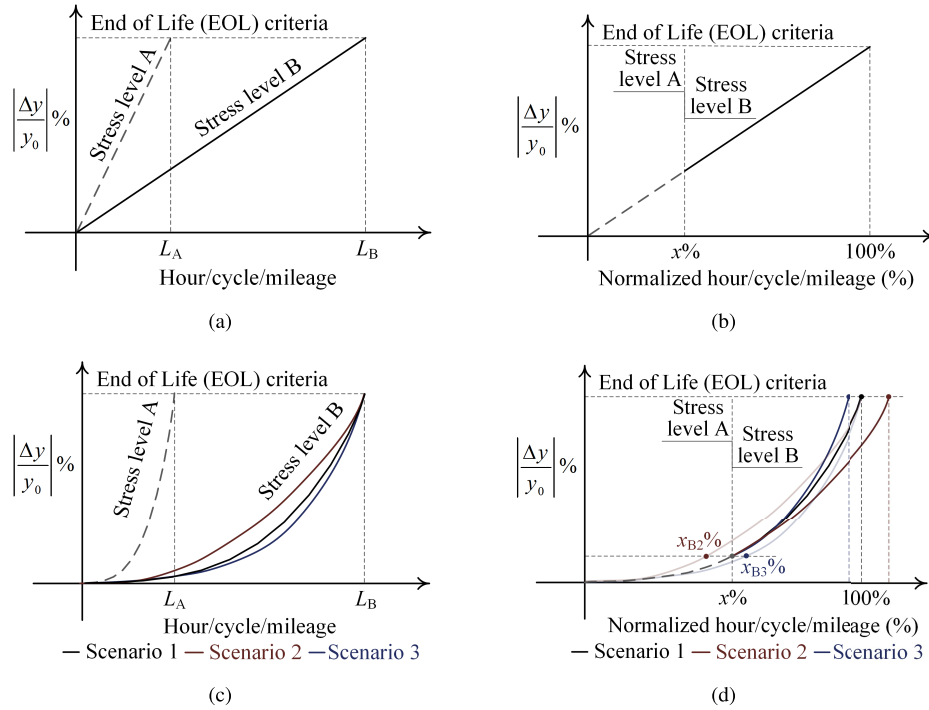

Fig. 13. Illustration for accumulated damage based on degradation curves under a sequence of two stress levels for a given failure mechanism. The normalization of the x -axis in (b) and (d) is with respect to the time-to-failure L_A and L_B , respectively, for the curves under stress Level A and Level B. (a) Linear degradation curves. (b) Normalized linear degradation curves. (c) Nonlinear degradation curves. (d) Normalized nonlinear degradation curves.

Level B of operation after $x\%$. In this scenario, the linear accumulated damage model is valid. In Scenario 2, the change of Δy at $x\%$ of operation under Stress Level A is equal to that until $x_{B2}\%$ under Stress Level B. The degradation curve from $x\%$ of operation under Stress Level B is equivalent to shift the degradation curve from $x_{B2}\%$, resulting in a time-to-failure more than 100%, which is higher than that predicted by the linear accumulated damage model. Similarly, in Scenario 3, it can be derived that the superimposed stress results in a time-to-failure less than 100%.

According to Fig. 13, it is possible to check if the linear accumulated damage model is valid by analyzing the degradation curves from the testing under individual stress conditions. For instance, the degradation curves presented in [77] feature a large portion of linear degradation shown in Fig. 13(a) and a sharp and short period of nonlinear degradation shown in Fig. 13(c). Unlike the case shown in Fig. 13(a), the boundary between the linear degradation and nonlinear degradation could correspond to different Δy . This implies a slightly different slope of the degradation curves for Stress Levels A and B in Fig. 13(b). According to Fig. 3, the degradation curve consisting of Stage III can be assumed linear within a short time interval. Therefore, as indicated by the tests in [78] and the sixth test in [77], the linear accumulated damage model is valid for the cases under more frequent changes of stress levels, which differs from the fourth and fifth tests in [77]. The perspectives provided in Fig. 13 are based on theoretical analysis and are consistent with superimposed stress testing observations, focusing on the Palmgren–Miner rule’s validity. However, more tests to verify the assumptions are necessary in the future.

C. Humidity-Induced Failure Mechanisms, and Failure Mechanisms of SiC MOSFETs, GaN devices, and Magnetic Components

The level of attention to the humidity-induced failure mechanisms of power electronic systems is relatively lower than that for electrothermal and thermalmechanical induced failures. Nevertheless, they are closely relevant to field applications, as discussed in Section II. Consequently, more research on modeling of humidity impact and microclimatic design and control for power electronic systems is suggested.

