(4) Western blotting: Non-decalcified teeth were separated into caries-affected and -unaffected regions and homogenized using a bead crusher and ultrasonic homogenizer. Each sample was pepsin-solubilized or treated with 3 N HCl [2].
(5) Mechanical hardness test: Hardness of demineralized sections was evaluated using a mechanical indentation tester equipped with an indentation probe of micro-size diameter. Based on the resultant force-displacement curve, the slope corresponding to a spring constant was calculated. More than 25 points were probed in demineralized dentin to examine regional heterogeneity in dentin hardness.
(6) HPLC analyses: dentin samples were hydrolyzed in 6 N HCl at 110°C for 20 hours.
(7) Statistical analyses were presented as mean ± SEM for statistical analysis. Obtained values were analyzed using one–way ANOVA and Tukey-Kramer tests with a significant level of $p<0.05$

RESULTS AND DISCUSSION

Immunohistochemical staining showed localization of AGEs in dentin. AGEs were detected around the pulp and pre-dentin in aged roots. In immuno-EM, AGE accumulation was observed in collagen fibrils around dentinal tubules only in aged dentin. The fluorescence lifetime of aged dentin was shorter than that of young dentin. Electrophoresis analysis also demonstrated differences between young and aged dentinal collagens. After pepsin-solubilization, type 1 collagen was observed only in young dentin. These findings suggest that the AGE-rich collagen fibers are tolerant to degradation by acid and enzymatic digestion. Furthermore, dentinal collagen in aged dentin was stiffer than that in young dentin (Figure 1). HPLC analyses showed that AGE accumulation (pentosidine) in aged samples was greater than that in young samples. AGEs generated *via* non-enzymatic glycation of dentinal collagen gradually accumulated in dentin tissue with aging. Since accumulated AGEs cause cross-linking between amino acid polypeptides in collagen molecules and modify mechanical properties of dentinal collagen, we speculate a significant interaction between the generation of AGEs and dentin physiology.

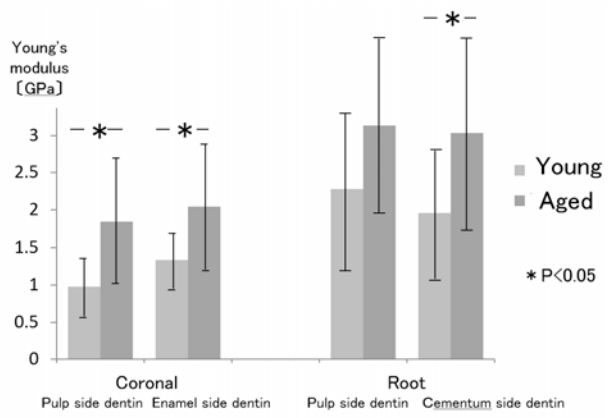

Figure 1: Microindentation hardness test of demineralized human dentin

CONCLUSIONS

Our findings suggest that the accumulation of AGEs with aging in human dentin may be responsible for changes in fluorescence lifetime and mechanical properties. Fluorescence lifetime imaging and electrophoresis can provide useful information with respect to the influence of cross-linking on aging in human dentin.

P178 - AN INFLUENCE OF DIABETICS TYPE II ON ACHILLES TENDON BIOMECHANICS - MULTISCALE EXPERIEMNTAL STUDIES

INTRODUCTION

Diabetes is a civilization disease which is affecting 8.5% of the world adult population. Moreover, diabetes global prevalence is constantly raising, reaching over 420 million cases in the past two years [1]. A diabetes causes chronic hyperglycemia (elevated sugar level), which cannot only be a severe issue to human health but it also leads to changes in mechanical properties of the soft tissues. Human tendons, as an example of such soft matter, are subjected to those changes as well [2].

There are a few mechanisms, occurring in tendon collagen tissue affected with diabetes i.e. reactions of glucose excess with extracellular matrix proteins (resulting in tissue ageing) [3], production of advanced glycation end products (AGE's) (resulting in extra cross-linking formation) [4] or increased rate of proteins oxidation (resulting in proteins thermal denaturation) [5]. On the other hand, an elevated sugar level is accompanied by increased expression of matrix metalloproteinase's (MMP's) enzymes, which may accelerate the degradation rate of collagen tissues [6]. As a consequence, the coexistence of tissue strengthening and weakening mechanisms leads to many discrepancies in literature – some reports confirm increasing and some of them decreasing stiffness of tendon in diabetes [2]. This lack of unanimity becomes explainable when we consider the tendon as a multi-scale hierarchical structure and notice that different processes may modify its mechanical properties at different levels. Therefore there is a need to investigate the changes of tendon mechanical properties at both – fascicle and fibril level, and correlate this results with structural changes resulting from diabetes.

The objective of our work was to investigate the causes of alteration of biomechanical properties of Achilles tendon in diabetes for each level of spatial scale – starting from Atomic Force Microscopy (AFM), through the Raman and Mass Spectroscopy, histochemical staining, ending with macroscale strength tests.

METHODS

The studies were conducted on Achilles Tendon (AT) fascicles derived from the Department of Forensic Medicine (Jagiellonian University Medical College, Cracow). The research protocol was approved by the Jagiellonian University Medical College Ethics Committee (registry number KBET/269/B/2011) and studies have been performed in accordance with the ethical standards established in the 1964 Declaration of Helsinki and its later amendments. The samples were subjected to experimental measurements using:

- Atomic Force Microscopy (AFM) to evaluate the Young modulus of collagen fibers,
- Strength tests – to measure the strength and stiffness of macroscale healthy and diabetic tendon fascicles samples,
- Raman spectroscopy to assess changes in collagen superhelix secondary structure,
- Mass spectroscopy – to determine an expression of the AGE's in tendon fascicles,
- Histochemical staining – to examine the presence of MMP's enzymes.

RESULTS AND DISCUSSION

The results of our AFM experiment showed a triple decrease in Young modulus of collagen fibers for diabetic samples. A reduction of tendon fascicles stiffness and the strength, was also observed in tensile tests. On the other hand, the results from mass spectroscopy revealed an increase of collagen cross-linking at the molecular level. However, the data obtained from Raman spectroscopy did not indicate any changes in collagen secondary structure but histochemical staining confirmed an elevated level of MMP's enzymes within tested tissue.

Obtained results confirmed that diabetic causes a decrease in stiffness of collagen fibers, however this change seems to be driven exclusively by enhancing activity of MMP's enzymes rather than modification of protein secondary structure (collagen superhelix stays unfolded). On the other hand we observed an increasing number of collagen cross-linking which may indicate the higher stiffness of diabetic samples. However, the fascicle samples intended for mass spectroscopy tests, required prior homogenization, thus results included cross-linking present in collagen fibers as well as in the interfascicular matrix (IFM). This conclusion also explains many other reports of increasing stiffness of diabetics tendons measured at macroscale, where ratio of IFM to collagen content is even higher than for a single fascicles.

CONCLUSIONS

Due to the lack of the comprehensive studies on the influence of MMP's and AGE's on mechanical properties of the tendons at different spatial scales, we decided to investigate those phenomena using several experimental techniques. We confirmed that diabetes causes a decrease in stiffness of collagen fibers, despite increasing cross-linking at fascicle level. We showed that, at fiber level, the activity of MMP's enzymes has a greater impact on overall stiffness, than an extra linking at fascicle level. Therefore, we conclude that already reported cases of increasing stiffness of macroscale units of diabetic tendons, are resulting from other alterations at IFM level.

INTRODUCTION

The majority of the people in low-income countries, who need assistive technology do not have access to prosthetic devices [1]. Instead of these people having to make a long journey to one of the few prosthetic workshops, solutions like the Modular Socket System (MSS, Össur®) may be useful, because potentially they could be delivered and manufactured on site, at the location of the person [2]. This could make it suitable for application in a Community Based Rehabilitation (CBR) setting.

The aim of this study was to evaluate the technical feasibility of the MSS for implementation in a CBR setting in terms of required tools, skills and required production time.

METHODS

The study was performed at the Department of Prosthetics & Orthotics of the Jakarta I Polytechnic School of Health Science (JSPO). Four JSPO students received a three days training in manufacturing of the MSS. Lower limb amputees were recruited to participate in this study from the region of Jakarta (n = 5) and Bali (n = 10). A set of standardized instruments including the two minutes' walking test (2MWT) and Prosthesis Evaluation Questionnaire (PEQ) were used to measure performance and satisfaction with the prosthesis. Production and maintenance logbooks were filled out by the involved prosthetists to evaluate the technical feasibility of the MSS.

RESULTS AND DISCUSSION

Performance (2MWT) and satisfaction (PEQ) scores were comparable to that of similar studies with other lower leg prostheses [3,4]. Both measures did not decrease significantly over time (**Figure 1**). This suggest that the JSPO students were able to reach sufficient quality.

It took the prosthetists 3.5 to 10.5 hours to fit an amputee with a MSS prosthesis. Mean socket production time was 2.0±0.6 hours and mean prosthesis assembly and fitting time was 4.1±2.6 hours. The only non-portable machine needed for the production of the prosthesis was a grinding machine (router). Smaller portable machines used were a cast cutter/jigsaw, Icecast® Compact and resin injection tool. If in the future the grinding machine will be replaced by a handheld tool, production of the MSS could be performed on site, making it suitable for use in a rural setting.

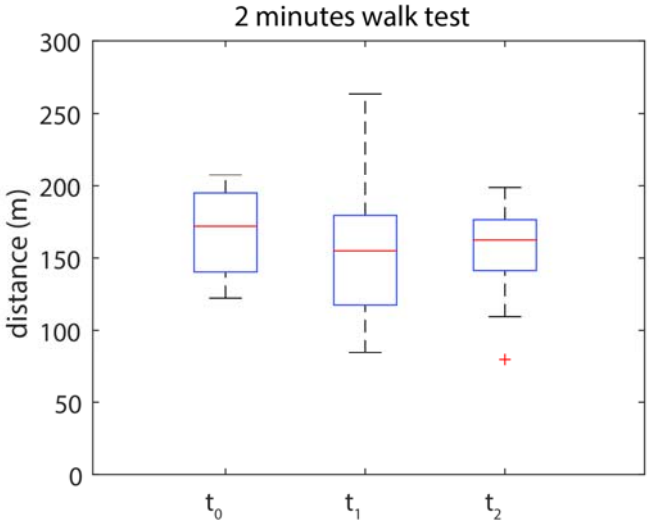

Figure 1: The results of the 2MWT at the moment of fitting (t_0), at 1-3 months post fitting (t_1), and at the end evaluation at 4-6 months post fitting (t_2).

CONCLUSIONS

Patients who normally have to travel long distances to access prosthetic services were only required to make one visit to the health facility in order to receive a prosthesis. From a technical and quality perspective the method seems feasible, although, high costs remain an issue.

ACKNOWLEDGEMENTS

Materials and training for the production of all prostheses were sponsored by Össur®.

P180 - DEVELOPMENT OF PUNCTURE TREATMENT BASED ON HIGH-SPEED NEEDLE INJECTION BY ELECTROMAGNETIC ACCELERATOR

[1] **Hirotatsu Kato**, [1]Kenta Nomura, [1]Hiroshi Takemura, [2] Kohei Soga, [3]Hideo Yokota, [4]Masaaki Ito, [4]Naoto Gotoda, and [4] Yuji Nishizawa

INTRODUCTION

Issues of the current puncture treatment are needle bending and target moving. Such issues depend on the doctor's experiences and skills. Conventional researches have proposed a simulation of a puncture trajectory [1] and developed robot puncture treatment system [2]. However, the simulation is not realistic when considering all material parameters on the organ of each patient and calculation costs. The robot system has the same issues of doctor, because the robot substitute the doctor's manual treatment same as the doctor's treatment way. Tsumura et al. proposed the needle rotating puncture method with a microscopic needle [3]. However, the method still needs high accuracy control and real time observation systems. In order to solve these problems, we propose novel puncture treatment system based on high-speed needle injection by using electro-magnetic accelerator mechanism and optical fiber laser. The high-speed needle puncture becomes possible to solve the problem of needle bending, target moving and observation problems. In this paper, we describe the development of a high-speed needle puncture mechanism for a versatile puncture treatment.

METHODS

Figure 1 shows the concept of the proposed high-speed needle puncture treatment system. (1) Prepare some super-fine needles with a thread and puncture them at high speed. (2) Insert catheters by using threads as a guide and extract threads after inserting them. (3) Use the optical fiber lasers for ablation of cancer tumor. (4) 3D ablation of the cancer tumor by the laser from the optical fiber and evaporate the cancer tumor.

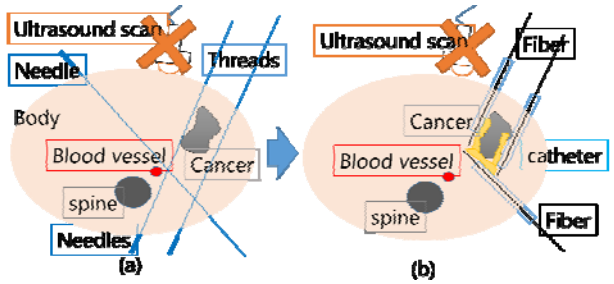

Figure 1: Novel of puncture treatment system (Patent submitted)

In order to verify the proposed concept, we developed the high-speed needle puncture mechanism by using electro-magnetic force. One important feature of this mechanism is puncturing a very fine needle with a thread linearly. We used the principle of coil-gun to get stable speed with electromagnetic force. The coil-gun accelerates the magnetic material, using the electromagnetic force generated by passing a current through the coil. The lead wire of the coil is 1 [mm] in diameter and 10 [m] in length. The voltage of the capacitor is 500 [V]. Its capacitance is 3000 [μF]. The needle has a thickness of 0.5[mm] (25G) and a length of 27[mm], a mass of 0.034[g].

A basic experiment was conducted to investigate the performance and reproducibility of the coil gun. The speed of needle by using the puncture system was examined five times in the same conditions. The needle speed was calculated by using high speed camera (6000 [fps]). For the results, the maximum needle speed with one coil was 43.2 [m/s]. The average in the same conditions was 42.7 ± 0.45 [m/s]. The variability of the needle speed under the same condition was small. The highest needle speed by using two coils achieved 49.1 ± 1.54 [m/s].

10% gelatin [4] block, which is a material regarded as muscle tissue parameters, was used for adaptation to puncture test. The gelatin block kept in 4.0 [°C] and experimented within 2 minutes. The speed of the needle was set to 30 [m/s], 40 [m/s] and 50 [m/s]. Each trial was five times. In the experiment, we investigated whether the needle entered the gelatin block linearly and the length of the needle entered into the gelatin block.

RESULTS AND DISCUSSION

The penetrated length is 28.5 ± 2.23 [mm] at 30 [m/s], 31.9 ± 2.97 [mm] at 40 [m/s] and 33.9 ± 0.24 [mm] at 50 [m/s]. The penetrated length was deeper by increasing the speed. The needle was slow down significantly in the skin. It is necessary to increase speed for real puncture treatment. However, the needle speed can be easily increasing by using multi-coils.

CONCLUSIONS

In this research, we proposed an innovative puncture treatment system. We developed a mechanism for puncturing a needle at high speed for puncture treatment. As the results, the developed mechanism demonstrated that reproducible injection can be realized. In the future, the needle speed will be increased by multi-coils system.

P181 - PARALLEL LINKAGE MECHANISM OF THE RECTUS FEMORIS DURING STANDING UP

[1,2] **Takuya KOIDE**, [1] Masanobu MANNO [3] Tomokazu ABE and [1] Tomohiko FUJIKAWA

INTRODUCTION

The human action of standing up is regarded as a key aspect of maintaining a basic standard of daily life. At clinical sites, a different phenomenon that departs from the standard theory for this action has been observed, suggesting that a distinctive biarticular muscle function is involved. We have previously showed by dynamic electromyographic analysis of the action of moving the trunk to the vertical that the main agonists are the knee joint monoarticular extensor and the rectus femoris. In the present study, we focused on the function of biarticular muscle acting in a parallel linkage to direct the floor reaction force toward the center of gravity, by constructing a model with the rectus femoris linked in parallel and measuring these changes to clarify the contribution of the rectus femoris to trunk stability in standing up.

METHODS

We constructed an experimental model having a monoarticular extensor spring and a parallel linking wire involved simultaneously in joints H and K, and a monoarticular flexion spring on joint K as an antagonist to maintain joint stiffness. We used this model to investigate the effect of differences in trunk weight on the action of standing up. The knee flexion θ_2 was set to obtain 105° for the initial posture in the model as a condition for its generation of a reaction force vertically upward.

RESULTS AND DISCUSSION

We found that with a trunk (S-H) weight M [120 g], the wire restrains the trunk (S-H) from falling over due to inertial force, and that the parallel linkage can constantly direct the floor reaction force generated at joint A toward the center of gravity and thereby facilitate the action of standing up (Fig. 1a)). With a trunk (S-H) weight of 2M (240 [g]), the action of standing up slowed but was still smooth and successful despite the increased inertial moment resulting from the increased mass (Fig. 1b)). This showed that even with changes in trunk weight and inertial moment, the force generated can be constantly directed toward the center of gravity by the rectus femoris in conjunction with the parallel linkage, thereby enabling the human action of standing up.

CONCLUSIONS

We found that the wire corresponding to the rectus femoris can keep the trunk from being tilted over by inertial force and that the floor reaction force generated at the calcaneus region can be constantly directed by the parallel linkage toward the center of gravity, and thus that the parallel linkage with the rectus femoris results in a mechanism for application of the driving force by the knee joint monoarticular extension alone, thereby enabling the human action of standing up.

INTRODUCTION

Most mechanical joint systems have motors and mechanical elements. Each component consumes energy when it makes motion. In the case of an exoskeleton suit, operating time is short because the energy source is limited. So, energy efficiency should be considered to increase operating time of an exoskeleton suit. In this study, we propose control method and concept design of exoskeleton joint and we manufactured magnetorheological brake that main units and measured braking torque.

METHODS

In general, motion is divided into static & dynamic. But, joint of many exoskeletons consist of only motor regardless of motion state. Therefore, motor is always consuming energy at static and dynamic state. So, we propose the MR(Magnetorheological) brake unit that consumes less energy than motor at static state. First of all, we must design and manufacture the MR brake unit before comparing proposed concept.

MR fluid has three working mode (shear mode, flow mode, squeeze mode). In the case of the shear mode, the MR fluid is located between surface moving in relation to each other with the magnetic field flowing perpendicularly to the direction of motion of these shear mode [1]. So, designed MR brake has several disks and is filled with MR fluid in each gap. This concept of MR brake was designed in 1947 by Jacob Rabinow [2].

RESULTS AND DISCUSSION

Our proposed unit has MR brake, harmonic drive and motor. Coil inside MR brake generated closed loop flux path through ferromagnetic material around coil. We used steel (AISI 1045 steel, KS SM45C) for ferromagnetic material and Stainless steel (AISI303, KS SUS303) for paramagnetic material. And, used coil is 20 AWG.

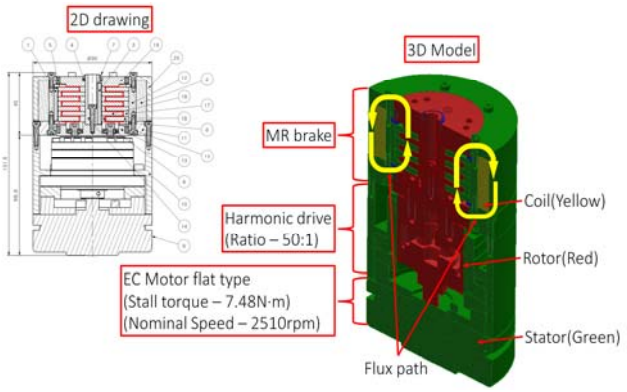

Figure 1: 3D model & 2D drawing of MR brake.

To predict flux path, we performed the magnetostatic study by ANSYS. Boundary condition was applied 1mA current source and 320 number of turns.

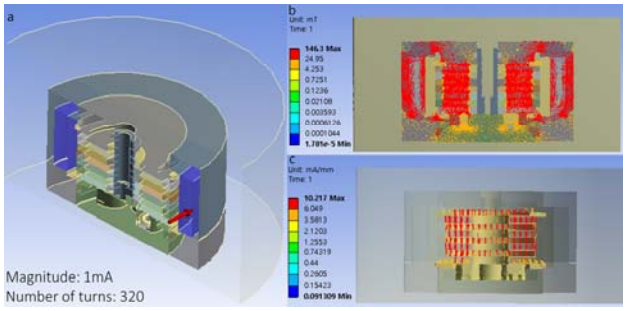

Figure 2: F.E.M results of MR brake (a. boundary condition, b. result of flux density of all parts, c. result of flux intensity of MR fluid)

After checking the F.E.M results, we manufactured the MR brake for measurement. The measurement was carried out in the following.

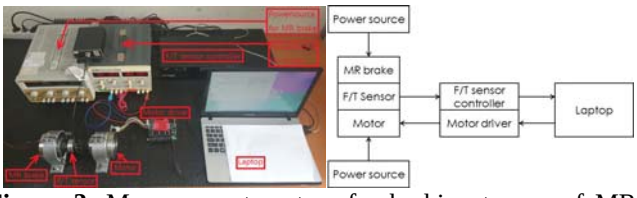

Figure 3: Measurement system for braking torque of MR brake

Braking torque of MR brake was measured 10 times at 20rpm. And, torque was measured by varying the current from 0A to 3A. Measured result is below.

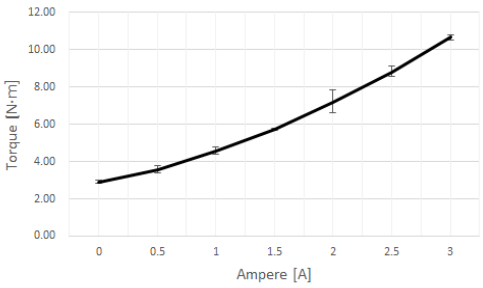

Figure 4: Braking torque of MR brake at 20rpm.

CONCLUSIONS

MR brake was designed and manufactured for energy efficient exoskeleton suit. As results of F.E.M, we checked the closed loop flux path of MR brake. Finally, we measured 10.69 Nm of braking torque at 3A current source.

INTRODUCTION

Landing action accompanied by a large amount of energy and strong impact can cause muscle injuries such as pulled muscles, as well as avulsion fractures that can make walking difficult. Muscles that are particularly vulnerable to these kinds of problems include biarticular muscles such as the gastrocnemius, rectus femoris, and hamstrings. Because a biarticular muscle crosses two joints, contraction of that single muscle affects the articular movements of both joints. In many analyses, this mechanism is considered redundant, and therefore is not taken into consideration. Considering, however, that humans and animals inescapably have biarticular joints, some necessity for this mechanism must exist in terms of action. Given this, our research focused on a landing action in which the heel serves as the contact point stabilizing the trunk after the heel has landed. As part of our study, we attempted to clarify the mechanisms and properties of biarticular muscles in the femur during the landing action.

METHODS

In our electromyographic analysis of action, we made measurements at a total of six locations: gluteus maximus, vastus medialis, rectus femoris and hamstrings of the femoral area, and the gastrocnemius and tibialis anterior muscles of the lower leg. We measured floor reaction force synchronized to muscle activity using a floor reaction force gauge, and posture during the landing action using a high-speed camera. Experimental conditions were as follows: subjects landed by dropping from a suspension bar, and landed with the weight on the heels. Subjects were also instructed to keep the trunk perpendicular at all times when landing. Theoretical analysis was used to clarify the properties of muscle activity confirmed by means of electromyographic analysis, using the link model shown in Figure 1 for the theoretical analysis. In this theoretical analysis, we clarified the properties of output force generated in the heel area as a result of the contractile force differential of the driving source and the stiffness that occurred in the heel area as a result of the contractile force sum of the driving source.

RESULTS AND DISCUSSION

In the electromyographic analysis of the action, we were able to confirm the muscle activity of the gluteus maximus, vastus medialis, rectus femoris and semitendinosus muscles in the landing action of the heel. Based on these results, we confirmed that electric discharge occurs simultaneously in the antagonistic biarticular muscles of the femur. Robotic theoretical analysis using a link model found that the simultaneous discharge in biarticular muscles of the femur was adjusted in response to the output force and stiffness generated in the heel area, as the tip of the link. We believe that this contributes to a landing action in which the trunk is stabilized.

CONCLUSIONS

Our research used robotic theoretical analysis to elucidate the necessity for simultaneous discharge from antagonist biarticular muscle pairs in the femur. Without this simultaneous discharge from these biarticular muscle pairs when the heels land, we believe landing with weight positioned on the heels would be extremely difficult for humans.

P184 - EVALUATION FRAMEWORK OF PROSTHETIC KNEE JOINT PERFORMANCE USING DYNAMICAL SIMULATION

Hisashi Naito, Kengo Osaki, Masamichi Nogawa and Shinobu Tanaka
Kanazawa University
Corresponding author email: hisashi-naito@se.kanazawa-u.ac.jp

INTRODUCTION

Prosthetic knee joint is an essential component for above knee prosthesis. Nowadays, many types of knee joint are commercially available. The functions of the knee joints are wide-ranging from primitive one, mode is changed manually fixed during walking and flexed only at sitting phase, to sophisticated one, with powerful actuators and an autonomous controller. Its price is grown with higher functionality. Each prosthetic user chooses one component, which is fitted with each physical condition, lifestyle and other demands, among many options during prosthesis fitting process with assistance of prosthetic experts. The fitting of prosthesis is not so easy in practice.

Although there are many types of knee joint with unique feature, even mechanical properties, e.g. inertial property, passive joint moment property and position center of gravity, etc., of each knee joint is hardly shown in a specification sheet. It might be caused partly by that the required performance of the prosthetic knee joint is not clear theoretically yet.

In this study, we propose an evaluation framework of prosthetic knee joint using rigid multibody dynamical simulation. The framework consists of kinematic and kinetic simulation of knee joint and forward dynamical walking simulation combining human skeletal model with above knee prosthesis model including knee joint part. Using these simulations, the required mechanical performance of the prosthesis knee joint will be considered.

METHODS

Structures of prosthetic knee joint are categorized into 2 main types, i.e. single axis type and multi-linkage type. Multi-linkage knee joint has at least one closed link structure.

Rigid multibody mechanical simulation of mechanisms with closed link structure is more severe than that of mechanisms without it, because of compatibility requirement of linkages connecting constraint condition and existence of singular condition. To perform simulations, a method using differentiation algebraic equation, therefore, are modified so as to be with much more calculation stability nearby singular condition.

The simulation can treat 5 types of mechanical joint, i.e. ball (3 degree of freedom; DOF), universal (2DOF), hinge (1DOF), cylindrical (2DOF) and parallel (1DOF).

Solving equation of motion (EOM) applying full degree of freedom motion pattern, external force and moment which realize applied motion pattern are available, i.e. it is inverse-dynamics simulation. On the other hand solving EOM applying external force and moment, motion pattern can be estimated, i.e. it is forward dynamical simulation.

For forward dynamical human walking simulation, neuro-skeletal human model is constructed as a human body skeletal structure with a neuronal motor controller by reference to earlier study [1]. Simulation of walking with prosthesis is performed by combining the human model with an above knee prosthesis.

RESULT AND DISCUSSION

Figure 1 shows an example of simulation of a trans-femoral prosthesis with 6 linkages knee joint (3R106, Ottobock inc.). Pattern of femoral segment translation displacement and posture is subjected to an experimental femoral motion path during swing phase.

Simulated motion shows similar to practical motion patterns of trans-femoral prosthesis during swing phase. Simulated results such as motion pattern, applied force and moment to handle the prosthesis might be materials for evaluating knee joints.

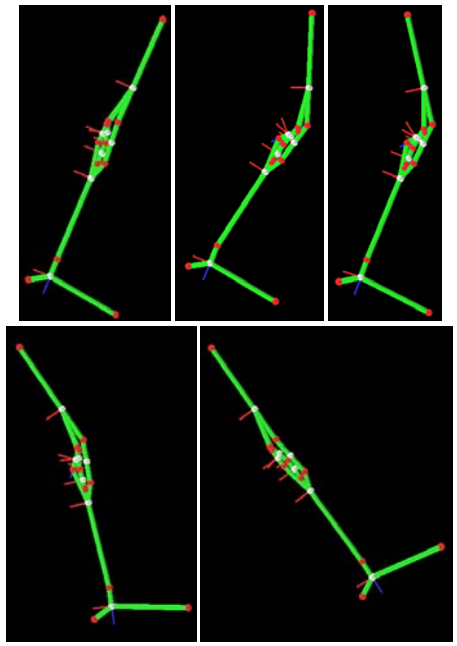

Figure 1: Example of simulated motion of trans-femoral prosthesis with 6 linkages knee joint subjected to a femoral segment motion pattern during swing phase.

INTRODUCTION

The inverted pendulum model (IPM) represents the mechanical function of bipedal walking as the centre of mass (CoM) height and forward velocity data present as sine curves 180 degrees out of phase. In able-bodied (AB) gait peak CoM velocity and minimum height, and minimum velocity and peak height are synchronous during level over-ground walking [e.g. 1,2]. Results from individuals with a unilateral transtibial amputation demonstrate, that these events do not coincide during prosthetic limb initial double support. Therefore, the IPM might be less appropriate for the transtibial amputee gait [3], but it is not known, if the IPM might be suited to describe the unilateral transfemoral amputee (UTF) gait on level ground, which is likely to retain a more vertical projection of their CoM at prosthetic limb toe-off [4]. Additionally, the aim of this research was to investigate the appropriateness of the IPM model for gait of both, AB and UTF, on slopes as due to the difficulty of this task interlimb-asymmetry might be increased for UTFs.

METHODS

In addition to a level ground condition [5] kinematic and kinetic data of 2 UTFs (1.81. ± 0.11 m, 74.1 ± 14.9 kg) wearing the same prosthetic foot (Esprit; Chas. A. Blatchford & Sons, Basingstoke, UK) and 15 AB individuals (1.81 ± 0.05 m, 75.1 ± 9.1kg) were collected during ascending and descending a ramp (-12°, -6°, +6° and +12°). Reflective markers were placed according to the Cleveland Clinical model. Timings of the minimum and maximum CoM vertical position and forward velocity were identified and their difference in timings (relative time shift) with respect to gait cycle duration was calculated in four phases: Prosthetic/right initial double support (IDS_P), single support (SS_P), prosthetic/right terminal double support (TDS_P) and intact/left single support (SS_I). A Friedman ANOVA was used to identify differences in relative time shifts between the inclinations in each phase for the AB group. Post-hoc tests were conducted for the relevant comparisons using a Wilcoxon signed rank test ($p < .050$) and Cohen's d for effect sizes. Due to the low sample size results for the UTF group remain descriptive.

RESULTS AND DISCUSSION

During level over-ground able-bodied gait the median relative time shift was between 1.2-1.8% in all gait phases. During the double support phases the peak velocity occurred with increasing slope gradient significantly earlier to the minimum CoM height (-6.6- -9.1%), and significantly later during incline (7.1-8.1%) (Figure 1). During the single support phases the relative time shift was similar in all phases (1.4-3.6%), except the +12° inline, at which the minimum peak velocity occurred significantly later to maximum CoM height (-3.2%) (Figure 1). The UTF participants displayed a greater median positive relative time shift in IDS_P and SS_I (4.4-5.7%), similar in SS_P (1.7-3.7) and a negative time shift in TDS_P (-1.0- -2.2) during the level condition. During the sloped conditions the trend of the UTF relative time shift data is similar to the AB-group, except in the TDS_P phase, during which the UTF participants display a relative time shift closer to zero (Figure 1).

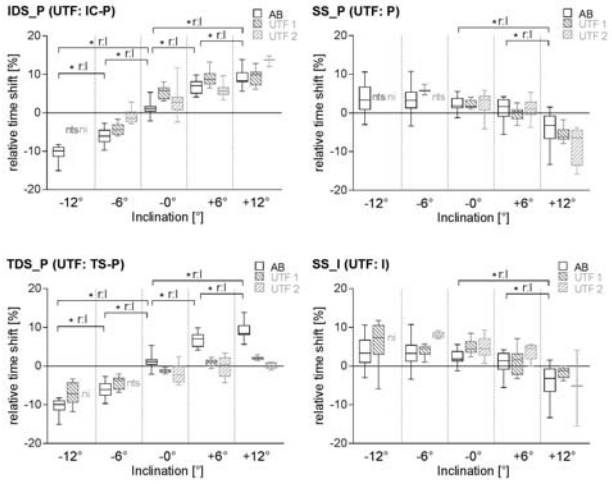

Figure 1: Boxplots of the relative time shift between minimum/maximum CoM height and minimum/maximum CoM velocity incidence over 5 slope gradients for AB and UTF participants. Note: ni: the inclination was not managed, nts: no timeshift-events were able to be identified in this phase.

CONCLUSIONS

The IPM does not represent the UTFs gait well during level walking and even less during slope walking. During slope walking neither the AB nor the UTF gait is well represented by the IPM, except during the TDS_P, with increased relative time shifts compared to level walking in all phases of the gait cycle.

P186 - DYNAMIC HEAD RESPONSE FOR HELMETED (AMERICAN FOOTBALL) AND NON-HELMETED AT VARYING HORIZONTAL IMPACT OFFSETS

Kevin Adanty, Karen Taylor, Fadi Salama and Thomas Blaine Hoshizaki
University of Ottawa
Corresponding author email: kadan039@uottawa.ca

INTRODUCTION

The material design of an American football helmet consists of a polycarbonate or polyethylene exterior shell and an expanded polystyrene (EPS) interior liner to absorb energy transfer to the head [1]. However, with an increase in thickness of these materials, the resulting geometry of the helmet may convey an increased risk of rotational acceleration to the head at varying impact locations to the helmet [1]. Because impacts occur at multiple locations on the head, location and angle of impact may be determining factors of specific brain responses leading to injury [2,3]. Although past studies have examined the dynamic response of football helmeted head impacts at centric and non-centric locations [4], no study has examined how much the helmet's geometric design influences the reduction of impact energy at horizontal impact offsets. Determining the magnitude at which helmets reduce horizontal impact offsets may refine how helmet designers modify the material thickness of a football helmet. The objective of this study was to measure the percent reduction of dynamic response; peak linear acceleration and peak rotational acceleration between a helmeted and non-helmeted Hybrid III head at various horizontal impact offsets from front center of gravity (CG) and side CG.

METHODS

Collisions: A linear impactor was used to impact a bare 50th percentile Hybrid III male head form and helmeted head form (standard American Football Helmet). The impactor arm was capped with a modular elastomer programmer pad (MEP). The bare and helmeted head form was impacted at 5.5 m/s. Each condition was impacted at the following location offsets:

Front offset impact locations in inches (“): Front CG, +1’’ horizontal offset from front CG and + 2” horizontal offset from front CG

Side offset impact locations (+ forward & - rear) in inches (“)*:* +3” offset from side CG, +1.5” offset from side CG, side CG, -1.5” offset from side CG and -3” from side CG.

Nine single axis Endevco 7264C-2KTZ-2-300 accelerometers are imbedded within the Hybrid III head form and (Endevco, San Juan Capistrano, CA, USA) were sampled at 20 kHz and filtered using the SAE J211 class 1000 protocol. The accelerometer signals were processed and filtered low-pass by TDAS software to obtain peak linear and rotational acceleration variables.

RESULTS AND DISCUSSION

Using an ANOVA and post hoc Tuckey analysis, there was a significant difference in percent reduction for linear and rotational acceleration for front CG and +2” ($p<0.05$) (Figure 1). The side CG and side +3” had significantly higher and lower percent reductions for linear and rotational acceleration compared to the other side offset locations respectively ($p<0.05$). These findings report an overall decrease in percent reduction of dynamic response as impacts deviated from the CG. As the magnitude of linear and rotational acceleration decreased with lateral impact offsets in the bare conditions, the helmet conditions produced consistent magnitude responses regardless of the horizontal impact offset.

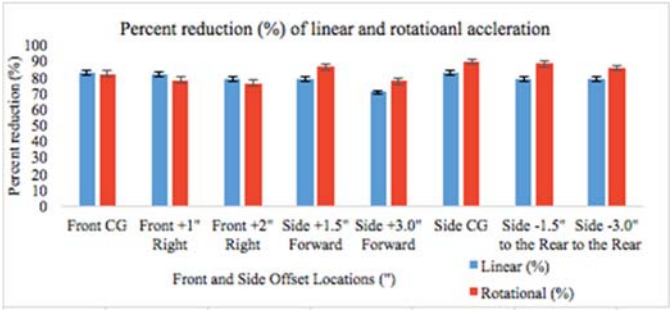

Figure 1: Percent reduction (%) between bare and helmeted impacts at front and side offset locations

This explains for the percent reductions depicted in Figure 1. The helmet's round shell and consistent liner material throughout it absorbs the impact and distributes the energy over a greater area [1]. The consistent materials such as the shell and liner thickness structuring the whole helmet may explain for the helmet's consistent magnitude response across the horizontal offsets. Bare conditions have less contact with horizontal impact offsets, therefore, they experience less absorption and dispersing of the impact energy across the horizontal offsets [5]. Based on these findings, helmet designers should refine the geometric shape of a helmet to accommodate energy absorption at impact offsets.

CONCLUSIONS

The percent at which the football helmet reduced dynamic response decreased with horizontal impact offsets from CG. Therefore, the geometric thickness and shape of a helmet may not appropriately account for decreasing energy transfer at horizontal impact offsets. Future research should investigate how the of the design of a football helmet responds to vertical impact offsets. Additional research should also discover methods to optimize the geometric shape and materials that make up football helmets, such as shell and liner material.

P187 - DOES METATARSAL LENGTH AFFECT RUNNING FOOT STRIKE PATTERN?

[1,2] **Morten B Simonsen**, [2]Jan Sørensen, [2]Anders S Jørgensen, [2]Marc B Boesen, [2]Mark de Zee and [2]Uwe G Kersting.

INTRODUCTION

Stress fractures are a common cause of pain in runners, it has been reported that 55% of stress fractures of the foot and ankle occur in the metatarsals [1]. An explanation for this this observation might be found in foot morphology. From a mechanical standpoint, runners with a shortening of the first metatarsal relative to the second will experience a greater load onto the other metatarsals during forefoot contact, which may increase the risk of stress fractures [2]. Therefore, when running barefoot, runners with a shorter first metatarsal might unconsciously prefer heel running, to minimize load on metatarsals. The aim of the present study was to investigate if foot morphology influence running foot strike pattern.

METHODS

Forty healthy recreational runners where recruited for this study (Thirty-two males and eight females and the means ± SD for the group was: Age: 25.6 ± 6.3 year, Height 178.9 ± 6.6 cm and Weight 76.5 ±10.6 kg). Participant's toe length difference was quantified by 3D scanning (Dream GP Inc, Osaka Japan) (Figure 1) measuring the length from heel to the tip of hallux and subtract it from the length from the heel to the digituss pedis II. Protocol: After a 4-minute warmup, participants ran barefoot at a fixed speed of 12 km/h for 2 minutes on a treadmill (Woodway Pro XL, Woodway, USA), the last 15 running cycles where filmed by a high-speed camera (Basler acA2000 – 349km, Basler AG, Germany) with 200 Hz. 2D analyses were performed in Kinovea (V 0.8.24, France). Ankle angle: was determined from three markers placed on the head of first metatarsal, medial malleus and medial tibia at the height of tibia tuberosity. Medial foot strike angle: was determined as the angle between the floor and a line formed by two markers placed on the head of first metatarsal and calcaneus, in a fixed height of 19 mm above the ground.

RESULTS AND DISCUSSION

Results show no correlation between toe length difference and ankle angle r = 0.008, p = 0.97 or toe length difference and medial foot strike angle r = 0.032, p = 0.84. Additional Kruskal Wallis test showed no difference in foot type and ankle angle, p= 0.5 and Medial foot strike angle, p=0.7.

Results from the present study indicate that runners do not use specific foot strike pattern based on toe length difference, as no correlation was found between toe length difference and ankle angle or medial foot strike angle, or difference in groups. The 3D foot scanner can measure a difference of 0.1 mm. However, it is not certain that the difference in toe length reflects the exact difference in metatarsal length. Future studies could use X-ray to determine the exact metatarsal length.

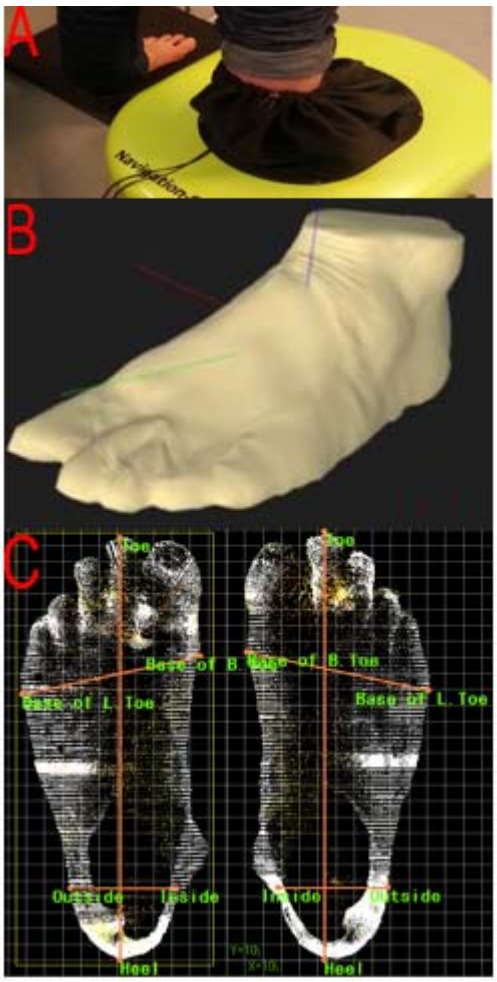

Figure 1: A: Foot in 3D scanner. B 3D file of foot. C: measurement of foot length and metatarsal length.

CONCLUSIONS

The results of this study indicate that there is no relationship between metatarsal length and foot running strike pattern.

P188 - VALIDITY OF WEARABLE TECHNOLOGIES TO MEASURE KICKING BIOMECHANICS

[1] **Stephanie Blair**, [12]Grant Duthie, [13]Sam Robertson and [1]Kevin Ball
[1]Institute of Sport, Exercise and Active Living (ISEAL), Victoria University, VIC, Australia

INTRODUCTION

Wearable technology systems (WTS), such as the Xsens MVN system have emerged, allowing an unrestricted, three-dimensional analysis of performance, in both laboratory and field environments [1]. These systems overcome limitations within traditional biomechanical analysis techniques, allowing for 'real-world' testing scenarios, such as measuring rugby or soccer kicking infront of goal, to improve the ecological validity of biomechanical findings.

WTS have been shown to have acceptable levels of concurrent validly when measuring kick-leg kinematics for punt kicking (CV%=<4.0%; *r*=>0.91) in Australian football, when compared to a motion analysis (MA) system [2]. However, the kick-leg motion for punt-kicking is too dissimilar to running mechanics, requiring separate validation for other kick types that involve greater segmental rotations, such as soccer and rugby place-kicking.

The aim of this study was to examine the concurrent validity of kinematics measured by a WTS against a MA system during place-kicking in the rugby codes and soccer.

METHODS

Following ethical approval, 20 players (Age:21±3yrs; Height:182±6cm; Mass:82±6kg) performed 3 types of rugby (5x20m, 5x40m, 5xMax) or soccer (5x12m, 5x20m, 5xMax) place kicks towards a target, using their preferred foot.

The WTS utilized in this research was the Xsens MVN link system (Xsens, Enschede Netherlands), which is composed of 17 inertial measurement sensors built into a compression suit. Each sensor integrates a tri-axial accelerometer (±160m.s^2), gyroscope (±2000deg.s) and magnetometer (±1.9Gauss). Data fusion was made using the Xsens Kalman filter (XKF), to estimate sensor orientations and calculate full-body kinematics.

Three-dimensional kinematic measurements were captured at 240Hz, with concurrent acquisition of the WTS and a 12-camera MA system (T40-series, Vicon, Oxford, UK). Forty reflective markers where attached to the lower extremities [3] on the outside of the Xsens suit. Data analysis for both systems was conducted in Visual 3D software (C-motion, Inc. Germantown, USA), with all kicks analysed from kick foot toe-off until the instant before ball contact [2,3].

Concurrent validity was assessed using mean and standard deviations (SD), mean bias, Cohen's thresholds (ES) Pearson's correlations (r), typical error of the estimate (CV%) and 90% confidence limits (CL).

RESULTS AND DISCUSSION

Trivial differences between means, good correlations (*r*= ≥0.89) and low measurement errors (CV%= ≤9.8%) were reported for all parameters between the WTS and MA system (**Table 1**). Results were found to be similar between the rugby and soccer place kicks for each parameters.

The low magnitude of measurement error present in the WTS would still allow for true differences between different kicking tasks [4] or populations [5] to be detected. Therefore, the WTS demonstrated acceptable levels of concurrent validity (CV%= ≤9.8%; *r*= ≥0.89) for all parameters, which is consistent with our previous validation of WTS to measure punt-kicking in Australian Football [2].

CONCLUSIONS

Our findings demonstrated acceptable levels of concurrent validity between the WTS and MA system, advocating the use of WTS to measure place kicking kinematics in the rugby codes and soccer.