Even with increasing studies on the failure mechanisms and accelerated testing of SiC and GaN switches [10], [11], the relevance between these component-level investigations and converter-level applications is still largely unknown. SiC- and GaN-based industrial systems are limited at the early stage of its operation. It is, therefore, expected that the commercial use of SiC devices in automotive applications will provide more field experiences. The decreased short-circuit withstand time of SiC and GaN devices demands protection schemes with sub- μs or 1–2- μs decision-making and action.

The understanding of failure mechanisms of magnetic components in power electronic applications is still limited. The early studies presented in [51] and [52] show the need to further investigate the failure mechanisms and degradation models, especially for planar magnetic components and medium-voltage medium-frequency isolation transformers.

D. High-Resolution and Fast-Temperature Measurement

Thermal stress is related to various failure mechanisms. Temperature sensitive electrical parameters (TSEPs) are widely studied for temperature estimation, limited to

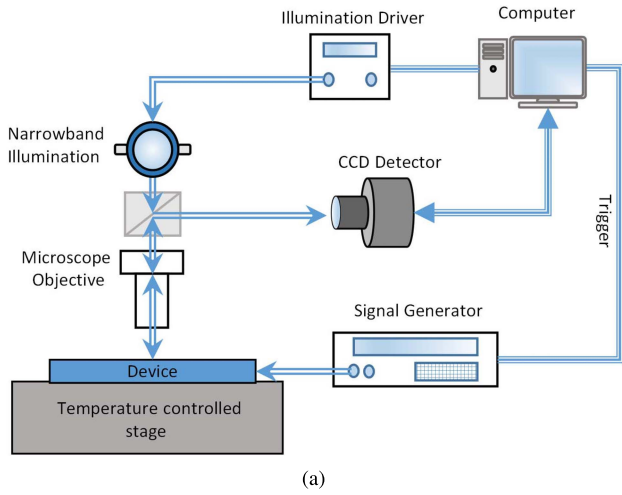

Fig. 14. Thermoreflectance measurement method and an example of the measured temperature profile proposed in [113]. (a) Schematic of the thermoreflectance measurement configuration, including the charge-coupled device (CCD) detector, illumination source, microscope objective, and the temperature-controlled stage. (b) Measured drain current, voltage and calculated power dissipation, temperature based on measurement and simulation of the CGH40025F Cree GaN HEMT operating in a class-A amplifier, and temperature measured with a temporal resolution of 50 ns.

100- μ s temporal resolution [114]. In [113], a noninvasive thermal measurement technique called thermoreflectance thermography is proposed with nanosecond time and submicrometer spatial resolutions. This technique is promising for temperature measurement during short circuits and MHz-level high-frequency converters. Fig. 14(a) shows a schematic of the measurement setup. Fig. 14(b) shows the measured temperature profiles with a temporal resolution of 50 ns. However, more studies are necessary to lift the maturity level and extend it to other applications.

E. Reduction of Reliability Testing Time

It is necessary to reduce the required time of accelerated degradation testing and reliability demonstration testing. Two promising directions are briefly discussed in the following.

- 1) *Virtual-Physical Hybrid Testing Method*: A digital platform can be built to simulate the degradation of power electronic components under accelerated or normal stress levels. Physical testing is used to calibrate the

models used in the digital platform. Since a significant part is to be done by simulations, it is possible to reduce the required time without compromising the relevance of the results.

- 2) Accelerated testing combined with early wear-out prediction. The prediction for degradation curves based on early testing results is applied for film capacitors [115] and batteries [116], [117]. In the recent case study [117], it has been demonstrated that the required time for identifying high-cycle-life charging protocols among 224 battery candidates is reduced to 3.2% of the expected time without early prediction. It is, therefore, worth exploring the concept of the degradation testing of power electronic components and converters.

F. Reliability Modeling of Power-Electronics-Based Power Systems

The impact of power electronic converters on the reliability of power systems is still an open question with their increasing penetration level. Hundreds and thousands of power electronic converters may be used in a local electrical network. Consequently, reliability performance plays a role in the availability and security of the electric network. The interconnects, interactions, and control dynamics among different converters all add extra layers of complexity. This brings new challenges in scaling up the mission-profile-based reliability prediction methods discussed in Section IV. FMEA is a useful tool to prioritize the available resources to deal with the top-ranked failure causes in a system. Consequently, new multitime-scale modeling approaches are needed to simplify the modeling procedures, meanwhile maintaining reasonable prediction accuracy. Real-time simulation of large-scale systems could also become feasible for reliability study, extending its scope from the electromagnetic domain.