P189 - SUBJECT-SPECIFIC ANALYSIS ON CRUCIATE LIGAMENTS DURING CYCLING: A THREE DIMENSIONAL FINITE ELEMENT ANALYSIS

INTRODUCTION

Cycling has been thought to be a low-impact activity for the knee joint and has been used in the rehabilitation program for patients with cruciate ligament injuries and reconstruction. The cruciate ligaments primarily maintain the joint stability with keeping the tibia from slipping relative to the femur, so they are commonly injured during sport and physical accidents, especially as anterior cruciate ligament [1-2]. However, there is few study regarding ligament loading during cycling, and the effect of pedaling direction on ligament loading still need more discussion [3]. In rehabilitative cycling, forward pedaling is often used, and only more recently backward pedaling is also proposed. With a validation of finite element analysis, the main target is to give the subject-specific 3D finite element analysis to study the ligament loadings during cycling and discussing the effect of the pedaling direction on the ligament loading.

METHODS

The knee morphological and kinematic data for FE modeling were captured from 5 healthy subjects (males, average age 23). The resistance of the cycling was defined as 20 N-m. Bones and ligaments' geometric models were reconstructed with CT and MRI images respectively. With CT-to-MRI bone contraposition, ligament's attachment positions were labeled on the bone models. Ligaments were constructed and tied to bones. The bone was modeled as rigid and ligaments' material properties were got from a transversely isotropic hyperelastic strain-energy function with in vivo records in KT-2000 arthrometer. The positions and orientations of bones from the 3D fluoroscopy image contraposition were imported to be boundary conditions of bone's position and rotation. At the end, whole FE model was meshed and analyzed in ABAQUS 6.14.

RESULTS AND DISCUSSION

As observed, primary ligament loadings were appeared near the top dead center of a cycle in different pedaling direction. Ligament loadings decline in crank angle from 0° to 180° because of the compressive joint force during the knee extension. During the knee flexion, ligament loadings increase because less compressive force and ligaments will be responsible for constraining the excessive motion of the knee joint.

In cruciate ligaments, the load of ACL near crank angle 90° and 335° were larger in forward pedaling; the load of PCL near crank angle 225° was larger in forward pedaling, but they were less in crank angle 0° to 135°. In collateral ligaments, the MCL and LCL loads were not apparently different in different pedaling direction.

The cruciate ligaments primarily endure the loading and the PCL was endured the largest loading in whole cycling cycle significantly. It is caused by the primarily sagittal plane kinematics during cycling and the larger stiffness of PCL. Comparing the different pedaling direction, ACL loads are larger in forward pedaling commonly, while PCL loads are less in low crank angle and larger in high crank angle in forward pedaling which is caused by different relative joint kinematics.

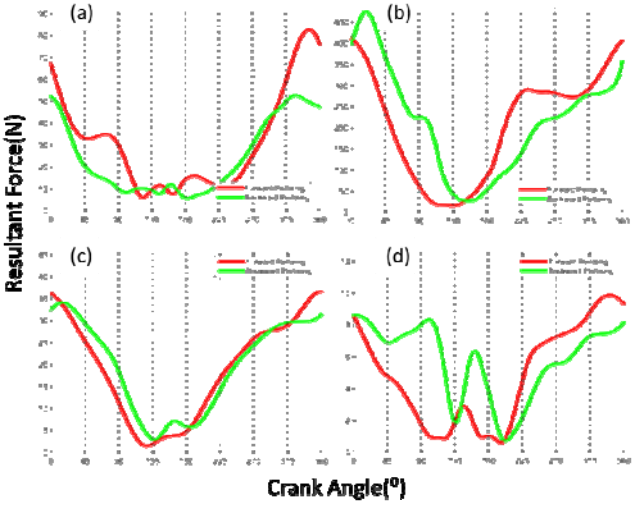

Fig.1 Ligament forces during forward and backward pedaling for (a)ACL (b)PCL (c)MCL (d)LCL. (Red line: forward pedaling, green line: backward pedaling.)

CONCLUSIONS

In conclusion, cycling exercise might not be suitable for patients with PCL injured or reconstruction. Meanwhile, it confirms that the lower load in ACL during cycling exercise and backward pedaling is more suitable for patients of ACL injured or reconstruction.

P190 - THE CORRELATION OF THE PITCHED BALL VELOCITY AND LOWER EXTRMITIES ISOKINETICS STRENGTH IN PROFESSIONAL PITCHERS

[1]**Chung-Nan, Tsai**, [1]Yu-Lin, Chen and [1]Wen-Tzu, Tang[1]
[1]National Taiwan Sport University
Corresponding author email: wentzutang@gmail.com

INTRODUCTION

The purpose of this study was to discuss the correlation of the ball velocity during baseball pitching and the isokinetics of lower extremities including the hips, knees and ankles in Chinese Professional Baseball League (CPBL) baseball pitchers.

METHODS

The subjects were 6 CPBL baseball pitchers aged 25.67±2.06 yrs, height: 1.8±0.02 m, weight: 82.33±4.32 kg and pitched ball velocity: 120.21±7.53 kilometers per hour. This research did in the inside place that set the pitcher's plate height 10 cm from ground and the net distance 5 m from pitcher's plate in pitching direction. The fastest ball velocity is according to one of the three strike balls which ball velocity was fast. Use Biodex System 4 pro isokinetics strength machine to detect the subjects maximum isokinetics strength in angular velocity 60 º/s, 180 º/s, 300 º/s and 360 º/s on hips adduction/ abduction, hips extension/ flexion, knees extension/ flexion and ankles dorsiflexion/ plantarflexion. To eliminate any effect of variation in body size, isokinetics strength data were normalized by dividing it by body mass. All data analyses the pitched ball velocity and lower extremities isokinetics strength by SPSS 12.0 for windows system with Pearson product-moment correlation.

RESULTS AND DISCUSSION

The results showed that the maximum isokinetics strength of pivot leg hip adduction in angular velocity 180 º/s, 300 º/s, 360 º/s (r=.815, r=.813 & r=878; p<.05), pivot leg hip abduction in angular velocity 180 º/s, 300 º/s (r=.955; p<.01, r=.908; p<.05), pivot leg hip flexion in angular velocity in 60 º/s (r=.890; p<.05), pivot leg ankle dorsiflexion in angular velocity 300 º/s (r=.832, p<.05), stride leg hip abduction in angular velocity 60 º/s, 300 º/s, 360 º/s (r=.839, r=.885 & r=.842; p<.05), stride leg knee flexion in angular velocity 300 º/s, 360 º/s (r=.887 & r=.851; p<.05) and the pitched ball velocity have correlation (table.1).

The hip abduction, hip internal rotation and knee extension torques of the pivot leg and the hip adduction torque of the stride leg when it contacted the ground were significantly greater in the high pitched ball velocity groups than in the low pitched ball velocity groups [1]. But in this study the isokinetic strength did not detect hips internal rotation and external rotation, so the study cannot compare with references.

CONCLUSIONS

The current results indicate that high-ball-velocity is characterized by maximum isokinetics strength of lower extremities on hips abduction/ adduction specially. The present study suggests pitchers can increase maximum isokinetics strength of hips abduction and adduction in the both legs, and they can increase the ground reaction force. Also can increase the transferring energy from lower extremities to torso and pitching arm during pitching. Thus, the results obtained here indicate that for high ball velocity, lower extremities isokinetics strength during pitching plays an important role in order to increase the rotation and forward motion of the trunk and pitching arm.

INTRODUCTION

Badminton is a type of racket sport that has been one of the most popular sports in the world. Mastery of the overhead stroke is the most fundamental requirement to be a skilled players. Overhead movement is traditionally divided into four phases. They are the wind up, cocking, acceleration and the deceleration phase. Successful and efficient overhead stroke requires excellent upper extremity coordination as well as postural control ability.

Previous studies related to the overhead movement focused on baseball pitching and tennis serving. There are few quantitative analyses to characterize the muscle activation patterns of the upper extremity as well as the postural control properties of the badminton players. The purpose of this study was to investigate the differences of the reaction time, activation sequence of upper extremity muscles and the postural control between experienced and inexperienced badminton players performing the overhead stroke movements.

METHODS

Thirty young healthy subjects were recruited in the study. They were divided into two groups, i.e. the experienced (15 male from the team of university, 7.1±2.6 years of experience, 20.6±1.8 years old) and inexperienced (15 male without any experience of badminton, 21.6±1.9 years old) group. All of them were right hand dominant.

A 3-axis accelerometer (ADXL377, Analog Devices) was embedded in the badminton ball to detect the hitting event. An 8-channel surface electromyography (Trigno Wireless System, Delsys) was used to measure the activations of the upper extremity muscles (infraspinatus: IS, upper trapezius: UT, middle deltoid: MD, pectoralis major: PM, biceps brachii: BB, triceps brachii: TB, wrist flexor: WF, wrist extensor: WE). Two force-plates (Kistler 9260AA6, and Bertec 9090-15) were used to record the trajectory of the center of pressure (COP) during the initial movement and overhead stroke.

Subjects were asked to stand on the first force-plate initially in preparation to catch the shuttlecock. Upon receiving a LED light signal, the subject ran to the second force-plate as soon as possible in the right-backward direction 3 meters away and hit the shuttlecock overhead. It was to simulate the overhead stroke during the game while moving from the center of the field to the right-back corner. They were allowed to practice several times and ten best trials were recorded. Four variables were analyzed including the reaction time (the time from the light onset to that of an initial COP movement), onset of the EMG burst before hitting, and the velocity and sway area of the COP. Independent t-test was used and significance was set at $p<0.05$.

RESULTS AND DISCUSSION

The reaction time in the experienced group (132.7±25.4 ms) was significantly shorter than that in the inexperienced group (183.6±27.6 ms). The firing sequence of upper extremity muscles was not significantly different in both groups (Figure 1), while the onset of activations were earlier in the inexperienced group as follows: IS (583.9±65.3 ms and 645.6±77.8 ms in experienced and inexperienced group respectively), UT (655.7±222.1 ms and 689.2±117.4 ms), MD (593.4±188.6 ms and 678.5±120.7 ms), PM (332.7±150.1 ms and 410.0±134.3 ms), BB (539.1±191.9 ms and 604.9±121.6 ms), TB (170.8±97.4 ms and 251.5±133.4 ms), WF (118.7±104.9 ms and 228.5±93.4 ms), and WE (545.1±174.2 ms and 659.3±170.9 ms).

The velocities of COP from the two force plates were all greater in the experienced group (1287.4±703.1 mm/s and 1922.1±862.3 mm/s) than in the inexperienced group (1035.2±401.3 mm/s and 1824.6±990.1 mm/s). The sway areas were also smaller in the experienced group (66381.3±3267.1 mm^2 and 238837.7±128057.9 mm^2) than in the inexperienced group (175141.1±162892.3 mm^2 and 265847.6±149316.7 mm^2).

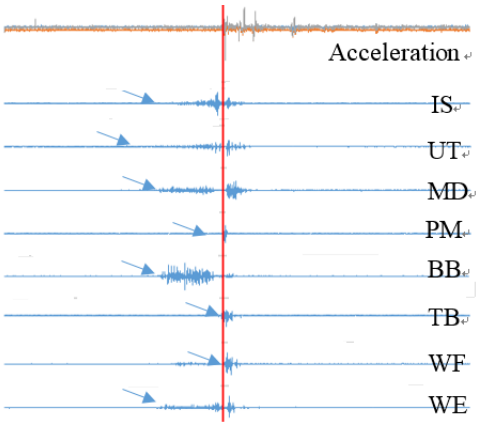

Figure 1: Schematic sequence of the muscle activations during the overhead stroke in the experienced group.

CONCLUSIONS

The performance of the experienced badminton players can be characterized as a faster reaction to the target, more concentrated muscle activations, rapider body movement, and more stable postural control to hit the ball comparing with the inexperienced player. Future studies are warranted to explore if the training programs aiming at improving the specific abilities would help to ameliorate the performance in badminton.

INTRODUCTION

Golf is emphasized on coordination and stability of the movement in order to have a good performance. The lower limbs play a very important role in the performance of the down swing during impact. Lower limb mobility affect the transmission of lower limb momentum, thus affecting the performance of golf speed and distance. The first movement of Functional Movement Screen (FMS^{TM}) is Deep Squat which assesses mobility and stability of the hips, knees and ankles. Many sports events require basic components of the deep squat. The deep squat is a movement that challenges total body mechanics and neuromuscular control when performed properly (3). The FMS^{TM} deep squat movement requirement for the full score including: 1. Upper torso is parallel with tibia or toward vertical 2. Femur is below horizontal 3. Knees aligned over feet 4. Dowel aligned over feet (4). The compensation shown in the movement would increase the injury risk, however, it did not show if it will reduce the performance. Therefore, the purpose of this study to compare FMS deep squat between compensation group and control group to exam the effect on the golf swing speed performance.

METHODS

Eighteen National Taiwan Sport University Division 1 man's golf team golfers. All of them are top amateur player in Taiwan. Each subject was actually hit with ten balls using a driver. Swing performance data were collected by the Golf Achiever Infra golf simulator. The purpose of the report by FMS^{TM} first movement (Deep Squat) divided into two groups. The Control group (CG) is made up of players without compensation. The Compensation group (CPG) is composed of compensated action players. Comparing the difference in the club speed, driving distance and ball speed between the two groups in the golf swing. Scoring criteria and guidelines follow Verbal Instructions for the Functional Movement Screen by G. Cook at 2006.

RESULTS AND DISCUSSION

Ball speed average in the following Figure 1. We found that CG average slightly better than CPG. We can found that driving distance and club speed were not significantly, but ball speed was significantly shown on Table 1. It represents the compensation movement may influence ball speed but did not influence club head speed. It may suggest that players may still can swing a good club head speed with compensation movement. However, the compensation movement may decrease the impact quality to affect ball speed performance. The further study is still need for continued to confirm. The distance did not show the difference between groups and it may due to the launch angle of hitting, which it should be examined further as well. Besides, the ratio of ball speed to club head speed present smash factor and related to the amount of energy transfer from the club head to the golf ball. Therefore the result show the CPG would decrease the energy transfer quality. Furthermore, Titlist Performance Institute (TPI) the swing performance center identified golfers who could not perform the deep squat showed 67% with early hip extension.

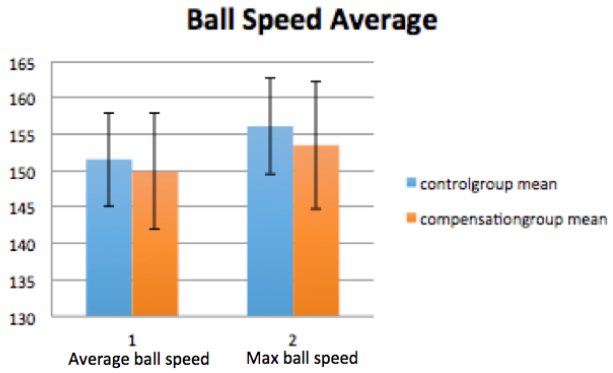

Figure 1: The mean and standard deviation of ball speed.

Table 1. Golf speed performace comparsion between control group (CG) and compensation group (CPG)

		MEAN	STD	*P* value
Total Driving Distance	CG	260.2	16.2	0.097
	CPG	255.9	18.1	
Total Club Head Speed	CG	107.4	4.4	0.085
	CPG	106.2	5.5	
Total Ball Speed	CG	152.3	6.7	0.031*
	CPG	149.9	7.9	

CONCLUSIONS

In this experiment, CPG had tendency in reduced ball speed and smash factor and it may due to energy transfer and hip improper extension, but it need further study to understand detail mechanism. In this study, the limited number of subjects may not be able to make consistent conclusion, more subjects need to be recruited to conclude further. Our study suggests that the training should provide to help compensation movement correction in order to have better golf swing mechanics and energy transfer efficiency.

P193 - THE USE OF A 3D ACCELEROMETER TO QUANTIFY SUBJECT-SPECIFIC 'TYPICAL' AND 'ATYPICAL' RUNNING GAIT PATTERNS

[1]**Christian Clermont,** [1]Lauren Benson, [1,3]Sean Osis, [1]Dylan Kobsar, & [1,2,3]Reed Ferber

INTRODUCTION

Determining a runner's individual 'typical' running pattern can provide an objective method to monitor and alert the runner of 'atypical' changes in their gait that may be related to injury and/or overtraining. With their portable nature, affordable cost, and recent improvements in accuracy, sensitivity, and computing power, 3D accelerometer based devices have become a popular tool in the field of gait analysis and running biomechanics [1,2]. Research has shown that 3D accelerometers can accurately detect changes in running patterns under experimental conditions [3,4]. However, a major limitation with this research is that individual running data were aggregated to create "average" running patterns for a group of runners, which may not identify unique characteristics of an individual runner [5]. Therefore, the objectives of this study were to (1) identify 'typical' running patterns for each individual runner using 3D accelerometer data, and (2) determine whether 'atypical' running gait patterns, as a result of different conditions, can be detected using anomaly detection.

METHODS

A single 3D accelerometer (Shimmer3 GSR+® ± 8g, Shimmer Inc., Dublin, IE) sampling at 201.03 Hz was securely mounted with semi-rigid elastic straps to the lower back of 16 healthy recreational runners (11 Males; Age = 30.81 ± 11.97; Running Experience = 4.78 ± 3.72 years). Participants completed one initial 5-minute run and four 60-second test conditions on a treadmill. The initial 5-minute run was conducted at the runner's preferred speed, and was used to define each runner's 'typical' running gait pattern. The four 60-second test conditions were then performed in a randomized order: (1) preferred speed, (2) preferred speed with a neoprene knee brace (McDavid Level 1 Elastic Knee Sleeve, Minnetoka, MN), (3) 25% faster than preferred speed, and (4) 25% slower than preferred.

Data processing was performed using customized MATLAB 8.3 software (The Mathworks Inc., Natick, MA, USA). Raw 3D acceleration data were filtered using a zero-lag 4th order low-pass Butterworth filter with a cut-off frequency of 25 Hz. The 3D acceleration waveforms were then separated into individual steps using a peak detection algorithm, and each waveform was normalized to 100 points. Next, bilateral mediolateral, anteroposterior, and vertical acceleration waveforms were combined into one vector for each stride (*m*), which created an *m*-by-600 matrix for each runner. A one-class support vector machine (SVM) was used to identify each runner's 'typical' gait pattern based on the *m*-by-600 matrix based on the 5-minute initial run. The four test conditions were then examined to determine the percentage of strides that fell outside of this 'typical' pattern and were thereby deemed atypical ('anomalous') strides for each runner. A repeated-measures ANOVA ($p < .05$) was used to determine if the percentage of anomalous strides was significantly different between the different conditions.

RESULTS AND DISCUSSION

The percentage of 'atypical' strides compared against the 'typical' training set was significantly affected by the running condition, $F(3,5) = 19.16$, $p < .001$. Further p*ost hoc* analyses revealed that the percentage of 'atypical' strides was significantly higher in slow and fast conditions compared to the 'preferred speed' test condition ($p < 0.05$); however, although there were more 'atypical' strides in the 'preferred speed with knee brace' compared to the 'preferred speed no brace' conditions, this differences was not significant ($p > .05$) (see Figure 1).

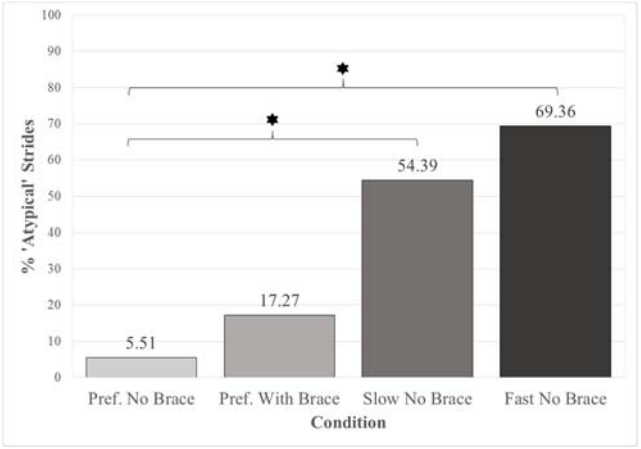

Figure 1: Percentage of Strides defined as 'Atypical' by the One-Class SVM.

CONCLUSIONS

We were able to use 3D acceleration data and a one-class SVM to accurately identify subject-specific 'typical' and 'atypical' running gait patterns under different speed conditions. Specifically, our method was able to detect significant differences in the percentage of 'atypical' strides due to changes in speed (+25% and -25%). However, we did not find a significant difference in 'atypical' strides when the knee brace was introduced. Further research should apply similar methods but in other conditions to continue in the development of a way to provide runners with valuable information as to whether changes in running gait patterns have changed as a result of injury and/or overtraining.

P194 - THE EFFECT OF RUNNING STRIDE FREQUENCY ON LOWER LIMB MUSCLE ACTIVATION

[1] **Mark J Connick** and [2] Francois-Xavier Li
[1]University of Queensland

Corresponding author email: m.connick@uq.edu.au

INTRODUCTION

Running is a popular sporting and recreational activity in which the body undergoes repetitive, high impact loads that can be twice the loads observed in walking [1]. Repetitive loading of the knee joint can increase the likelihood of overuse injuries such as Patellofemoral pain which is the most widespread pathology in runners [2]. While knee loading in running can be reduced with increased stride frequency (SF) there is an associated increase in hip muscle loading during the swing phase [3].

Given this reorganization in muscle loading, we hypothesize that higher and lower SFs will be associated with greater changes to proximal leg muscle activation compared to distal leg muscle activation. The aim of this study was to test this hypothesis by quantifying the effects of running SF on biceps femoris (BF), vastus lateralis (VL), gastrocnemius (GAST) and tibialis anterior (TA) muscle activation.

METHODS

Twelve trained runners volunteered to take part. Participants mean (±SD) age(yrs), height(cm), body mass(kg), and personal best 10km time (minutes) were 27.3(7.2), 178.2(6.7), 68.4(7.9), and 34.9(3.9). The study was approved by the university ethics committee and all participants signed an informed consent form. Participants visited the laboratory on two occasions.

Preferred SF was obtained in visit 1 using 3D kinematic data (Vicon, Oxford Metrics Ltd., England) collected at 240Hz during one minute of running at 13km/h [4]. In the second visit, participants performed 3x5-minutes of running at 13km/h adopting three different SFs. The SFs for these bouts were timed using a digital metronome (NCH Software, USA) which was tuned to a) the preferred SF from visit 1, and b) ±8% of preferred SF. Bout order was randomised with 4 minutes recovery. Electromyography (EMG) data were collected for 30 seconds during each bout.

EMG data were recorded using a Delsys Myomonitor III (Delsys Inc., USA) at 1000Hz. Electrodes were placed over BF, VL, GAST and TA of the right leg. Mean amplitude values (MAVs) were calculated for each muscle for the first and second half of the gait cycle then normalised to the maximum recorded value. ANOVA with repeated measures were used to test for effects of SF on BF, VL, GAST and TA MAVs (SPSS V.20, IBM Corporation, USA). Effect size was estimated using Cohen's d. Levels of significance were set to p=0.05.

RESULTS AND DISCUSSION

Significant effects of SF were found in BF and VL muscles during the first and second half of the gait cycle ($p<0.05$, d=0.54–1.15) (Figure 1). All effects of SF on GAST or TA muscles were non-significant and small ($p>0.05$; d=0.07-0.33). In the first half of the gait cycle BF activation decreased by 5.3% (d=0.81) at the greatest SF and increased by 8.8% (d=0.93) at the smallest SF compared to the preferred SF (Figure 1A). Similarly, VL activation decreased by 3.5% (d=0.65) at the greatest SF and increased by 4.8% (d=0.87) at the smallest SF (Figure 1C). In the second half of the gait cycle BF activation increased by 5.3% (d=0.83) at the greatest SF and decreased by 7.1% (d=1.15) at the smallest SF (Figure 1B). In addition VL activation significantly increased by 2.2% (d=0.54) at the greatest SF and decreased by 2.1% (d=0.45) at the smallest SF, although the latter was not significant (Figure 1D).

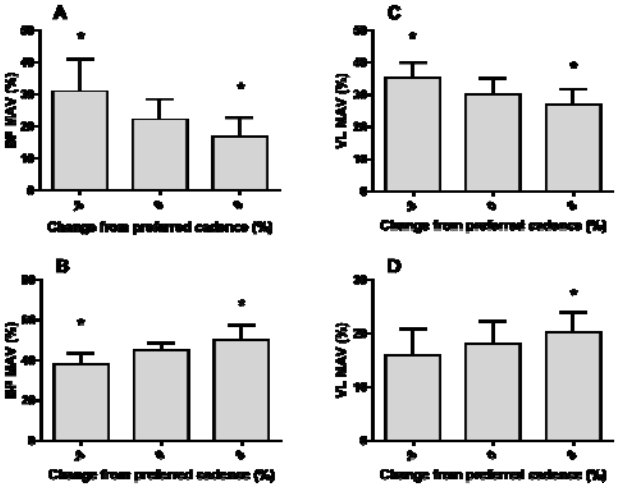

Figure 1: A and B show MAVs for BF during the first (A) and the second half (B) of the gait. C and D show MAVs for VL during the first (C) and the second half (D) of the gait cycle. * indicates a significant difference from preferred SF.

CONCLUSIONS

The results show that one of the neuromuscular adaptations to altered SF during treadmill running is an associated change in the magnitude of BF and VL muscle activation – the most proximal leg muscles tested in this study. This indicates that BF and VL play a role in the regulation of preferred SF, possibly in order to balance the need to regulate angular velocities in the swing phase against the requirement to regulate braking forces during stance.

P195 - ANALYSIS OF CHANGES IN JOINT TORQUE IN RESPONSE TO ALTERATIONS IN GEOMETRICAL CONDITIONS

[1,2] **Kazuo Uchida**, [1]Kazunori Hase

INTRODUCTION

In the field of biomechanics, human movement is often analyzed in relation to the motion used in sports, such as golf and cycling [1,2]. However, it would be useful for sports coaches if a reliable motion prediction method could be established for situations where the geometric and/or inertial features of the tool used in analysis are changed. For example, if it were possible to predict how the torque or muscular tension changes when the position of the bicycle saddle or handlebars is changed, it would be possible to determine a superior position for a cyclist to adopt to achieve a higher performance. This prediction method could also consider the skill characteristics of individuals. For example, as joint torque during pedaling motion generally varies with competitive level and the pedaling habits of individuals, there are inevitable changes in torque due to alterations in the cyclist's position and that this varies between individuals. To date, limited studies have been conducted on such personal differences using a quantitative approach based on biomechanics.

METHODS

Joint torque is described as

$$\boldsymbol{\tau}(h) = \boldsymbol{J}(h)\boldsymbol{f}_{pedal}(h) + \boldsymbol{K}(h) \qquad (1)$$

where h is change of saddle height measured from a reference position; $\boldsymbol{\tau}$ is joint torque, which is an assumed function of h; $\boldsymbol{J}$ is Jacobian; $\boldsymbol{f}_{pedal}$ is the reaction force from the pedal; and $\boldsymbol{K}$ is a kinematics term. To investigate the joint torque response to h, Equation (1) is partially differentiated with respect to h as

$$\left.\frac{\partial \boldsymbol{\tau}}{\partial h}\right|_{h=0} \cong \left(\frac{\partial \boldsymbol{J}(0)}{\partial h}\right)\boldsymbol{f}_{pedal}(0) + \boldsymbol{J}(0)\left(\frac{\partial \boldsymbol{f}_{pedal}(h)}{\partial h}\right) + \frac{\partial \boldsymbol{K}(0)}{\partial h} \qquad .(2)$$

The first term denotes the torque required to keep the pedal reaction force the same as that at the reference position ("Component 1"); the term $\boldsymbol{f}_{pedal}(0)$ shows the reaction force distribution at the reference position and the unique pedaling characteristic of the individual; the second term shows the torque change component when the pedal reaction force is changed, assuming that the same geometry as that of the reference position is maintained ("Component 2"); and the third term is the inertia term ("Component 3")

To investigate the contribution of each term to torque change, a pedaling experiment was performed on 18 healthy cyclists.

RESULTS AND DISCUSSION

A significant linear relationship was confirmed between h and joint torque. Accordingly, the decision to use partial differentiation with respect to h shown in Equation (2) is justified. Figure 1 shows the change in the knee joint torque change rate to h and its components. It is evident that Component 1 is dominant in the case of the knee joint, and this trend is nearly the same regardless of the competitive level of the subjects. The contribution of Component 1 is also dominant for the hip joint, which means that the $\boldsymbol{f}_{pedal}(\boldsymbol{0})$ term in Equation (2) is still functional, even when h is changed. The term $\boldsymbol{f}_{pedal}(\boldsymbol{0})$ shows the reaction force distribution at the reference position, but it also shows the unique pedaling characteristic of the individual, therefore, personal characteristics affect the joint torque change rate, even when h is changed.

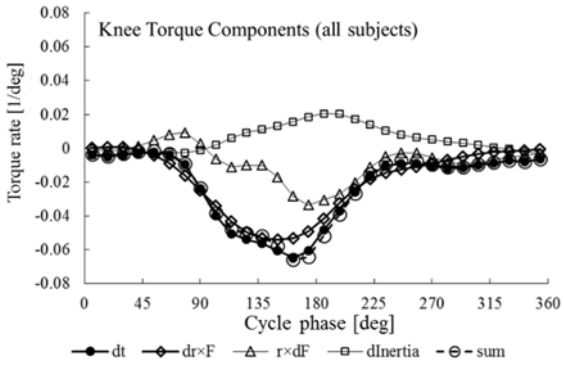

Figure 1: Change rate of knee joint torque and its components.

CONCLUSIONS

This study analyzes joint torque change in cyclists during pedaling motion when geometrical conditions are changed, and the following conclusions are obtained.

1) A method for decomposing the rate of torque change into causal factors is proposed. Decomposition is performed to identify Component 1, which is forced to change in accordance with geometrical change; Component 2, which reflects control; and Component 3, which reflects the change in inertial force.

2) It is found that the contribution of Component 1 is large for the hip and knee joints.

3) This method provides useful information for joint torque prediction and for identifying proper human motor task models.

P196 - ALTERATIONS IN PRESSURE DISTRIBUTION DURING AGILITY ACTIVITIES IN WHEELCHAIR RUGBY

[1]David S Haydon, [1, 2]Amy Lewis, [3]Ross A Pinder, [1]William S P Robertson, and [1]Paul N Grimshaw
[1] School of Mechanical Engineering, University of Adelaide
[2]Australian Institute of Sport, Canberra
[3]Australian Paralympic Committee

INTRODUCTION

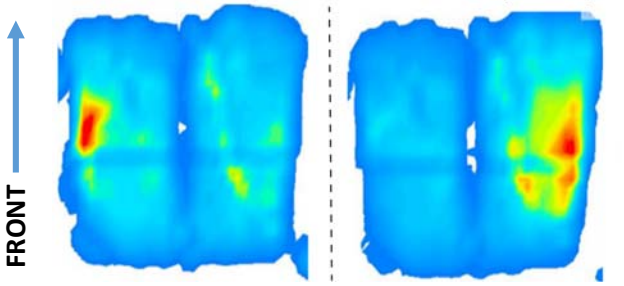
Quantitative assessment of motion in wheelchair court sports has recently begun receiving greater attention [1, 2]. This includes linear and rotational acceleration, both of which are key propulsion parameters for performance in sports such as wheelchair rugby (WCR) [2]. The ability to change direction quickly is crucial, and is dependent on athlete impairment, particularly hand and trunk function [3]. Improving this acceleration would enable athletes to more quickly manoeuvre around the court, increasing their opportunities both for scoring and preventing opponents from scoring. Understanding pressure distribution within the chair may allow athletes to improve their turning capabilities; however, to date there have been no investigations into how the pressure distribution changes during on-court performance. Here, we aimed to provide an initial exploratory assessment of a method to measure pressure distribution using a common agility test in WCR.

METHOD

An elite, experienced 3.0-point WCR player completed two Illinois agility tests while a pressure mat (XSENSOR LX100; Calgary, Alberta, Canada) monitored peak pressure and contact area at 4Hz, using Foresite SS software (version 1.0.16.20481). The player was experienced at the test as it formulates a regular part of their training program. The thin (6mm) pressure mat was placed on the seat ensuring the athlete perceived no changes to seating conditions or performance. Prior to data collection, the mat was placed flat, such that no artefacts due to crinkling were evident during initial settling time.

RESULTS AND DISCUSSION

Figure 1 shows an example of the peak pressure distributions during left (a) and right (b) turns; where it is shown that the athlete shifts pressure to the direction of the turn, shown by the increased region of high pressure (red). Peak pressure increased for turns in both directions compared with a stationary measure taken at the start of the trial. For the left turn, a peak pressure of 22.14kPa was reported (13% increase), while the right turn produced 25.61kPa (30% increase), compared with 19.57kPa for the stationary measure. In addition, the contact area increased by 3% and 5% for left (0.1279m^2) and right (0.1313m^2) turns respectively, compared with the stationary measure (0.1247m^2). The greater increase in peak pressure and contact area for the right turn indicate that it was likely sharper than the left turn, with the athlete able to adjust their pressure distribution for different turning requirements. This is reflective of the path of the athlete during the agility test, where the beginning and end of the weave section were performed using right turns and hence greater wheelchair rotation occurred. The ability to discern differences in contact area and pressure for left and right turns of equal size, may assist in chair design or strength and conditioning programs to minimise any undesirable athlete asymmetry.



(a) Left turn (b) Right turn

Figure 1: Peak pressure distribution during left and right turns, where red represents regions of high pressure.

While it was possible to view key performance points (e.g., left and right turns during an agility test), for pressure mapping to be a more effective assessment tool, systems with higher recording frequency and improved numerical analysis are required. This would include a pressure value for each sensor, allowing variables such as the centre of pressure to be determined. These measures would allow transient analyses of pressure within a stroke for both linear and agility motions, or following seating interventions, than currently available. While this case-study provided some initial insights into pressure distribution, trunk function of a high-point player is significantly greater than a large proportion of WCR players. Further work is needed to understand the effects of small pressure changes on performance, as well as focusing on a greater range of trunk impairments.

CONCLUSION

Pressure distribution of a single high-point player completing an agility test was investigated, with clear changes in pressure evident through qualitative and quantitative measures. Further work and improved equipment is required to provide more detailed assessment of pressure distribution during wheelchair court sports.

P198 - A NEW METHOD FOR TRACKING AND CALCULATING THE PATH OF A FOOTBALL

Jamie Hetherington, Duncan Blair, John Whitting, Shi Zhou and Rosanne Coutts
Southern Cross University
Corresponding author email: jamie.hetherington@scu.edu.au

INTRODUCTION

Ball tracking is a critical aspect in 3D motion analysis for certain sports [1, 2]. In the sport of football (soccer), methods have been developed to track and calculate the trajectory and rotation of a ball in the analysis of free kicks [3, 4]. These methods tracked a moving ball in the air analysing various ball flight characteristics at specific points of interest. However most were over small temporal and spatial scales and used a small number of markers (<5) to track the ball. There is a paucity of literature on tracking and calculating the path of a ball rolling on the ground using 3D motion analysis in sport. The previously developed methods were not considered suitable for tracking the trajectory of a rolling ball through 3D space due to issues such as frequent occlusion of most ball markers, an insufficient number of markers tracked per frame and having to manually label all ball markers in each frame. Therefore this pilot study set out to develop a new method based on using a point cloud on the time series data to address previous limitations and contribute novel solutions to the problem.

METHODS

20 Vicon cameras (Vicon Motion Systems, Oxford) were used to track a FIFA approved football (2016 Euro replica ball, ADIDAS) and a participant who interacted with the ball using the University of Western Australia (UWA) lower body and torso model [5], at a sampling rate of 250 Hz. Twelve pieces of retroreflective tape (2 cm^2) were placed on the surface of the ball. A custom MATLAB (Mathworks, Natick, Massachusetts, USA) script was used to extract the ball marker data in order to calculate the path of the ball and then write that path back to the C3D file in a new marker channel. This enabled the path to be treated as a new marker, visible in Vicon Nexus and Vicon Bodybuilder software.

Due to the methodological challenges of tracking a rolling ball it was not possible to label each of the ball markers in post capture data processing as the occlusion of most of the ball markers in any frame caused the recorded ball markers to be fragmented over a number of marker channels in the C3D file and only show the “top” few markers of the ball in any frame. The trial C3D file contained both the data from the markers on the participant and the markers on the ball. This required processing of the whole file as a point cloud which enabled the identification and separation of the ball marker data from the participant data. The ball path calculation was based on the following assumptions (i) the dimension of the ball being relatively constant (ii) the ball marker data and participant data clustering together consistently enabling distinct marker paths to be followed and (iii) the majority of the participant body markers being generally visible throughout the entire trial. The solution consisted of following each of the markers over time to create a path for each marker. The algorithm was applied to look forwards and backwards from specific key frames to deal with the frequent occlusion. Following each marker forward and backward until all the available path was discovered enabled the collection of all the paths within the point cloud. Where marker path segments were small and scattered far away from the known ball diameter or were single frames, allowed them to be discarded as ghost markers/noise. The algorithm using the above mentioned assumptions was then able to remove the participant body data to leave only the valid ball markers. A geometric solution and an averaging solution were developed to calculate the path of the ball from the identified ball data. The geometric solution used a sphere fitting algorithm which required a minimum of four valid markers per frame. This was used to fit a sphere to the valid data points in a frame and calculate the centre of the sphere, which represented the path of the ball. The averaging solution was used to average the positions of all the valid markers in a frame and then apply a smoothing function to clean the path of the ball over time.

RESULTS AND DISCUSSION

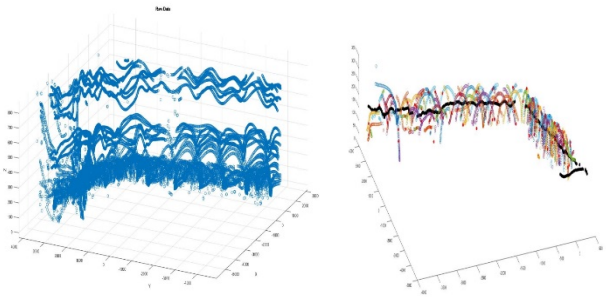

Figure 1: (Left) Point cloud of raw data paths of participant and ball markers. (Right) Isolated ball marker data and calculated path in black.

The solution deemed, ‘visually’, to be the most appropriate was the marker averaging solution and is depicted in figure 1. This resulted in a robust ball path which was recorded for later analysis. To our knowledge this study is the first to utilise this method for this specific type of task.

CONCLUSIONS

The processing of a C3D file using the point cloud method has advantages over previous methods by eliminating any need to label specific markers as well as using an algorithm to isolate valid ball markers for the calculation of the path. Being able to calculate a ball path and saving this data as a new marker opens up possibilities to analyse player to ball interactions in research using 3D motion analysis.

INTRODUCTION

Sprint canoe is competed over 200-m, 500-m, and 1000-m distance. Theoretically, canoe velocity (V_c) is a product of stroke rate (SR) and displacement per stroke (DPS). However, previous study has not been reported these parameters for junior paddlers. Therefore, the purpose of this study was to clarify the race profile and stroke parameters in the junior paddlers of the 200-m sprint canoeing.

METHODS

We analyzed 40 junior male canoe single (C1) paddlers (Race time: 48.380 ± 2.836 s, ranging from 42.799 to 54.231 s). Also, paddlers were divided into high-level (n=11, Race time: 44.990 ± 1.227s) and low-level (n=11, Race time: 51.945 ± 1.190s) groups according to race time. The race movies were taken at the Japan Canoe Sprint Junior Championship in 2015 in Fujikawaguchiko-machi using three video cameras (Sony Handycam HDR-PJ800, Sony Inc., Tokyo, Japan, and 60fps). Video cameras were positioned on the front of the 25m section of all 9 courses that are all based on the buoy installed in 25m intervals on the course. Video for each kayaker was analyzed frame-by-frame in Apple QuickTime Pro. During the competition, three parts of race course; 0-25m (Initial part), 100-125m (Middle part), and 175m-200m (Final part) were selected for the analysis of parameters such as V_c. V_c was calculated by dividing the each part distance (25m) by the 25m interval times, thus,

$$V_c = 25 / \text{interval times} \quad (1)$$

The SR (strokes/min) was calculated as

$$SR = 60 / (3 \text{ stroke times} / 3 \text{ strokes}) \quad (2)$$

Further, we calculated DPS (m) by

$$DPS = V_c \times (60 / SR) \quad (3)$$

Pearson's correlation coefficients were used to examine the relationships between V_c, SR, and DPS in all paddlers. Further, the two-way repeated ANOVA was performed to examine the effect of different groups and sections on V_c, SR, and DPS. A Bonferroni post hoc multiple comparison test was performed if a significant main effect was observed. In each statistical analysis, the level of significance was set to be $p < 0.05$.

RESULTS AND DISCUSSION

A significant positive correlations were found between V_c and SR (Initial part: r = 0.448, $p < 0.01$, Middle part: r = 0.447, $p < 0.01$, Final part: r = 0.537, $p < .0001$). A significant positive correlation was found between V_c and DPS (Initial part: r = 0.396, $p < 0.05$, Middle part: r = 0.424, $p < 0.01$, Final part: r = 0.309, $p > 0.05$). V_c and SR of initial, middle, and final part was significantly higher in the high-level group ($p < 0.05$). These results of the presents study agrees with past findings that SR was significantly related to kayak velocity in adult kayaker, where higher SR was due to the decrease water phase time [1]. DPS was significantly higher in the high-level group only at the middle part ($p < 0.05$). According to a previous study, SR of international adult kayakers was higher than in the national kayakers [2]. It might be suggested that the difference in canoe performance time differences high- and low-level paddlers can be maintain attributes to SR.

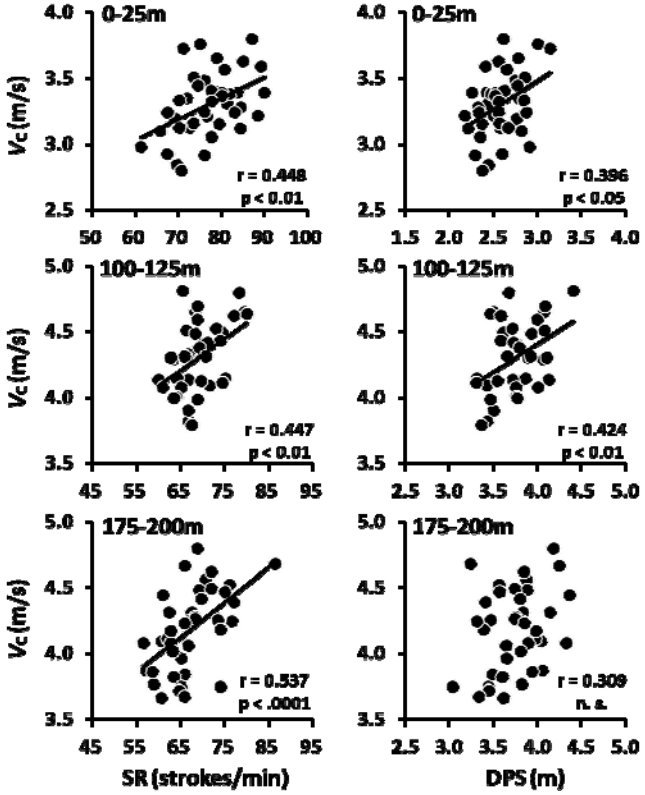

Figure 1: Relationship between canoe velocity (V_c) and stroke rate (SR) or displacement per stroke (DPS) for three parts of race course (Initial part: 0-25m, Middle part: 100-125m, Final part: 175-200m).

CONCLUSIONS

For junior paddlers, key factor to improve the performance in the 200-m sprint canoeing is to increase the stroke rate without loss of the displacement per stroke.

P200 - PRELIMINARY STUDY OF IMMEDIATE EFFECT OF ILIOTIBIAL BAND RELEASING TAPING ON STIFFNESS OF ILIOTIBIAL BAND AND MODIFIED OBER'S TEST

[1]**Chi-An Hsieh**, [1,2]Shwu-Fen Wang, [1,2,3]Huei-Ming Chai

INTRODUCTION

Tightness of the iliotibial band (ITB) is commonly present in marathon runners, leading to abnormal patellar position [1]. Stretching exercises of the ITB is suggested as part of warm-up and cool-down exercises for runners to prevent from its tightness [2]. Clinically, iliotibial band releasing taping (ITBRT) has been employed as an alternative method for releasing a tight ITB and has showed some effects [3]. However, it is unclear whether extensibility of the ITB is really changed after ITBRT.

The shear wave elastography (SWE), a new imaging technology, has been used to measure tissue stiffness [4]. The purpose of this study, therefore, is to examine the efficacy of ITBRT using SWE. Significance of this study provides a new insight into release of ITB.

METHODS

Ten healthy participants (3 females and 7 males) with regular exercise were recruited in this study. Extensibility of the ITB was verified by the modified Ober's test. Two sessions of taping within a 7-day interval, including ITBRT and sham ITBRT separately, were applied to the area over the distal ITB. The stiffness of the ITB was evaluated using SWE and the result of the modified Ober's test was quantified as the angle of hip adduction using a fluid-filled inclinometer.