VI. CONCLUSION

This article reviews the latest power electronics reliability research in field experiences, failure mechanisms, component-level EOL criteria, testing methods, and system-level mission-profile-based reliability prediction methods. The discussions on failure mechanisms have focused on the short circuits of SiC MOSFETs and GaN devices and the magnetic components. Perspectives on the degradation curve, lifetime definition, lifetime model applicability boundary, and linear accumulated damage model validity are provided. In addition, the limitations in existing lifetime models and mission profile-based reliability prediction methods are discussed. Finally, future research demands and opportunities are identified: 1) physics-of-degradation and condition monitoring; 2) accumulated damage modeling; 3) humidity-induced failure mechanisms, failure mechanisms of SiC MOSFETs, GaN devices, and magnetic components; 4) high-resolution and fast-temperature measurement; 5) reduction of reliability testing time; and 6) reliability modeling of power-electronics-based power systems. For further background information on these aspects and other relevant research topics, we refer the reader to [1]–[13].

Huai Wang (Senior Member, IEEE) received the B.E. degree in electrical engineering from the Huazhong University of Science and Technology, Wuhan, China, in 2007, and the Ph.D. degree in power electronics from the City University of Hong Kong, Hong Kong, in 2012.

He was a Visiting Scientist with ETH Zurich, Zürich, Switzerland, from August to September 2014, and the Massachusetts Institute of Technology (MIT), Cambridge, MA, USA, from September to November 2013. He was with the ABB

Corporate Research Center, Baden, Switzerland, in 2009. He is currently a Professor with the Center of Reliable Power Electronics (CORPE), Department of Energy Technology, Aalborg University, Aalborg, Denmark. His research addresses the fundamental challenges in modeling and validation of power electronic component failure mechanisms and application issues in system-level predictability, condition monitoring, circuit architecture, and robustness design.

Dr. Wang received the Richard M. Bass Outstanding Young Power Electronics Engineer Award from the IEEE Power Electronics Society in 2016 and the Green Talents Award from the German Federal Ministry of Education and Research in 2014. He is also the Chair of the IEEE PELS/IAS/IES Chapter in Denmark. He also serves as an Associate Editor for the *IET Electronics Letters*, *IEEE JOURNAL OF EMERGING AND SELECTED TOPICS IN POWER ELECTRONICS*, and *IEEE TRANSACTIONS ON POWER ELECTRONICS*.

Frede Blaabjerg (Fellow, IEEE) received the Ph.D. degree in electrical engineering from Aalborg University, Aalborg, Denmark, in 1995.

He was with ABB-Scandia, Randers, Denmark, from 1987 to 1988. He became an Assistant Professor in 1992, an Associate Professor in 1996, and a Full Professor of power electronics and drives in 1998 at Aalborg University. Since 2017, he has been a Villum Investigator. He is the honoris causa at Universitatea Politehnica Timisoara (UPT), Timisoara, Romania, and the Tallinn University of

Technology (TTU), Tallinn, Estonia. He has published more than 600 journal articles in the fields of power electronics and its applications. He is a coauthor of four monographs and an editor of ten books in power electronics and its applications. His current research interests include power electronics and its applications, such as in wind turbines, photovoltaic (PV) systems, reliability, harmonics, and adjustable speed drives.

Dr. Blaabjerg received 32 IEEE Prize Paper Awards, the IEEE PELS Distinguished Service Award in 2009, the EPE-PEMC Council Award in 2010, the IEEE William E. Newell Power Electronics Award in 2014, the Villum Kann Rasmussen Research Award in 2014, the Global Energy Prize in 2019, and the 2020 IEEE Edison Medal. He was nominated in 2014–2019 by Thomson Reuters to be among the 250 most-cited researchers in engineering in the world. He was the Editor-in-Chief of the *IEEE TRANSACTIONS ON POWER ELECTRONICS* from 2006 to 2012. He was a Distinguished Lecturer of the IEEE Power Electronics Society from 2005 to 2007 and the IEEE Industry Applications Society from 2010 to 2011 and 2017 to 2018. From 2019 to 2020, he has served as the President of the IEEE Power Electronics Society. He is also the Vice-President of the Danish Academy of Technical Sciences.