The participants were asked to lie in the supine position with knee extension for 10 minutes for preconditioning. One of 2 interventions was randomly employed and the other one was performed seven-day later. All outcome variables were measured 3 trials before and after intervention and averaged values were used for statistical analyses.

Demographic data of all participants were analyzed using descriptive statistics. A 2 × 2 analysis of variance with repeated measures was used to examine the relationship between taping condition (ITBRT vs. sham ITBRT) and time (pre- vs. post-intervention) for stiffness of the ITB and hip adduction angle in modified Ober's test.

RESULTS AND DISCUSSION

Comparing pre- and post- ITBRT data, significant improvement was found in stiffness of the ITB (p=0.001) for the ITBRT group, but no significant change for the sham group (p=0.253). However, hip adduction angle in the modified Ober's test remained similar (p=0.370) between two groups.

Taping on the ITB for 1 hour provide a translator force to stretch the ITB, resulting in significant decrease in stiffness after taping. There was no significance on shame group indicates no psychological effect.

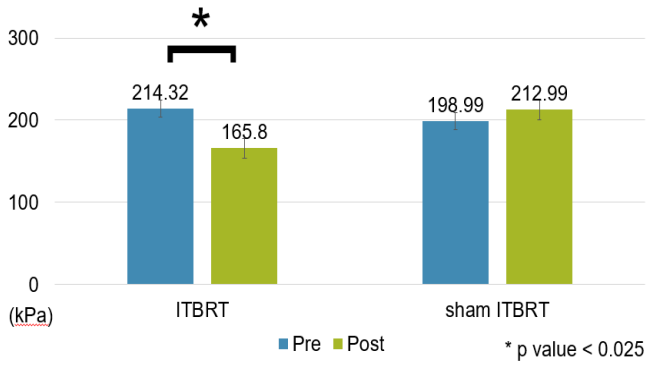

Figure 1: Stiffness after ITBRT and sham ITBRT conditions in all participants. Blue bar represents pre- taping and green bar represents post- taping.

CONCLUSIONS

Results of this study suggest there was satisfying immediate effect due to ITBRT in individuals with regular exercise, indicating significant changes in tissue extensibility. It provides solid evidence in release of ITB using taping. Further studies will direct to examine the effect of taping on individual with tightness of the ITB. in addition, finding needs to be confirm using a big sample size, and ITBRT will have to compared with standard conservative treatment options.

ACKNOWLEDGEMENTS

We would like to thank Professor. Chung-Li Wang and Dr. Che-Yu Li for his support throughout this study and offer the SWE to use. We also thank Yuan-Yuan Wang for her technique assistance.

P201 - THE EFFECT OF TAI CHI EXERCISE ON COUNTERMOVEMENT JUMP OF THE ELDERLY

Chen-Fu Huang, Bo-Jen Ko
National Taiwan Normal University
Corresponding author email: huangchenfu@gmail.com

INTRODUCTION

Muscle weakens with age, making it more difficult for the elderly to engage in daily activities. Tai chi chuan is a form of aerobic exercise that combines self-defense, stretching, and its related movement and intensity can be adjusted for individual learners. Thus, tai chi chuan is a suitable exercise for the elderly. Past studies have shown that tai chi chuan helps delay the functional declines in daily activities involving gait and balance and improves lower extremity muscle strength in the elderly [1,2].

The countermovement jump (CMJ) is a dynamic extremity. This assessment could be used to estimate muscle strength and power performance in older adults. Both components of muscle power, muscle force and contraction velocity can be observed during a maximal CMJ. Many studies have reported that muscle strength of lower limbs could be enhanced through Tai Chi training. However, these studies have largely examined isometric or isokinetic strength of single lower extremity joints. These strength assessments do not address muscle power output during a dynamic, multijoint, weight bearing task such as required in the CMJ. Therefore, the purpose of this study was to investigate biomechanical effects of tai chi chuan on the lower-extremity in the elderly during countermovement jump.

METHODS

Twelve elders with regular Tai Chi exercise experience (tai chi chuan group: age: 71.1 ± 5.6 years old, height: 162.8 ± 6.4 cm, mean weight: 56.7 ± 6.3 kg) and twelve healthy elders (healthy group: age: 69.0 ± 3.8 years old, height: 160.3 ± 5.7 cm, weight: 59.2 ± 6.9 kg) participated in this study. The tai chi chuan group included five men and seven women, and the healthy group included four men and eight women. The tai chi chuan group have practiced the Yang long-form of tai chi chuan that consisted of 108 postures at least five days a week for more than two years, whereas the participants in the healthy group engaged in recreational activities such as walking, jogging, or hiking from time to time.

Ten infrared cameras (Vicon MX13+, 250 Hz) and a force plate (Kistler 9281: 60×40 cm, 1000 Hz) and Visual 3D were used to collect and analyze the kinematic and kinetic parameters. Forty-five retro-reflective markers were attached on the anatomical landmarks according to the plug-in-gait model. Kinematic data were low-pass filtered at 6 Hz using 4th order zero-lag Butterworth filters. Force plate data were low-pass filtered at 50 Hz.

The data are reported as the mean and standard deviation. An independent-samples t-tests was used to compare the effect of tai chi chuan on the performance of a standing vertical jump between the elderly.

Table 1: Biomechanical variables during the counter movement jump.

	Tai chi chuan	Healthy
	M±SD	M±SD
Jump height (m)*	0.13±0.03	0.09±0.03
COM velocity at takeoff(m/s)*	1.72±022	1.40±0.26
Peak hip angular velocity(deg/s)*	-384.94 ±56.41	-331.67 ±62.75
Peak knee moment (N*m/Kg)*	1.16±0.26	0.94±0.22
Peak ankle power (W/Kg)*	24.85±4.66	21.41±5.49
Peak COM Velocity (m/s)*	2.16±0.20	1.86±0.28

Note: * indicates a significant difference ($p < 0.05$).

RESULTS AND DISCUSSION

Table 1 show the tai chi group have significantly greater jump height, body COM velocity at takeoff, peak hip angular velocity, peak knee moment, peak ankle power during the jump than the control group. These findings support our hypothesis that Tai Chi group had greater jump height during air phase.

These results shows that tai chi elderly appears to have better capacity to generate muscle strength and power during countermovement phase. This better jump ability may due to the effect of regular long-term traditional Yang's Tai Chi exercise. The specific movements, such as two-leg deep squat, jumping, and one-leg deep squat are required in 108-forms of Yang's Tai Chi exercise. These movement forms provide an exercise training stimulus for lower limb muscle groups. In this study, those who had regular and Tai Chi exercise may have maintained or even enhanced low extremity joint muscle strength and joint power.

CONCLUSIONS

This study showed that elderly who practice tai chi chuan over the long term squatted in a slower and steadier manner, greater lower extremity muscle and have better greater jump ability. We recommend that the elderly engage in the long-term regular practice of tai chi chuan to improve their lower extremity muscle strength and delay the age-related degeneration of the lower extremity muscles, thereby slowing down the decline in daily activity performance and reducing the risk of fall.

P202 - DYNAMIC IMPACT RESPONSE OF INJURY EVENTS LEADING TO CONCUSSION IN PROFESSIONAL MEN'S RUGBY LEAGUE

[1] **Talia Ignacy,** [2]Andrew Post, [3]Andrew J. Gardner, [4]Grant L. Iverson, and [5]T. Blaine Hoshizaki

INTRODUCTION

Concussions are a problem in competitive sports, whereby participation in contact sports, such as rugby, increases risk of sustaining a head injury. In rugby league, there are between 8.0-17.5 concussions/1000 player hours, representing roughly 10-15% of all injuries [1]. Shoulder, head, and hip are reported to be the most common regions that impact the head and are responsible for the greatest number of concussive injuries in the sport [2]. Research has been conducted in an effort to describe incidence and mechanisms of concussive injury in rugby, however, little is known about the biomechanics of head injury in the sport [3]. To develop effective interventions for reducing the incidence of injury, research must first be targeted at understanding the differences between injury events. Therefore, the purpose of this study was to determine whether there are differences in peak dynamic response between common injury events that lead to concussive injury in professional men's rugby league.

METHODS

297 impact videos from the 2013-2015 seasons of National Rugby League game footage (www.nrl.com) were reviewed of which twenty-seven (27) met inclusion criteria. Three distinct head injury events associated with the most common concussive injuries were recorded and reconstructed in the Neurotrauma Impact Science Laboratory: (1) hip-to-head (n=7), (2) head-to-head (n=9) and (3) shoulder-to-head impacts (n=11). Video analysis using Kinovea software 0.8.20 (open source, Kinovea.org) was used to determine velocity and location of impact from video of actual concussive injuries diagnosed by team doctors. The Hybrid III 50th percentile adult male head form was equipped with nine single-axis Endevco 7264C-2KTZ-2-300 accelerometers (Endevco, San Juan Capistrano, CA) used for all reconstructions to measure three-dimensional motion of the head form during impact [4]. The head form was attached to a sliding table via an unbiased neck form. Head-to-head impacts were reconstructed in this study using a pendulum system [5], while hip and shoulder-to-head impacts were reconstructed using the pneumatic linear impactor [6]. Dynamic response (DR) data were presented in terms of means and standard deviations of peak resultant linear and rotational head accelerations. One-way ANOVAs were used to compare DR between injury events.

RESULTS AND DISCUSSION

There was a significant effect of injury event on peak resultant linear acceleration [$F(2, 78) = 109$, $p < .01$] and peak resultant angular acceleration [$F(2, 78) = 66.9$, $p < .01$] for the three events. Post hoc comparisons using the Tukey HSD test indicated that the mean peak linear head acceleration data for the head-to-head condition (M = 205, SD = 88.2) was significantly higher than the hip-to-head condition (M = 24.7, SD = 12.13) and the shoulder-to-head condition (M = 24.2, SD = 11.84). Post hoc Tukey HSD test indicated that the mean peak angular head acceleration data for the head-to-head condition (M = 15890, SD = 8030) was significantly higher than the hip-to-head (M = 2650, SD = 876) and shoulder-to-head conditions (M = 3276, SD = 1185) (Figure 1). The hip-to-head condition did not significantly differ from the shoulder-to-head condition with respect to linear or angular acceleration.

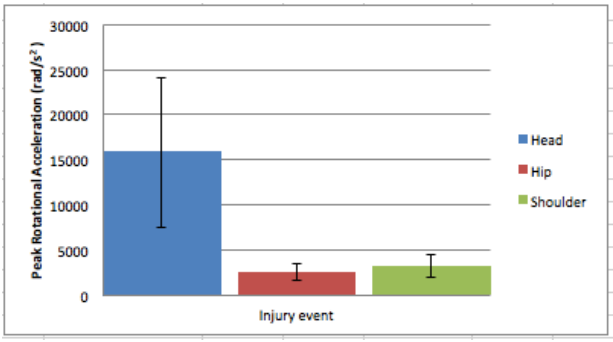

Figure 1: Peak resultant rotational acceleration of head-to-head, hip-to-head and shoulder-to-head injury events.

Each of the common injury events have different combinations of the input variables: mass, compliance, velocity, and location of impact. Head-to-head collisions had the shortest duration event (~3ms) of the three injury events, while the hip and shoulder injury groups are characterized by longer duration (~30ms). While the short duration of the head-to-head event creates a large magnitude response, the long duration of hip and shoulder impacts to the head create a greater relative strain response of the brain tissue. As each of the injury events are created differently, this study reveals that harm reduction interventions should treat each of the injury events as distinct groups. This research has implications for developing protective equipment but also provides a better understanding of differences between the common injury events creating concussion in men's rugby league.

CONCLUSIONS

Better understanding of the biomechanics of injury events and how they relate to risk will help inform decisions about interventions and is a first step in developing strategies to reduce the incidence of concussion in rugby.

P203 - CHANGE IN LOWER LIMB JOINT WORKS DURING TAKE-OFF PHASE IN JUMP MOVEMENT BY WEARING ALPINE SKI BOOTS

[1] **Yu Kashiwagi**, [1]Mari Soma, [1]Yuki Inoue, [1]Tomoya Hirano, [1]Michio Yamagishi, [1]Makoto Takegoshi, [2]Noriko Hakamada and [1]Kazuo Funato
[1]Nippon Sport Science University
[2]Japan institute of sports sciences, Tokyo
Corresponding author email:kashiwagi@nittai.ac.jp

INTRODUCTION

Jump test such as counter movement and squat jump is one of the most important tests in order to evaluate whole body power output even in alpine ski athletes [1]. Jump performance might be mainly ankle joint power output [2]. As in alpine ski, ankle joint movement is fixed by wearing ski boots, effects of ankle joint fixed during take-off in jump performance might be cause by knee and hip joint work compared with normal jump performance [3].

The purposes of the present study were to estimate the contributions of lower extremity joint works by wearing ski boots during take-off phase in jump performance.

METHODS

Thirteen male college alpine skiers (Age; 20.3 ±1.2yrs, BH; 171.1±3.3cm, BW; 74.1±7.7kg,) were participated in this study. We used establish by international ski federation in order to evaluate subject's performance (FIS point : GSL; point 64.6±13.1 and SL;point 89.6±25.8). Subjects performed normal squat jumps (NJ) and squat jump wearing ski boots (BJ). Kinematics and Kinetics data were obtained from motion capture system (Vicon MX20 Camera×8, 200fps) and force plates (Kistler 9287B, 1kHz).Anatomical land-marker were attached 35points (Plug-in gait model) on the skin of the subjects.

Lower extremity (hip, knee, ankle) kinetics data (peak torque:Nm, power:W, work:J) was calculated from the inverse dynamics methods during take-off phase.

All statistics analysis was used by paired t-test performed on selected means to detect significant differences (effective $p<0.05$) between BJ and NJ (JMP ver . 8.0, SAS inc.). The relationship between jump performance and FIS point (alpine ski performance) was analyzed by Pearson's correlation coefficients (effective $p<0.05$).

RESULTS AND DISCUSSION

BJ height was a significantly lower than NJ (BJ:20.1± 3.5cm, VS NJ:36.2±5.1cm, $p<0.001$). BJ and NJ jump height were significantly correlated with GSL FIS point respectively (BJ: $r=0.595$, $p<0.05$, NJ: $r=0.592$, $p<0.05$). Jump tests indicated significantly correlated with assessment for alpine skier performances.

Range of motions in BJ condition was significant restricted compared to NJ condition (Fig.1a). Peak joint torque was not significantly different between BJ and NJ condition (Fig.1b). However, peak ankle joint power in BJ was lower than NJ condition (Fig.1c). Furthermore, peak knee joint power output in BJ condition was greater than NJ condition ($p<0.01$). Ankle joint work in BJ decreased compared with NJ condition. On the other hand, hip joint work significantly larger than NJ condition (Fig.1d). Therefore, contribution of hip joint work on BJ condition might be increased compared with NJ condition (BJ:54. 3±15.7% VS NJ:30.7±10.9%, $p<0.001$). In preliminary research [3], dipping of an ankle elevated work of knee joint, however this study showed different results from it. It was speculated that this difference might be associated with ski boot mass and range of motion by wearing ski boots.

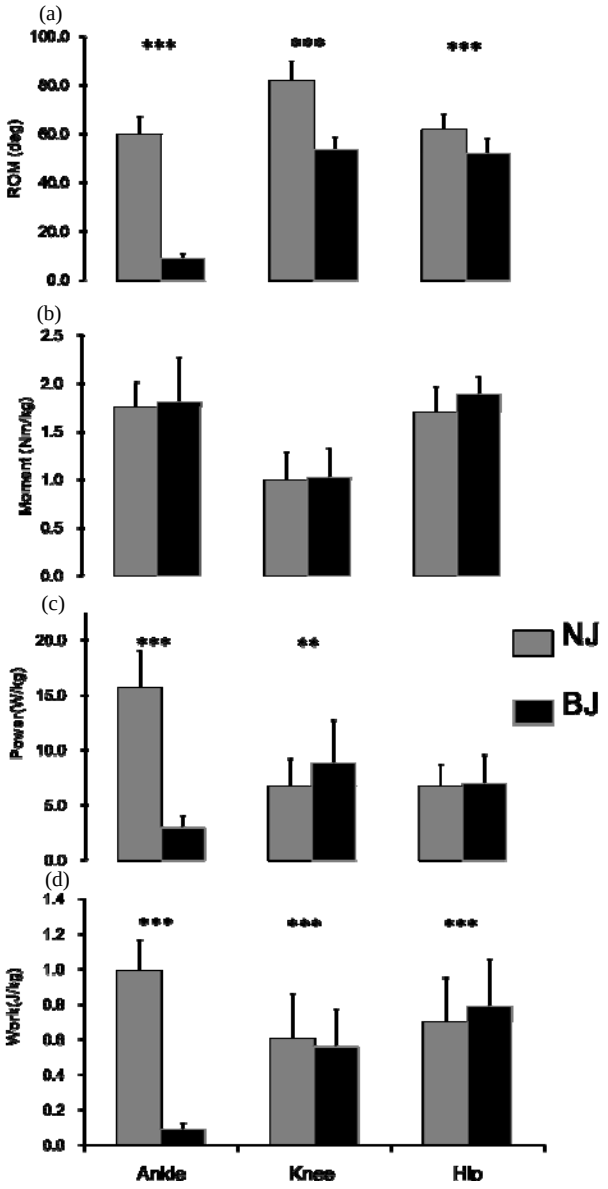

Figure 1: Comparison of kinematics and kinetics data during take-off phase in squat jump between normal jump and ski boots jump conditions. ***: $p<0.001$, **:$p<0.01$

CONCLUSIONS

This study was clearly indicated positive relationship between jump performance with wearing ski boots condition and alpine ski performance (FIS point). It might be suggested that effective ski specific training is recommend for limiting excursion of ankle joint so as to generate greater hip joint work during take-off phase with wearing ski boots .

P204 - THE SOFT FOOT-ARCH SUPPORT INSOLES CAN INCREASE PROPULSIVE FORCE DURING RUNNING

[1] Zong-Rong Chen, [2] Kwantae Kim, [3] Chen-Yi Song, [4] Hsien-Te Peng
[1,2,4] Chinese Culture University
[3] Taipei College of Maritime Technology
Corresponding author email: mczest@hanmail.net

INTRODUCTION

The medial longitudinal arch (MLA) of the foot is a key structure of the foot and plays a crucial role in the transfer of forces through the foot during running. Previous researches have stated that the primary support for the MLA comes from the plantar fascia [4]. Nevertheless, the excessive deformation of MLA cannot provide enough stiffness of the foot to exert sufficient propulsive force [3]. We hypothesize that foot-arch support insoles could decrease excessive deformation of MLA and increase propulsive force during running. The purpose of this study was to examine the effect of hardness of foot-arch support insoles on kinetics for the flatfoot and normal foot during running, respectively.

METHODS

Fifteen subjects with flatfoot (age= 22.2±3.0 years, weight= 75.5±11.3kg, height= 175.2±7.1 cm, BMI= 24.5±2.6 and FND= 9.2±1.1 mm) and fifteen subjects with normal foot (age= 24.9±4.9 years, weight= 71.5±10.5kg, height= 172.9±5.7 cm, BMI= 23.8±3.4 and FND= 4.8±0.6 mm) who were free from lower extremity injuries volunteered to participated in this study. The subjects with flatfoot were grouped according to the functional navicular drop (FND) which was defined as the difference in navicular heights beteen seating and standing performed in a bilateral relaxed calcaneal position being greater than 0.7 mm [2].

Three running trails were performed at self-paced speed in three conditions which were with shoes only (S), with shoes and soft foot-arch support insoles (SS, hardness shore D60; Hard boot, Foodisc Inc., Taipei, Taiwan), and with shoes and hard foot-arch support insoles (HS, hardness shore D65; Proactive, Foodisc Inc., Taipei, Taiwan). One force-platform (Model OR6-5, AMTI, USA) with 1000 Hz sampling rate was located in the middle of a 5-m runway to collect the vertical ground reaction force (GRF). The data were analyzed using MATLAB software. The subjects were rear-foot runners. So the impact peak force (IPF) during initial contact and propulsive peak force (PPF) during take off were analyzed. Loading rate (LR) was defined as the IPF divided by the time from heel strike (GRF > 30 N) to IPF.

Repeated-measures one-way ANOVAs were performed for the flatfoot and normal foot, respectively, to compare the variables among three conditions. The significance was set at α= 0.05.

RESULTS AND DISCUSSION

Table 1 shows the mean ± standard deviation of the variables for the S, SS and HS conditions of the flatfoot and normal foot groups. The flatfoot group showed the significant greater PPF in the SS than that in the S. The normal foot group showed the significant greater IPF in the HS than those in the S and significant greater PPF in the SS and HS than that in the S.

Table 1: Kinetic variables.

	Flatfoot group		
Condition	**S**	**SS**	**HS**
LR (BW/s)	30.9±11.1	29.31±8.4	32.65±11.1
IPF (BW)	1.17±0.28	1.18±0.18	1.20±0.21
PPF (BW)	2.11±0.34	2.20±0.30*	2.20±0.29
	Normal foot group		
Condition	**S**	**SS**	**HS**
LR (BW/s)	37.27±14.73	35.82±11.99	39.78±17.37
IPF (BW)	1.26±0.24	1.37±0.25	1.37±0.26*
PPF (BW)	2.22±0.2	2.30±0.2*	2.32±0.18*

* indicates a significant statistical difference compared to S. $p < 0.05$.

The major finding of this study was that soft foot-arch support insoles can help to increase the propulsive force for people with the flatfoot; both the soft and hard foot-arch support insoles can help to increase the propulsive force for people with the normal foot during running. These may confirmed that the foot-arch support structure of the insoles could reduce the deformation of medial longitudinal arch to provide appropriate stiffness of the foot to exert sufficient propulsive force and forceful push-off during running [1,3].

Nevertheless, we found that there was great impact peak force in hard foot-arch support insoles for people with the normal foot. This may expose them to the risk of the lower extremity injury..

CONCLUSIONS

People with flatfoot and normal foot can improve their running performances using soft foot-arch support insoles. The hard foot-arch support insoles may increase the impact force for people with the normal foot. The soft foot-arch support insoles are recommended for rear-foot runners.

INTRODUCTION

It has been reported that barefoot running may reduce risk factors for running-related injuries by lowering impact force, loading rate, and strides lengths [1]. However, it is unclear if barefoot running is truly ideal for preventing injuries. There are several studies examining the effect of barefoot running on the lower limb, but the running bout was generally very short [2]. Moreover, there are no studies evaluating the acute radiologic changes of the foot and ankle in response to long-distance barefoot running using Magnetic Resonance (MR) Imaging (T2* mapping). T2* mapping is a biochemically sensitive modality, which allows detecting the earlier changes of the articular damage. This case study presents the plantar pressure (pre and post 5km run) and possible acute radiologic changes (pre and post 5km run) of a former professional dancer with no previous history of the ankle and foot injury.

METHODS

A 40-year-old former female dancer (63kg, 167cm, 22.59 kg/m^2), currently involved in recreational sports activities (i.e. yoga, Pilates, and gym), participated in this study. She reported no pain and no lower limb injuries at the time of enrollment in the study. After obtaining her written informed consent form, pre-MR (baseline) scans of the right foot (involved T2* maps) were acquired with a 3.0 Tesla MR scanner (Siemens Skyra 3T, Erlangen, Germany) while she was lying down in a natural position for the foot. MR scans were analyzed by OsiriX software.

Pre-plantar pressure (baseline) was also measured by the Novel emed® pressure platform during barefoot running. Peak pressure under each region of interest (ROI) was obtained from the right foot. ROIs were determined based on MR scans, subdividing into nine areas including toe regions (T1-5), metatarsal 1-5 (M1, M2, M3, M4, M5), midfoot (MD), medial heel (HM), and lateral heel (HL). Eight days later 5km barefoot running was performed at a self-selected speed on a treadmill. Immediately after, post-plantar pressure (follow-up) was measured with the same methodology as the pre-measurement. Three hours later (due to travel time) a post-MRI (follow-up) was obtained.
The differences in foot pressure of baseline versus follow-up were evaluated with a paired t-test (two-tailed) with a significance set at p=0.05.

RESULTS AND DISCUSSION

After 5km barefoot running, T1-5, M1, M3, M4, and MD exhibited a trend of reduced pressure, while the HM and HL showed a trend of increased pressure. However, only M1, M3, and HM were significant after running (Fig 1). These results may not be in accordance with the previous study that as barefoot running naturally encourages a midfoot or a forefoot strike, the plantar pressure under the metatarsal regions should be increased, while the heel region is decreased [1].

ROIs	Baseline		Follow-up		Sig. (<0.05)
	Mean	SD	Mean	SD	
T1-5	117.92	23.68	111.56	14.54	
M1	156.63	3.70	150.47	7.86	* ↓
M2	175.22	19.29	181.12	17.99	
M3	222.88	6.68	202.04	9.62	* ↓
M4	213.58	6.05	210.78	1.89	
M5	149.02	16.30	155.68	14.17	
MD	104.26	3.13	100.63	17.35	
HM	213.08	17.05	229.13	16.80	* ↑
HL	199.65	16.07	205.66	17.52	

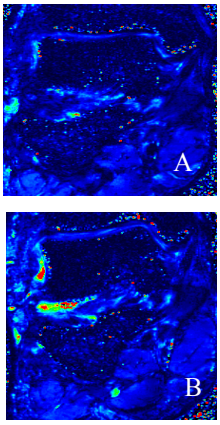

Figure 1: (Left) Mean and standard deviation for peak pressure (kPa) from three trials for regions of the foot and (Right) T2* map changes in the tibiotalar cartilage in a coronal view. A-baseline, B-follow-up.

A subtle inflammation on the base of the 5th metatarsal was identified pre and post run. Based on T2* mapping, the medial heel showed visible changes, increasing extracellular water level after running, while other regions had no changes. Hence, pressure was transferring from the metatarsal, toes, and midfoot to the heel regions over 5km running probably due to the subtle inflammation on the 5th metatarsal.

CONCLUSIONS

These results suggest that barefoot running (for subjects who do not normally run unshod) does modify gait and T2* relaxation time on the heel but not on the pre-existing inflammation site and hence the pressure pattern on the sole of the foot. In this case of a dancer's foot the gait has been modified to off-load the non-symptomatic diagnosed inflammation forefoot and metatarsals, and hence increase pressure on the heel. Ongoing work is being conducted to evaluate these results against non-dancers, professional and amateur runners.

P206 - A CORRELATION OF VERTICAL JUMP AND STANDING LONG TO ISOKINETIC RESULTS IN FOOTBALL ATHLETES

[1]J. Russell Smotherman, [2]**Suanne M. Konz**, [2]Zach Garrett, and [2]Komika Toma:

Corresponding author email: konz@marshall.edu

INTRODUCTION

The focus for the NFL Football Scouting Combine evaluation process for most is the on-field performance tests. Medical testing is a piece of evaluation.An isokinetic dynamometer tests the knees of NLF prospects assessing knee health. Results from the isokinetic test become part of each NFL prospect's medical profile. While the injury assessment is an important part of the evaluation process, a lack of incentive for some athletes to perform to their highest ability during isokinetic testing occurs .Current research has examined the relationship between the NFL Combine, draft order (drafted and non-drafted), and the NFL Combine field assessments [2,3]. Through field assessment tests like vertical jump and standing long jump, which are used to determine power development, athlete development, and quantify training room protocols, we can determine if a correlation is present between isokinetic and these field assessment tests. Such correlations would help scouts and team owners better gauge athlete ability. The objective of this study was to determine whether a correlation exists between isokinetic dynamometer results and performance in the vertical jump and standing long jump.

METHODS

Medical records along with strength and conditioning testing records of 68 NCAA-I 2014/2015 football athletes from Marshall University were selected. The data were extracted from parts of standard athlete testing conducted by strength and conditioning and sports medicine staff at the University. The study received IRB approval. The data extracted from the athlete records included the isokinetic test results including peak torque, power, and time to peak torque for both knees at speeds of 60°/sec and 180°/sec along with vertical jump distance, and standing long jump distance. Isokinetic data was allometrically scaled [1]. Correlation and a two-tailed regression analyzed data. Significance was set at the .05 level.

RESULTS AND DISCUSSION

Correlation for VJ at 60°/sec included time to peak torque in the right hamstring (p= .017, r = .289), and time to peak torque time in the left hamstring (p= .019, r = .284). Correlation for VJ at 180°/sec included peak torque in the left quadriceps (p= .012, r = .302), and power in the left quadriceps (p= .012, r = .303), peak torque in the left hamstring (p= .033, r = .259), and power in the left hamstring (p= .041, r = .248). Correlation for SLJ at 60°/sec included power in the right quadriceps (p= .014, r = .295), peak torque in the right quadriceps (p= .003, r = .360), peak torque in the right hamstring (p= .018, r = .286), and peak torque in the left hamstring (p= .022, r = .278). Correlation for SLJ at180°/sec included power in the right quadriceps (p= .000, r = .475), power in the left quadriceps (p= .001, r = .409), peak torque in the right quadriceps (p= .000, r = .573), peak torque in the left quadriceps (p= .000, r = .482), power in the right hamstring (p= .000, r = .417), power in the left hamstring (p= .000, r = .413), peak torque in the right hamstring (p= .001, r = .402), and peak torque in the left hamstring (p= .000, r = .421). For VJ at 180°/sec, predictors were power (p=.026) and peak torque of the right quadriceps (p=.020) and for scaled data, performance predictors were power of the right quadriceps (p=.027) and peak torque of the right quadriceps (p=.020). Predictors for SLJ at 60°/sec were time to peak torque of the right hamstring (p=.011), right quadriceps (p=.029) and peak torque of the right hamstring (p=.047), and at 180 °/sec time to peak torque in the left hamstring (p=.046).

CONCLUSION

The results of this study found significance and indicated weak to moderate correlations exist between isokinetic variables at 60°/sec and 180°/sec and the ability to perform the VJ and SLJ. The results of this study indicate that the isokinetic variables of power, peak torque, and time to peak torque in the muscles surrounding the knee predict success in the the VJ and SLJ. Allometric scaling is useful for the sport of football with the different sized athletes. Isokinetic testing can assist in assessing performance in the VJ and SLJ.

INTRODUCTION

One of the shortcomings related to investigating injury patterns is the current running protocol under laboratory conditions. Within this framework, either only a few strides (overground), or treadmill runs are recorded. The use of inertial sensors is considered a promising alternative for field testing [1]. By combining accelerometers and gyroscopes, Inertial Measurement Units (IMU) enable the kinematic description of all six degrees of freedom without the spatial restrictions inherent to other devices. In contrast to the large number of publications applying IMU for detecting strides or measuring joint angles, there are only few studies examining the validation of inertial sensors for measuring frontal plane foot kinematics. Moreover, adequate explanations regarding the observed measurement error are rare.

METHODS

54 recreational runners (33.9 ± 8.2 y, 177.9 ± 7.6 cm, 70.9 ± 10.1 kg) participated. All subjects completed a single continuous treadmill run, running three minutes each at 10, 12 and 15 km/h. Data was recorded simultaneously using an IMU (aims datalogger DX3.2, Xybermind GmbH., Germany) and a 3D motion analysis system (MA) (Qualisys AB, Gothenburg, Sweden), both sampling at 400 Hz. The IMU comprised a triaxial accelerometer (16 g) and gyroscope (2000 °/s). The IMU was attached to the heel cup in the sagittal plane of the right shoe. The applied MA marker set consisted of three retroreflective markers on the forefoot and four markers on the rearfoot. Starting times, required for synchronization, were defined as the initial contact of an instrumented trigger rod in both measurement systems.

Data were pooled across 100 strides for each subject and velocity. For this purpose, 101 events of initial ground contact of the foot (TD) were set manually utilizing shoe marker trajectories. For MA data, 3D rearfoot orientation was calculated according to [2]. Gyroscope raw data was first sectioned into single stride intervals using the previously determined TD and subsequently integrated to derive the orientation of the rearfoot. Frontal plane foot kinematics were analyzed using the discrete parameters eversion range of motion (EVrom [°]) and maximum eversion velocity (EVvel [°/s]). EVrom corresponded to the difference between eversion maximum and minimum within the first 45% of the stance phase [3]. EVvel was defined as the steepest slope of the tangent at the eversion angle curve within the previously defined maximum-minimum interval (MA) and the maximum value in the eversion rate signal (IMU), respectively. Data was analyzed using Bland & Altman plots to control for mean differences MA-IMU and limits of agreement (LoA).

RESULTS AND DISCUSSION

A mean deviation of -2.56° (LoA ±4.78°) was found for EVrom and 95.04° (±145.55°) for EVvel. The observed errors were therefore considered large. No relevant differences were found between the three velocities (Table 1).

	10 km/h	12 km/h	15 km/h
Bias (LoA)$_{EVrom}$ [°]	-2.34 (4)	-2.7 (4.4)	-2.65 (5.3)
Bias (LoA)$_{EVvel}$ [°/s]	-76.7 (114.4)	-93.4 (118.9)	-114.9 (142.1)

Table 1: Mean differences MA-IMU and Limits of Agreement in frontal plane parameters.

The results are similar to those reported for overground running [4]. However, the error showed considerable intraindividual variation. Twelve out of 54 subjects showed a bias of < ± 1°, while five subjects showed a bias of > ± 6°. A possible explanation for these large discrepancies might be differences in foot strike behavior, causing varying impact magnitudes on the IMU. Resulting external vibrations have the potential to disturb the performance of MEMS gyroscopes [5].

CONCLUSIONS

For the investigated treadmill runs, IMU showed deviations when compared to a reference system (MA). However, errors might be reduced when sources of vibration are understood and accounted for.

P208 - ARE DISCRETE PLANTAR PRESSURE VARIABLES RELATED TO RUNNING SHOE COMFORT?

Chris Lam, Maurice Mohr, Aimee Smith, Sandro Nigg, Benno M. Nigg
University of Calgary
Corresponding author email: Chris.Lam1@ucalgary.ca

INTRODUCTION

Commercially available running shoes can vary substantially in their construction and fit and could appeal to different consumers depending on their preferences related to comfort, aesthetics or performance. Plantar pressure measurements can reveal the way a foot interacts with a shoe [1] and have been shown to change with the construction of a shoe [2]. Therefore, plantar pressure variables could provide insight into how or why someone might find a shoe comfortable or uncomfortable.

The objectives of this research were to determine if: 1) discrete variables of plantar pressure are related to whether an individual will perceive a shoe as comfortable, and 2) within a given shoe model, a variable of plantar pressure is related to comfort.

METHODS

Forty healthy, active adults (20♂/20♀, 25±4y) took part in the study. They determined their comfort preference (rankings) and subjective comfort (10 cm visual analog scale (VAS)) of five differently constructed commercially available running shoes on two separate days (Day one; blinded Day two; un-blinded). Day two involved the biomechanical assessment of each shoe while running a total of 180 m at approximately 3.5 km/h.

Within each subject, the most and least comfortable shoes were determined as the highest and lowest ranked shoes. Within each shoe, 'high' and 'low' comfort groups were established based on runners with the highest (top 25%) and lowest (bottom 25%) mean VAS scores, respectively.

Plantar pressure was measured from the right foot using PEDAR pressure insoles (sampled at 200 Hz; Novel GmbH, Munich, Germany). Center of pressure (COP) traces were established and each step was normalized to 100 data points from heel contact to toe off. Thirty steps were averaged for each shoe, and were normalized to insole length and width, then each step was reduced to 10-90% of the stance phase to remove the COP artifacts at heel contact and before toe-off.

From the COP traces, anterior-posterior (AP) and mediolateral (ML) excursions were calculated by subtracting the minimum from the maximum value in each direction. Peak AP and ML velocity was established by determining the maximum value of the differentiated raw, non-normalized COP displacement.

To assess whether the COP trace is related to shoe comfort, student's paired t-tests ($\alpha = 0.05$) were used to compare the four discrete COP variables between the most and least comfortable shoes within subjects. To evaluate whether a discrete COP variable was related to comfort within a particular shoe, two-way ANOVAs were used with 'shoe' and 'comfort' (top 25% vs bottom 25% VAS scores) as factors.

RESULTS AND DISCUSSION

No significant differences were found for any of the COP variables when comparing the most comfortable to the least comfortable shoe. This suggests that the variables were not sensitive to differences in comfort preferences within each subject. However, within shoes, main effects of 'comfort' were observed for ML-excursion ($F_{1,4} = 8.495$, $p = 0.043$) and peak AP-velocity ($F_{1,4} = 11.528$, $p = 0.027$) between the high and low comfort groups (Figure 1).

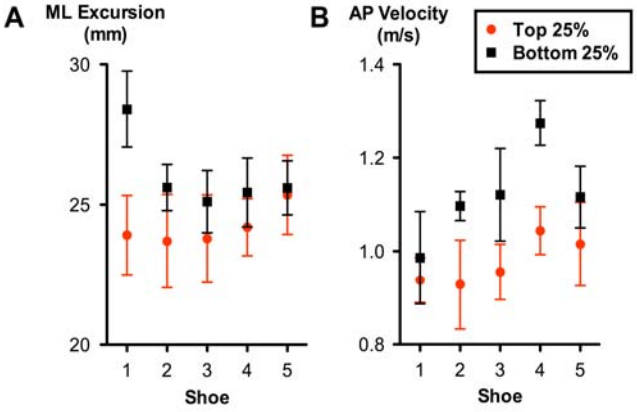

Figure 1: A) ML excursion and B) Peak AP velocity (Mean ±SD) of runners with top 25% (n= 10, red) and bottom 25% (n = 10, black) comfort scores for each shoe.

The ML excursion was significantly smaller for individuals who perceived the shoes as comfortable compared to individuals with low perceived comfort. A similar effect was also apparent in the peak AP velocity, with lower peak velocity in the high comfort group. This lower peak velocity and excursion of the COP would suggest that the foot experiences a slower, or perhaps smoother, transition from heel to toe of a shoe during the stance phase of running, which could be related to the perception of comfort.

CONCLUSIONS

ML excursion and peak AP velocity may provide insight into why a particular shoe may be perceived as comfortable between subjects. However, they may not be sensitive to comfort differences within each subject.

ACKNOWLEDGEMENTS

We would like to acknowledge Adidas Research Group for providing shoes and funding for this experiment.

P209 - CHANGES IN LEG PRESSURE DURING MODES OF RACING WHEELCHAIR PROPULSION

[1, 2] **Amy R Lewis**, [2]Elissa Phillips, [2]Marc Portus, [1]Paul Grimshaw, [1]William S P Robertson,
[1]University of Adelaide, School of Mechanical Engineering, South Australia, Australia
[2]Australian Institute of Sport, Movement Science, Australian Capital Territory, Australia Corresponding author email: amy.lewis@adelaide.edu.au

INTRODUCTION

Laboratory testing conditions are frequently scrutinised for their inability to accurately depict the physiological and biomechanical requirements of performance [1], and this is particularly true for phases of acceleration in wheelchair sports. Specifically, the low rolling resistance of rollers increases the ease of the acceleration phases. Treadmills follow designated speeds and accelerations, meaning it is unlikely that athletes will accelerate in a comparable fashion as that seen on the track or in a race. Consequently, it is unlikely in laboratory testing to truly identify the key kinematic parameters of performance, such as the use of lower extremities (when permissible) which may be utilised as a point of anchoring for enhanced generation of momentum.

Pressure mats have demonstrated success in measuring reaction forces [2] of running, and they have provided an indication of the quality of athlete-wheelchair interaction, which is a crucial aspect of wheelchair performance [4]. This research aims to address the efficacy of the pressure mat as a measure of seating interface movement under training and simulated race conditions.

METHODS

A single elite athlete (age 24 years, international experience 6 years, body mass 54.2 kg) completed four protocols of wheelchair propulsion; two at steady state (treadmill (TreadSS) and track (TrackSS)) and two accelerations (stationary start (Start), and 150m acceleration (TrackACC)). Treadmill speed was determined based on preferred speed in regular training, and was kept consistent with track speed.

Peak, Average and areal (Area) pressure at the athlete-seating interface were measured using a pressure mapping system (XSENSOR LX100; Calgary, Alberta, Canada) at 4Hz. Pressure mat placement facilitated the measurement of pressures applied normally (directly below shins), laterally (towards the seating bucket), and propulsively (in front of knees). No visible shear or crinkling of the mat was present during the settling time, which was used (30min) for sensor calibration and equilibration to account for creep within the sensors.

Three sets of 10s trials were collected for each condition and averaged. Significant differences between propulsion tasks were characterised by performing a repeated measures One-Way ANOVA with Bonferroni Adjustments. Statistical analysis was performed using SPSS software.

RESULTS AND DISCUSSION

Between-conditions differences between the three key performance parameters are compared visually in Figure 1. Repeated measures ANOVA revealed significant differences at the 0.05 level between most conditions for measures of Average Pressure and Area (all apart from between TreadSS and Start).

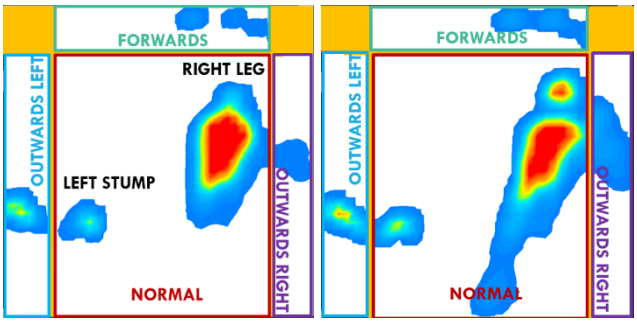

Figure 1: Variation in mean pressure parameters through different modes of propulsion (Tread SS: Left, TrackACC: Right).

Increased forwards leg drive was associated with an increased contact area in both acceleration trials, with negligible applied knee force demonstrated in both of the steady state conditions. The consistency in leg drive under both steady state conditions suggests the treadmill does not simulate non-steady-state conditions completely.

Generally, average pressure and contact pressure were inversely proportional, however under track acceleration conditions, these were directly proportional, and suggesting increased force application from the leg. Qualitative assessment revealed increased contact area was applied predominantly in the lateral and normal (downwards) directions of the functional leg. This suggests that although the leg is increasing its contribution, this contribution is not currently being directed optimally. As all athletes are unique in both functionality and anthropometry, it can be assumed this level of contribution will vary significantly between athletes, with respect to both magnitude and applied directions.

CONCLUSIONS

The efficacy of pressure maps in quantifying leg pressure was assessed on varying track surfaces and tasks. Although limited by recording frequency and sensor saturation, the pressure map was a suitable method of quantifying leg contribution to acceleration, and easily implemented to in-field measurements. When function is present, athletes use their legs during the acceleration phase of propulsion. The level and direction of this applied pressure, and hence force is largely varied between different propulsion methodologies, and hence should be assessed under performance conditions.

P210 - DOES GLOVE TYPE INFLUENCE WHEELCHAIR PROPULSION SYMMETRY IN JUNIOR ATHLETES?

[1, 2] **Amy R Lewis**, [2]Elissa Phillips, [3]Fred Periac, [2]Marc Portus, [1]Paul Grimshaw, [1]William S P Robertson, [1]University of Adelaide, School of Mechanical Engineering, South Australia, Australia
[2]Australian Institute of Sport, Movement Science, Australian Capital Territory, Australia
[3]Athletics Australia, Track and Field Unit, Australian Institute of Sport, Australian Capital Territory, Australia
Corresponding author email: amy.lewis@adelaide.edu.au

INTRODUCTION

It is commonly documented that asymmetries are present within both the kinematics [1] and kinetics [2] of wheelchair propulsion. These asymmetries are considered to detract from athlete performance, due to the resulting left and right weaving of the athlete within their lane, ultimately increasing total distance travelled, and hence increasing resultant completion time. Most commonly, these asymmetries are assumed to be caused through musculoskeletal and anatomical imbalance, as a consequence of individual spinal cord injuries, with specific focus into identifying the cause of these abnormal motions, and mitigate them through processes such as strength and conditioning as well as biomechanical assessment of technique.

It is also possible that such asymmetry can be caused by poor equipment interfacing, specifically between the hands and the wheels. Hard gloves are designed to be athlete specific, through scanning methods. However, their manufacture often means that one, most commonly the dominant hand, fits better than the other, whilst soft gloves, commonly used with junior athletes, are not customized at all. Consequently, it is uncertain whether the observed spatial and temporal discrepancies at the hand are a result of musculoskeletal bias and asymmetry within the athlete, or whether it is a result of a reduced interface between the hand and wheel, preventing maximal energy transfer to the chair. This research aims to compare gloved and un-gloved starting conditions to assess for a stationary wheelchair racing start whether this altered the distribution, rate of force development, or direction of force application.

METHODS

Four experienced National Level junior wheelchair racing athletes (16 years) in two classifications, T34 (athletes with cerebral palsy) and T54 (athletes with spinal cord injury), performed four stationary starts under two conditions: Gloved (G) and non-gloved (NG). Three force plates (Kistler 9281B-11, Switzerland), embedded in the floor and covered by a mondo track surface, were used to measure ground reaction forces at 1 kHz of each wheel separately. Data pre-processing, including filtering (fourth order Butterworth low pass filter) was completed using MATLAB 2015a (Mathworks, USA). Ground reaction force components were normalised to body weight.

Peak force (Fx, Fy, Fz), rate of force development (RFD), determined by the maximum slope of adjacent points of Fy, propulsive impulse (PI), vertical impulse (VI) and time to peak force (TPF) values were calculated. Data were expressed as a ratio of left and right measures (L/R) ×100% (i.e., >100% indicates left-side dominance). The effect of the overall influence of gloves was also assessed between classification samples. Paired t-tests were used to determine the influence of the independent variable (glove status) on each of the dependent variables. Statistical analysis was performed using SPSS 13.0 (SPSS Inc., Chicago, IL, USA), with significance set at $\alpha = 0.05$.

RESULTS AND DISCUSSION

No significant differences were observed between glove status on athlete asymmetry. It was observed gloves do influence overall performance, with significant differences observed for T54 RFD ($\alpha = 0.030$), and non-significant, yet large differences observed for T54 Fz ($\alpha = 0.063$). Further differences were observed in force development patterns between classification samples, as presented in Figure 1. The large variation in the T34 group (as represented by large error bounds) can be attributed to their functionality.

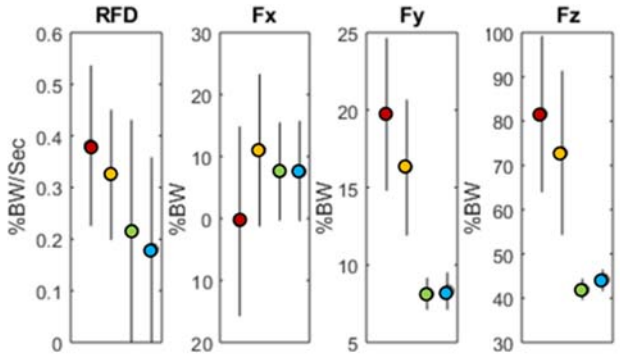

Figure 1: Differences in propulsion characteristics between non-gloved (T34: Red, T54 Green) and gloved (T34: Yellow, T54: Blue) conditions. Fx is the lateral GRF, Fy is anterior-posterior (in direction of motion) and Fz is the vertical GRF.

Large inter- and intra- athlete variability was observed in these athletes under both the gloved and ungloved conditions for all variables. This variability cannot be associated with glove type, as there was a 50-50 split in the use of hard and soft gloves used. Differences may however be present for more experienced senior athletes, who do have more consistent start patterns, and less easily trained out of poor movement patterns. Large differences between classifications were observed, as expected, with T54 athletes more affected by glove type.

CONCLUSIONS

The use of gloves do affect start performance, however does not influence the level of asymmetry within an athlete's technique.

P211 - IDENTIFYING THE LOWER EXTREMITY MUSCLE ACTIVITY DURING STANDING YOGA POSTURES IN YOGA INSTRUCTORS

[1]**We-Lan Wu**, [1]Ai-Min Liu, [1]Jing-Min Liang, [2]Feng-Hua Tsai, [2]Hsiu-Tao Hsu

[1] Department of Sports Medicine, Kaohsiung Medical University, Kaohsiung, Taiwan

Corresponding author email: wenlanwu@kmu.edu.tw

INTRODUCTION

Yoga as an exercise has rapid growth in recent year, from youth to senior, to look for keeping healthy or solving some unease physiological and psychological problems. Lower extremity strengthening is recommended for managing knee pathologies such as osteoarthritis (OA) [1]. It has been reported that squatting and lunging postures could induce higher quadriceps muscle activation [2]. However, the benefit for hamstring muscle training was not clarified. Thus, the muscle activation pattern of common yoga postures, need to be quantified from biomechanical data presented by qualified yoga instructors.

METHODS

Eleven Yoga instructors were recruited from a yoga studio voluntarily participating in this study. Each yoga instructor has a Registered Yoga Teacher 200-hour (RYT200) or Registered Yoga Teacher 500-hour (RYT500) qualification, and at least 1000 hours yoga teaching experience. Exclusion criteria included pregnancy, rheumatoid arthritis, osteoarthritis, and a history of knee surgery. This study focuses on modified versions of standard forms of asanas (yoga postures in Sanskrit) on the biomechanical analysis of five standing poses: Chair posture (Sanskrit name: Utkatasana), Tree posture (Sanskrit name: Vrksasana), Warrior 1 posture (Sanskrit name: Virabhadrasana 1), Warrior 2 posture (Sanskrit name: Virabhadrasana 2), Warrior 3 posture (Sanskrit name: Virabhadrasana 3).

Electromyography (Noraxon U.S.A. Inc., USA) was used to detect muscle activity signals. Signals were recorded bipolarly by pairs of 10-mm diameter Ag/AgCl surface disc electrodes placed at a distance of 20 mm (center to center). The electrode pairs were fixed lengthwise over the muscle belly on vastus lateralis obliquus (VLO), rectus femoris (RF), vastus medialis obliquus (VMO), biceps femoris (BF), and semitendinosus (SEM) muscle for both legs. EMG signals were recorded with a sampling frequency of 1000 Hz.

Before starting test, participants had to measure the maximum voluntary contractions (MVC) for each muscle. Then, participants began in a starting position, and moved into the posture. Once the participants moved into the position, and provided a verbal cue to the research associate to the data collection. Each posture was held static for 10 seconds and repeated three times.

EMG data during the static 6 seconds were normalized to each participant's peak activity in the maximum voluntary contraction (MVC) with MyoResearch XP Basic Edition 1.07.01 software, applies Bandpass filter with a cut-off of 80-250 Hz.

The data were analyzed with the one-way repeat-measure ANOVA method. The independent variables were seven postures (Warrior I and Warrior II were considered separately between the front and back limbs), EMG values were the dependent variables. Post hoc tests were used after significant main effects have been found. Statistical analyses were completed in SPSS (IBM, Version 20). In this study, we used a statistical significance level of 0.05.

RESULTS AND DISCUSSION

The average EMG values are showed in **Table 1**. No significant pose effects were observed in each muscle. RF shows the highest muscle activation in the Chair pose (33.0%). VLO had the highest muscle activation in the Warrior 2 front-limb pose (47.7%). VMO EMG shows the highest muscle activation in the Warrior 1 back-limb pose (50.4%). BF (28.5 %MVC) and SEM (37.2 %MVC) muscles EMG activations were both highest during Warrior 3 pose.

Table 1. Average EMG activity (mean (SD))

	VLO	RF	VMO	BF	SEM
Chair	47.2 (24.0)	**33.0 (10.1)**	35.0 (11.2)	9.5 (5.2)	10.6 (7.8)
Warrior 1 front-limb	38.9 (20.7)	24.5 (15.6)	27.7 (4.8)	10.7 (6.5)	13.8 (9.9)
Warrior 1 back-limb	14.6 (6.6)	32.5 (11.0)	**50.4 (11.7)**	13.8 (7.8)	19.1 (14.7)

Tree	31.4 (19.2)	25.7 (11.3)	27.9 (21.5)	11.0 (5.4)	11.1 (10.7)

Data are expressed as a percentage of activation achieved during maximal voluntary contraction (%MVC)

In the present study, the squat (Chair) and lunge poses (Warrior 1 and Warrior 2) had higher quadriceps muscle activation. RF shows higher muscle activation in Chair pose than other 6 poses (33.0% MVC). In addition, the Warrior 1 and Warrior 2 pose also show the highest EMG value for VLO (47.7 % MVC) and VMO (50.4% MVC), respectively. The results indicated that those commonly standing yoga postures, such as Chair, Warrior 1 and Warrior 2 may be ideal yoga exercises for beginners to strengthen quadriceps muscle. On the other hand, the results also show that BF and SEM muscle had higher EMG value in Warrior 3 pose (28.5% and 37.2% MVC, respectively) than other 6 yoga poses. It suggested the Warrior 3 yoga pose might be a good selection for training the hamstring muscles.

CONCLUSIONS

This study quantified the lower extremity muscle activation of 5 common standing yoga poses. The result of this research could provide self-practice or yoga instructors to guide beginners or people with special needs as references with appropriate postures to develop positive effect of thigh muscle strengthening.

P212 - THE HIP PRESSURE DISTRIBUTION AND CONTACT AREA DURING VARIOUS RUNNING AND FAST WALKING SPEEDS

[1]Hwai-Ting Lin, [1]Kai-Chu Kang, [2]Hong-Wen Wu
[1]Kaohsiung Medical University
[2]National Taiwan University of Sport
Corresponding author email: whiting@kmu.edu.tw

INTRODUCTION

The hip joint is the connection of trunk and lower limb, bearing the load of upper limb. It plays an important role on walking, running and other activities. Running and fast walking are the primary choice for regular exercises of many people, and also the rehabilitation programs after injury and the necessary motion in many sports. Running becomes a very popular exercise recently, however, with reputational loading on the hip, running is beneficial or harmful to hip is controversial. The previous study shown that running make Cartilage thicker, Cartilage Viscoelastic and Proteoglycans raised. However, the previous study also shown that running make less contact area, high peak value and then lead to cumulative pressure rose. During running and fast walking, the stance phase of the running and fast walking is bearing the ground reaction force by single leg, that is why the hip pressure higher than usual activities. And when speed become faster, the pushing power becomes stronger, the reaction force will be higher and the same of the hip pressure. Therefore, the purpose of this study is using the computer simulation technique and motion analysis system to investigate the hip pressure's magnitude, loading location and area at various speeds of running and walking.

METHODS

Ten healthy males (age: 21.9±1.6 years, height: 170.5±4.3 cm, weight: 70.8±9.8 kg) without lower extremity injury were participated in this study. Every subject took anterior-posterior view of the hip joint X-ray radiograph first to build their own three-dimensional possible contact area of femur and acetabular computer simulation model (Genda et al., 2001). The kinematics and kinetic data was collected by using the motion capture system (Qualisys AB, Gutenberg, Sweden) and force plate (9286AA, Kistler, Switzerland) during running and fast walking. Twelve reflective markers were attached on the anatomical position based on Helen Hays marker set for motion capture. After properly warm up, every subject tested at five different kinds of conditions including fast walking at velocity of 2 and 3 m/s, and running at velocity of 2, 3, and 5 m/s. The inverse dynamic and Newtonian analyses were applied to calculate the hip joint resultant force. Combined the kinematics data and joint resultant force information in the discrete element analysis (DEA), the contact area and pressure of the hip during running or walking could be analyzed (Bergmann et al., 2001).

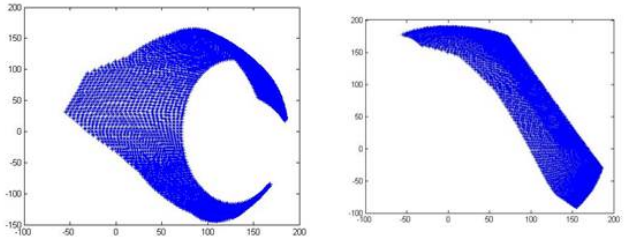

Fig 1. The possible hip joint contact area of femur and acetabular

RESULTS AND DISCUSSION

The results showed that the hip joint reaction force was increased when the running and walking speed was increasing (Joint force: 1.4 BW to 2.3 BW). At the same speed, the vertical and posterior hip joint force in running was larger than in fast walking. In DEA results, the contact area was not significant different at various speeds, and the pressure acting on the hip joint was concentrated on the lateral and medial roof, the peak pressure was higher when speed was increased (3.28 to 3.83 Mpa). Moreover, the higher contact area and higher peak pressure were also found during running. The unapparent contact pressure and contact area may result from the different strategy of the subjects when changing the running speed or the geometry difference of the hip joint. Among the all subjects, with increasing the running speed, in some subjects only the area of contact was increased, but in some subjects the maximum stress was increased.

CONCLUSION

During running, higher hip joint resultant force and moment loading was found than in walking. In DEA results, running have higher hip pressure, and concentrated on lateral and medial area both in running and walking. This algorithm could be used subject's hip model and can also apply to analyze the hip joint contact area and peak pressure during different kinds of exercise.

P213 - THE INFLUENCE OF SIDE KICKS ON DIFFERENT ANGLES OF ELECTRONIC BODY PROCTECTOR

[1]Yi-Chun Lin, [1]Yu-Lin Chen, [1,2]Tsun-Te Liu and [1]Wen-Tzu Tang*
[1] Graduate institute of Athletics and Coaching science, National Taiwan Sport University, Taiwan
[2] Office of Physical Education, Tamkang University

INTRODUCTION

Taekwondo is a kind of physical self-defense and martial arts that uses the hands and feet for sport. It is a combat sport where male and female athletes compete in different weight divisions. It is a game of speed and accuracy. It is also the major event for sport development of Olympic game and Asian game in Taiwan. Since the rule of 2008 Peking Olympic game had changed and started to use the official electronic body protector. The attacking skills and scoring strategy had been changed in the game.

The electronic scoring system utilizes inductive devices within the electronic chest, induction opponent wearing the corresponding gloves and foot socks to give the impact of the size of the judge to the points. It changes the distribution of attack technology scores. In the past emphasis on defensive use side kick that has become one of the means of scoring.

Recent studies showed the force sensor is not linear through the location with vertical impact. If the nonlinear relationship of angle of attack of side kick with the scoring level from electronic body protector can found.

METHODS

Twelve TKD practitioners (12 males) aged 18-21 years old (Height 176.75±6.78 cm and Weight 66.33±9.86 kg) were recruited from college division 1 Taekwondo team. Participants were excluded if they presented with cardiovascular, pulmonary, neurological or musculoskeletal disorders.

This study was approved by the human subjects ethics review subcommittee of The Fu Jen Catholic University. Testing procedures were explained to the participants and written informed consent was obtained. After warm up with called personal routine, the participants were asked to kick three of side kick in three different angles. At the same time record the results of electronic sensor protection.

Electronic Body Protector (EBP) used World Taekwondo Federation (WTF) approved Daedo brand EBP and International competition commonly used KP&P brand. For comparison within three different angles in the same scoring area.

SPSS version 20.0 (SPSS Inc., Chicago, IL, USA) was used to analyze the data and analyzed with one-way repeated measures ANOVA ($p < .05$). When the F value reaches a significant level, the LSD to do after the comparison to identify differences in the group

RESULTS AND DISCUSSION

The purpose of the present study was to analyze side kicking of three different angles in the same scoring area for Daedo brand EBP and KP&P brand EBP.

The comparison of different angles kick in KP&P EBP and in Daedo EBP were showed in Table 1. There were significant difference in KP&P EBP induction value (A:18.67±3.50<B: 20.25±2.66,p=.034; A:18.67±3.50<C: 21.75±4.78,p=.016). But in Daedo EBP is not significant difference (A>90°: 50.56±13.56; B=90°; 48.47±11.29; C<90°: 48.33±10.39, F=.195).

Table 1: Side kick in different angles to the EBP inductive value (N=12)

Inductive value	A >90°	B =90°	C <90°	F 值	P	Comparison
KP&P	18.67±3.50	20.25±2.66	21.75±4.78	3.850*		A<B，A<C (P=.034) (P=.016)
Daedo	50.56±13.56	48.47±11.29	48.33±10.39	.195	.753	

*p<.05

Taekwondo is a game of speed and accuracy. Electronic Body Protector can provide a good objective value for score. However, there are some factors to affect the Force Judgment of Dynamometer.
Past research found kick the real force of numerical and Electronic Body Protector measuring force is different. It showed the force sensor is not linear through the location with vertical impact [1]. It performed a consistency analysis with Taekwondo Electronic Body Protector of the kick area. It showed the EBP unreliability between the test room and the area [2].

Force measurements have measured by Acceleration Method or Pressure-Sensing Method. The force is by the mass and the acceleration, F=ma. Pressure-Sensing Method is that force is by the Pressure and the area.
According to the above theorem, this result may be the contact area. This study did not calculate the contact area of the foot area with the size of the Electronic Body Protector.
This result may also be the time of action. Acceleration is influenced to the time of action.
How to kick accuracy and play an effective power to get scores are all players and coaches looking for.

CONCLUSIONS

To win the game not just need skill, it include many factors. Provide coaches and players as a reference. It is suggested that the foot contact area and contact time action to be studied.

P214 - IMPACT OF EXTERNAL FOCUS AND INTERNAL FOCUS ON JUMP PERFORMANCE

[1] Yui Sato, [1]**Hitoshi Makabe**
[1]Yamagata Prefectural University of Health Sciences
Corresponding author email: hmakabe@yachts.ac.jp

INTRODUCTION

Attention to objects other than one's own body while in motion is called external focus[1)], and the attention to a part of one's own body while in motion is called internal focus. Past studies suggest that external focus is more effective during a vertical jump[2)], but such studies have not quantified the attention, which makes it difficult to verify the accuracy of the findings. Therefore, the aim of this study is to evaluate the impact of external focus and internal focus on a jump performance.

METHODS

The test subjects were 19 healthy adult males without neurological or orthopedic disorders (age: 21.6±1.3; height: 172.3±4.cm; weight: 66.2±6.9kg). The objective and method of this study were explained to the subjects in writing as well as orally before the experiment to obtain their consent. JUMP-MD (Takei Scientific Instruments) was used to measure the jump height in vertical jumps, and G-JUMP (BTS) was used to measure the acceleration and concentric power at take-off. The sampling frequency for G-JUMP was 100 Hz. A Mind Wave Mobile (NeuroSky) was used to measure Electroencephalogram (EEG) in the frontal lobe. The sampling frequency was 512 Hz, and the frequency power density in the beta region was calculated by analyzing the EEG frequency over a 1-second period before the jump. A countermovement jump was conducted for external Focus (EF) and internal Focus (IF). EF tests focused on a tennis ball above the head, and IF tests focused on the quadriceps femoris muscle. Measurements were taken twice and their average was calculated. The jump height, acceleration, and concentric power were compared for EF and IF.

RESULTS

The jump height was significantly higher for EF compared to IF (Figure 1). A comparison of power density of beta band in EEG showed a significant difference between the EF, the IF, and the Rest condition (Figure 2). No significant difference was observed in acceleration between the EF and the IF. No significant difference was observed in concentric power, similar to what was observed when comparing the accelerations for EF and IF.

DISCUSSION

The differences in attention had an impact on the jump height and power density of beta band in EEG. The alertness increased for the EF condition, where the participants had an easier time imagining their jump motion, which led to a better coordination between the jump timing and the necessary muscles, thus leading to the attainment of a higher jump height. Excessive internal attention and a conscious effort to control the details of the motion resulted in poor coordination of the entire body and therefore reduced the jump performance.

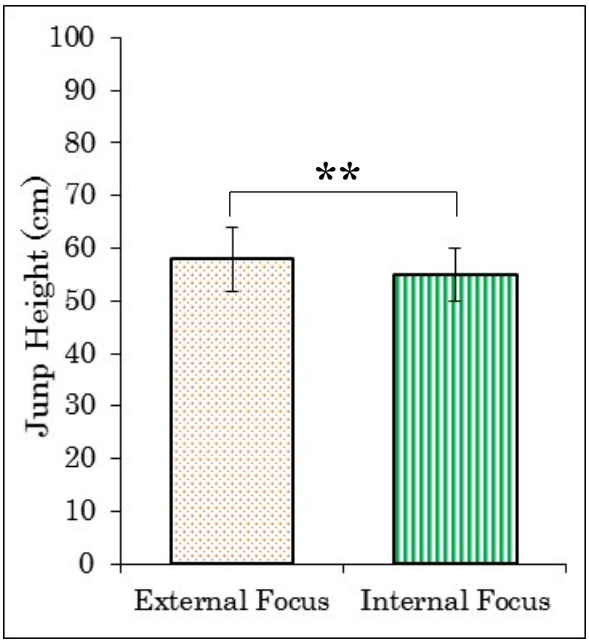

Figure 1: Jump height at external focus and internal focus.

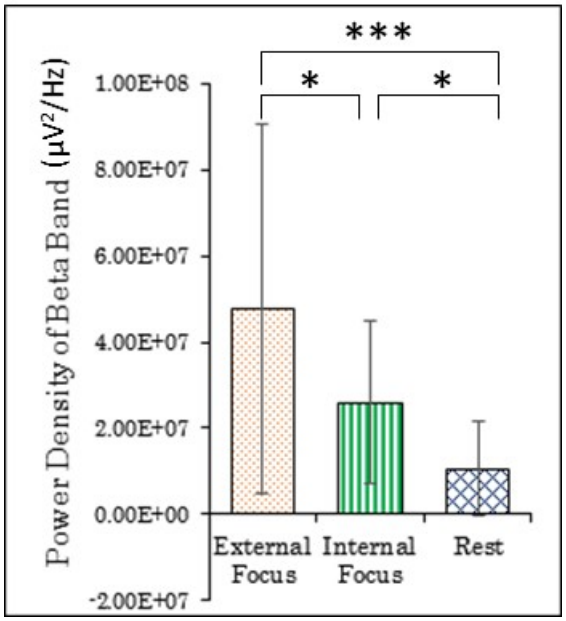

Figure 2: Power density of beta band in EEG.

CONCLUSIONS

It was suggested that the increase of alertness for the EF condition leaded the attainment of a higher jump height.

P215 - ENHANCEMENT OF GAMMA-RANGE EEG/EMG SYNCHRONIZATION DURING A KENDO FORM PRACTICE

[1] **Minato Kawaguchi**, [1]Kentaro Takahashi
[1]Kanto Gakuin University
Corresponding author email: minato@kanto-gakuin.ac.jp

INTRODUCTION

The dan-grades in material art, such as Kendo, are judged by the mental conditioning as well as delicacy of body movements in the examination. The bio-signals such as EMG and EEG should be a clue to coaching as an objective index of neuro-muscular coordination. The EEG-EMG coherence known as the correlation coefficient between an EEG signal and an EMG signal in the frequency domain has been investigated which focuses on the beta range [1-4] and the gamma range [4,5]. Previous investigations analyzed EMG signals [6] and EEG power spectral density during imaging or watching form practice in Kendo athletes [7]. Although our previous study has shown that the beta and gamma range of EEG-EMG coherence in the elite reached higher than those of subjects with the lower dan-grade while acting a form practice [8], it has been unclear the mechanism how it works. Therefore, in this study we tested the hypothesis that the coherence depends on the tasks related to accustomed forms: comparison between a task during contraction with constant force and that during contraction synchronized with a Kendo form.

METHODS

Five subjects were chosen from male undergraduate students having third-dan. Each subject performed following two sessions as follows. 1) A subject watches a movie which a pair of players acting a form 'Nihon Kendo Kata' and grasps a hand dynamometer (VM) in mimicry of a player '*Uchitachi*' simultaneously. 2) Subject grasps it by the constant strength as much as grasping a bamboo sword (M). Each session was repeated for five trials. A multi-channel EEG/EMG system ('eegosports', ANT Neuro) was applied in every trial.

The 32 channels of EEG electrodes were set at possessions following the international 10-20 system, while the surface EMG electrode were set at the right flexor carpi with a sampling frequency of 1024 Hz.

The EEG-EMG coherence was estimated as follows:

$$C_i(f) = \frac{\left|X_i^{EEG}(f) \cdot X_i^{EMG*}(f)\right|}{\overline{X_i^{EEG}(f) \cdot X_i^{EEG*}(f)} \cdot \overline{X_i^{EMG}(f) \cdot X_i^{EMG*}(f)}}$$

$$0 \le C_i(f) \le 1$$

where $X(f)$ stands for the power spectral density with a resolution of 1 Hz and the asterisk is the complex conjugation operation. The subscript i corresponds to time. The averaged values of the coherence for frequency components such as beta (13-30 Hz) and gamma (30-80 Hz) among trials were calculated.

RESULTS AND DISCUSSION

The averages among trials per session were compared between sessions. In the gamma range, the coherence magnitudes in VM reached significantly higher than those in M at the several locations such as F7, P7 and C4. Then the paired t-test was applied and the distribution of p values are shown in the figure 1. Moreover, the result shows there are significantly difference (p<0.05) around posterior area (POz). These results are agreed with the previous study [5]. On the other hand, there were not any differences in the beta range like the study already shown [8].

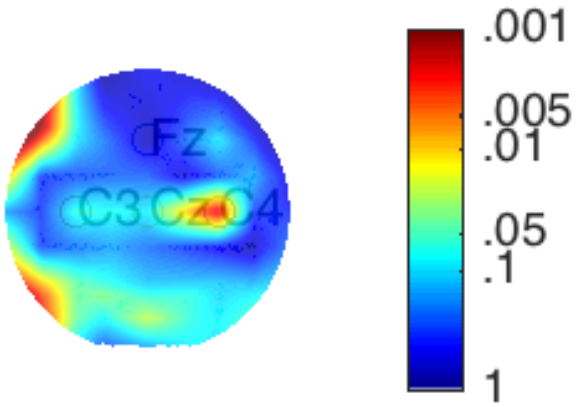

Figure 1: Distribution of p values from paired t-test compared between a condition of 'viewing a player with contraction (VM)' and that of grasping with the constant strength (M).

SUMMARY AND CONCLUSION

We have shown that EEG-EMG coherence with gamma band increased during acting a Kendo form at specific locations compared to the constant force contraction. It is implied that the coherence depends on the mental state during the muscle contraction. The experiments in subjects with the other dan-grades and novice are the future agenda.

P216 - IMPLEMENTATION OF A DATA ACQUISITION SYSTEM FOR JUDO TECHNIQUE *OSOTOGARI* ON *UCHIKOMI,* APPLYING *DUMMY.*

[1] **Eduardo Yoshinori Nagata**, [1]Tamotsu Hirata, [1]Walquiria Rodrigues Livramento e [1]Marcelo Sampaio Martins
[1]State University of São Paulo
eynagata@gmail.com

INTRODUCTION

Judo is a worldwide practiced sport which requires physical fitness for better performance [1].
For the fulfilment of the techniques, it is necessary the coordination of lower and inferior limbs, as well as the synchronization of power delivered by the limbs to achieve efficiency on the gesture [2].
The objective of the present study was to develop an equipment for the performance evaluation of the judo technique *Osotogari* during uchikomi training, through the behavior of strength signals.

METHODS

The device had 4 load cells placed on four locations of the *uke*'s body (one who receives the technique) on the *tori* (one who performs the technique) while applying the technique.
The device as built based on a dummy, with one load cell placed on the left side of the chest, other on the back side of the right thigh. The dummy was dressed in a adapted kimono, that received a load cell on the right sleeve and another one on the left side collar.
12 subjects of right side dominance took part on the survey, 7 of them were beginners and 5 were experienced. Each of these subjects performed 1 serie of 10 repetitions of *Osotogari.*

RESULTS AND DISCUSSION

A significant difference was observed between experienced subjects and beginners for the sleeve and the collar load cells data. In the other hand, no significant difference was observed on the chest and thigh load cells (Figure 1).

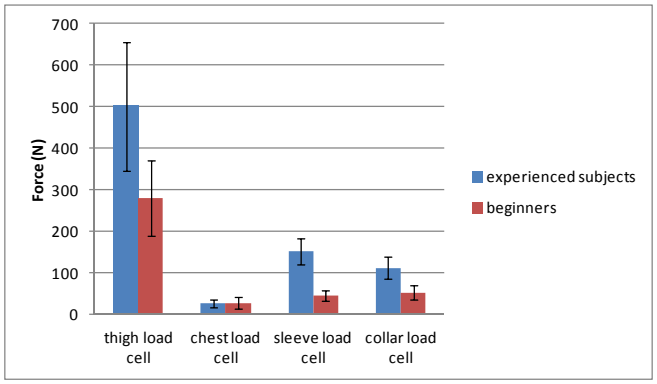

Figure 1: Peak force data of the thigh load cell and the force values of the other load cells.

Moderate linear correlation was observed between peak force data of the sleeve and collar load cells, which can be explained by the hands' temporal synchronization and rhythm.
It was observed that there is an ideal moment to apply strength when performing the technique, in order to achieve better performance.

CONCLUSIONS

The dummy is intended to meet the need for more practical performance analysis methods, contributing this way to the advance in athletes training.

P217 - A BIOMECHANICAL CASE STUDY ON THE TAKEOFF MOTION OF THE JAPANESE MEN JUNIOR LONG JUMPERS - TAKEOFF MOTION TO ACCOMPLISHED HIGH PERFORMANCE UNDER THE STRONG HEAD WIND CONDITION

Ikko Omura[1], Akira Iiboshi[2], Hiroyuki Koyama[3], Michiyoshi Ae[4]
[1]Kagoshima Women's College, Kagoshima, Japan, [2]Kagoshima Univ., Kagoshima, Japan,
[3] Kyoto Univ. of education, Kyoto, Japan,
[4] Nippon Sport Science Univ., Tokyo, Japan,
E-mail: oomura@jkajyo.ac.jp

INTRODUCTION

Performance of the long jump is affected by tail or head wind. Among the top 31 jumps listed in all-time ranking for the World's men long jump, 84% of total jumps were achieved under the tail wind condition. The remaining records were achieved under the head wind condition with -0.5m/s on average, and the strongest wind was -1.2m/s.

Most of previous studies concerning the effect of wind on long jump were done by mathematical view point, therefore we analyzed the effect of different wind condition on long jump takeoff motion at competition with biomechanical view point [Omura, 2011]. In that study, the Japanese junior men long jumpers were categorized into two groups based on the wind condition at the competition. Average wind condition for Group A was 0.3m/s, including the strongest head wing of -1.5m/s. Meanwhile, average wind condition for Group B was 4.6m/s due to strong tail wind. The results showed that the average performance for the Group B (7.47m) was higher than that of the Group A (7.35m), and the vertical velocity of the touchdown and the approach angle of the Group B were larger than those of Group A ($p<0.01$). Furthermore, the vertical velocity at the takeoff and the takeoff angle of Group B were larger than that of Group A. Based on the wind condition among the top 31 listed in all-time World ranking and the data of our previous study, it is easy to understand that to achieve the best performance under the head wind condition is very difficult in long jump. Since athlete can't control the wind, in order to achieve best or close to best performance under the head wind condition, biomechanical study is needed to clarify how to jump under such condition.

The purpose of this study was to obtain the fundamental findings to achieve the good performance under the head wind condition by analyzing the takeoff motion for a Japanese junior man athlete marked personal best record under the head wind condition.

METHODS

The subject was a Japanese man junior long jumper (Height: 1.82m, Weight: 72kg) won at the final of 2016 Japan High School T & F Championship with his best record 7.75m under head wind of -1.7m/s. His record was ranked at 7th in all-time high school man's long jump. His four trials ranging from 7.75m to 7.29m at the Championship were analyzed. The takeoff phase was filmed by the digital video camera (120f/s) which was placed at perpendicular to the takeoff board, and each trial was analyzed using FRAME DIAS system (DKH Co., Japan). Based on the digitized coordinate data calculated the kinematics data (horizontal and vertical approach velocity, horizontal vertical takeoff velocity, takeoff angle, several joint angles and angular velocities).

RESULTS AND DISCUSSION

The horizontal velocities at the touchdown were almost similar for four trials (9.7m/s – 9.8m/s). However, the release velocities at the takeoff were considerably different (8.3m/s – 8.8m/s). The release velocity reached at 8.6m/s in the takeoff for 7.75m jump. And the vertical velocity at the takeoff for 7.75m was larger (3.3m/s) than that of other trials (2.9m/s – 3.1m/s). And also, the takeoff angle at the 7.75m tended to be larger (20.8deg.) than those of other trials (18.3deg. – 19.9deg.). These results observed in 7.75m jump were similar to the values observed in Group B, categorized as strong tail wind group, reported by Omura [2011]. Therefore, the subject's best record of 7.75m might be due to the large horizontal velocity during the takeoff, large vertical velocity at the release of the takeoff, and the large takeoff angle.

Characteristic motions were observed in the trunk segment during the takeoff phase for four trials. Although, the trunk segment angle for all four trials showed negative value (i.e. the trunk leans backward) at the touchdown of takeoff, the trunk segment angle at 7.75m jump showed positive values (i.e. the trunk leans forward) during the second half of the takeoff. Such trunk motions observed at 7.75m jump were similar to those of World's class men long jumpers reported by Omura [2009]. Omura [2012] also reported that in case of the trunk segment angle showed positive values during the takeoff phase, the release velocity at the takeoff tended to be larger than that of negative values. In this study, nevertheless the horizontal velocities at the touchdown were almost similar for four trials (9.7m/s – 9.8m/s), the release velocities at the takeoff for 7.75m (8.6m/s) was higher that of other jump. From these results, motion of the trunk shifting from backward lean to forward lean seems effective preventing the loss of the horizontal velocity during the takeoff and superior performance.

The knee joint angle of the supporting leg at the touchdown was 155deg. and 132deg at the maximum knee flection. Therefore, change on the knee joint angle during the takeoff phase for the 7.75m jump was 23deg. Fukashiro [1994] reported the range of motion for the supporting leg from touchdown to maximum knee flection for the World's class men long jump (included Mike Powell's world record of 8.95m and Carl Lewis's jump of 8.91m.) was 20deg. on average. Based on these findings, trial 7.75m of his best record was achieved by similar knee joint motion to the World's class jumpers, in addition to higher horizontal velocity, vertical velocity and the takeoff angle at the takeoff. These results might suggest that the effective takeoff motions required under the head wind condition are same as the takeoff motion required under legal wind condition of 2m/s. Further studies are needed to clarify the suitable takeoff motion under the strong head wind condition exceeded 2m/s.

P218 - ANALYSIS OF ANKLE JOINT MOTION WITH DIFFERENT TYPES OF SPORTS CLIMBING SHOES

[1] **Seungbum Park**, [1]Kyungdeuk Lee, [1]Daewoong Kim, [1]Junghyeon Yoo, [1]Jaemin Jung, [1]Kyunghwan Park
[1]Footwear Biomechanics Team, Footwear Industrial Promotion Center, Busan Economic Promotion Agency, Korea
Corresponding author email: sbpark@shoenet.org

INTRODUCTION

Climbing shoes are the most important and the most basic equipment needed for sports climbing. Different from other leisure sports, the importance of the shoes is emphasized [1]. Climbing shoes stabilize the feet on the different types of holders on the artificial wall, improving climbing abilities of the wearer. The outsoles design of the climbing shoes are different based on the difficulty level of the climbing wall, which is related to different techniques required in different difficulties. Selection of unsuitable climbing shoes without taking into consideration the technical abilities of the wearer can lower the user's climbing ability and could produce injuries. Therefore, in this study, different ankle joint motions while wearing different types of shoes and performing climbing techniques were investigated to determine the possibility of injuries on the ankle joint.

METHODS

Twenty participants with over 5 years of sports climbing experience and who can perform the sports climbing motions required for this study were selected. All participants voluntarily participated in this study after detailed explanation of this study's purpose. The shoes used in this study were Type A, which is for intermediate and advanced-leveled climbers, and Type B, which is for beginners and intermediate leveled climbers. In an artificial climbing wall, the participants were asked to complete 3 sections using intermediate and advanced techniques, including outside step, inside step, foot switch, counter balance, and heel hooking in order. While the participants were performing the techniques and completing the climbing sections, their range of motion of the foot joint was recorded with 12 of 3D motion analysis infrared cameras (3D motion analysis, USA) and data were collected. The participants had plenty of practice time before the measurements and each participant underwent 3 trials. The average measurement was reported. To prevent fatigue, plenty of rest was allowed between trials and the order of shoe types were assigned randomly.

Figure 1: Shoes used in this study and Experimental Scene

RESULTS AND DISCUSSION

Lately, rock climbing, which requires professional higher-level skills compared to regular hiking, has been gaining popularity in South Korea. In 2012 and 2013, Korean climbers have won 1st places in International Sports Climbing World Cups, which caused the interest on climbing to skyrocket. Ankle stability is essential for sports climbing. Not limited to dorsiflexion of the ankle joint, large plantar flexion strength is required for rock climbing [2]. Based on the properties of sports climbing, ergonomic design for shoes that are tight fitting and that allow maximized scrunching strength are essential. Also, horizontal stability is a very influential factor that could affect performance [3]. The results of this study indicate that Type A shoes allowed larger range of motion for plantar flexion, which is equivalent to higher driving force, than Type B. Also, Type A shoes showed a narrower range of motion in terms of stability and shaking. Selection of inappropriate shoes can produce inversion and eversion stress while performing intermediate and advanced techniques. Also, inappropriate shoes can negatively impact the ankle joint structures after repetitive climbing motions [4,5]. Climbing shoes that allow stable support have large range of flexion, which could increase the effectiveness of climbing.

Figure 1. Range of motion of ankle joint during sports climbing

Motion(°)	Type A	Type B	t	p
Dorsi Flexion	19.90±13.06	20.28±8.78	.577	.56
Plantar flexion	22.49±15.91	20.40±17.21	2.139	.03*
Eversion	1.19±7.64	-3.08±14.04	6.432	.00**
Inversion	17.88±7.22	18.08±9.98	-0.385	.70
Pronation	2.35±8.82	-0.41±8.18	5.530	.00**
Supination	16.73±9.80	18.10±10.30	-2.306	.02*

CONCLUSIONS

Selection of shoes that are inappropriate for climbing technique level not only reduces performance but also increases stress on the ankle joint structures.

P219 - ANALYSIS OF FOOT PRESSURE AND TOE SPRING IN DIFFERENT PORTIONS OF BOBSLEIGH TRACKS TO DEVELOP BOBSLEIGH SHOES SPECIALIZED FOR KOREANS IN 2018 PYEONGCHANG WINTER OLYMPICS

[1] **Seungbum Park**, [1]Kyungdeuk Lee, [1]Daewoong Kim, [1]Junghyeon Yoo, [1]Jaemin Jung, [1]Kyunghwan Park, [2]Sungwon Park and [2]Jinhoon Kim

INTRODUCTION

Bobsleigh is one of the fastest winter sports where the difference of only 1/1000th of a second identifies the winner [1]. Improving time in the initial portion of the track is crucial to improve the overall time [2]. At the start of bobsleigh, the shoe should be able to transfer explosive power to the slippery floor surface to effectively push the heavy sleigh. Although time in the initial portion of the track is very important, most of bobsleigh shoes are designed to fit Westerners' foot shapes. Therefore, this study investigated the time in the initial portion of the track, foot pressure, and toe spring of Korean bobsledders while wearing sprint shoes in order to provide basis for the development of bobsleigh shoes specialized for Koreans.

METHODS

Seven bobsledders who represent South Korea from Gangwondo association of bobsleigh/skeleton and Sangji Daegwanryeong high school were the subjects of this study. The sprint shoes used in this study were Type A, Type B, and Type C with different toe springs. Bobsleigh start motion was conducted in a small field. While wearing their respective sprint shoes, the participants pushed bobsleigh for 15m, where the time and the foot pressure was measured and analyzed in the peak speed. The toe bending angle was measured and analyzed 5m from the start point using a high-speed camera.

Figure 1: Shoes used in this study

RESULTS AND DISCUSSION

At the start of the bobsleigh race, the bobsledders have to run as fast as they can by releasing explosive strength on short ice track. Therefore, bobsleigh shoes need to maximize traction between the slippery ice track and the shoe. Also, the shoes must be designed to improve the bobsledders' performance. Although the results of this study were not significantly different, Type B shoes were observed to be more effective than Type A and Type C shoes in improving time in the initial portion of the track. The foot pressure in Type B was significantly different than in Type A in terms of contact area. In the mid-foot, Type B was significantly different from Type A and Type C. The hardness of the shoe's outsole and midsole are related to energy return, which is required to acquire driving force [3,4]. Type B used in this study is a spiked sprint shoe designed for track & field, where the sole is harder than that of Type C, which was designed for mid-range and long-range races. Although no significant difference was statistically observed and Type A was also spiked shoes designed for sprinting, its toe spring was larger and starting record was slower than Type B. In summary, Type B shoes provided optimal toe spring and moment between surface-contact to toe off. Although the forefoot is similar to other control groups, Type B allows large contact area up to the mid-foot, which provides high traction on the ice track.

Table 1 : The results of experimental parameter

Shoe Type			Type A	Type B	Type C	p
Start lap time(sec)			3.55±0.19	3.52±0.17	3.56±0.18	.09
Forefoot bending angle(°)			16.47±6.01	14.30±4.96	15.90±5.17	.42
Foot pressure	Contact area(cm^2)	Foot total	108.56±12.59	123.19±8.67[a]	116.16±11.19	.00***
		Forefoot	57.73±2.49	58.03±2.74	58.07±2.78	.90

*p<0.05, **p<0.001, [a]: significantly different between Type A and Type B, [b]: significantly different between Type B and Type C, [c]: significantly different between Type A and Type C

CONCLUSIONS

Development of bobsleigh shoes specialized for Koreans using the properties and structures of Type B shoes will improve the start motion in bobsleigh races. In further studies, actual bobsleigh shoes should be made based on the Type B shoes used in this study to investigate its functionality and suitability on real ice tracks.

P220 - TRAINING THE INTRINSIC FOOT MUSCLES: TESTING ITS FEASIBILITY AND EFFECTS ON FOOT STRENGTH

[1] **Ulisses T Taddei**, [1]Alessandra Matias, [1]Rafael Inoue, [1]Fernanda Iacovanduano, [1]Isabel C.N. Sacco
[1]Physical Therapy, Speech and Occupational Therapy dept, School of Medicine, University of São Paulo, São Paulo, Brazil
Corresponding author email: utaddei@usp.br

INTRODUCTION

Evidences shows that when the intrinsic foot muscles are weak or dysfunctional, tasks such as maintaining the foot arches, absorbing, dissipating and returning kinetic energy during walking and running or generating power and torque during propulsion might be compromised. As a result, there will be increased loads carried by other passive structures, such as the plantar fascia, might occur excessive pronation and impairments in several activities' performance, which ultimately might end up increasing the incidence of foot deformities or injuries.

Therefore, interventions whose objectives focus in improving strength, health and foot-ankle range of motion can be beneficial to long-distance runners, a population that frequently abuse of these tasks for long periods.Increasing the intrinsic foot muscles strength and function to maintain an ideal foot structure, would enhance their capability of absorbing and damping forces, possibly delaying or even preventing the occurrence of running-related injuries.

However, how one can be sure that the foot exercises described in the literature are really capable of enhancing strength and trophism of intrinsic foot muscles either to have their effects dissipating thorough the whole musculoskeletal system?

Therefore, an eight-week foot and ankle therapeutic exercise protocol for strengthening and improving functionality developed exclusively for the study is to be tested regarding its feasibility and its effects on strength and muscle trophism.

METHODS

In this feasibility study of a major RCT (Clinicaltrials.gov Identifier NCT02306148), four healthy long-distance male runners (31.8 ± 2.5 years) with at least one year of running experience were recruited (Ethics Committee approval protocol HCFMUSP #031/15) and randomized to one of two groups: Intervention group (IG) with an eight weeks foot muscles training protocol or control group (CG) performing a placebo stretching protocol for the lower limbs. Foot strength test and foot MRI were performed at baseline, after eight (T8) and 16 weeks of study (T16). All participants had to enter their weekly training volume, time of practice and exercise protocol performance (IG) data at least once a week in a web-software developed. Toes and hallux strength was assessed using a pressure plate (EMED, Novel, Germany) [1]. Foot MRI images were acquired by the same technician using a 0.5T system and procedures according to Chang (2012) [2]. To assess the cross-sectional area (CSA) of foot intrinsic muscles, we used the ImageJ software [3] and the muscle volume (MV) was calculated according to Miller (2014)[4].

RESULTS AND DISCUSSION

Mean running volume during the 16 weeks of study was 294.8 km (±172.7 km) for IG and 117 km (±102.9 km) for CG. Isometric strength of toes and hallux flexors normalized by bodyweight for all participants is shown in Fig.1 and although only four subjects were quantified at the moment, the left hallux strength increased in all subjects at T16 comparing to T0 ($p<0.05$ Friedman's test). Qualitative analysis shows a decrease in hallux isometric strength for CG while these values were always higher than baseline for the subjects in IG.

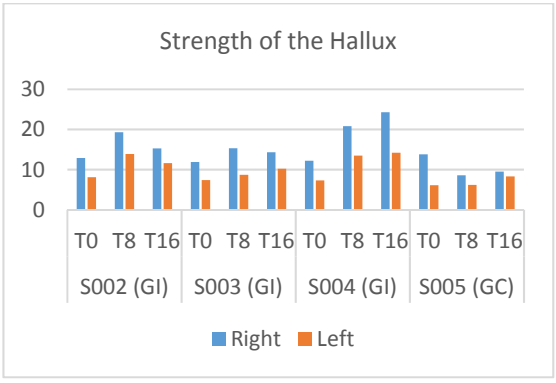

Figure 1: Hallux strength measured by EMED plate at baseline (T0), eight (T8) and 16 weeks (T16). Subjects are divided in intervention (IG) and control group (CG).

Regarding the CSA and the MV, a similar pattern was found, with the IG showing an increase from T0 to T8 for all muscles measured (15.5%), while CG only increased for *flexor hallucis brevis.* For T16, both groups decreased their MV and CSA, IG reduced 13.7% and CG reduced 29.9%.

CONCLUSIONS

Although it is early to conclude whether or not the training protocol is effective for strengthening the intrinsic foot muscles due to the number of subjects analyzed, graphic tendencies might point to future results when time is considered. These results also points that not only the training protocol but also the running volume are extremely important to intrinsic foot muscles strength, being important to consider the last one as a covariate while analyzing foot strength.

P221 - STRUCTURAL CHANGE OF SCAFFOLDS AS A RESULT OF EXTERNAL STRAIN

Jana Anderova, Frantisek Lopot, Martin Moravek, Daniel Hadraba and Karel Jelen Charles University in Prague, Faculty of Physical Education and Sport
Corresponding author email: ja.anderova@seznam.cz

INTRODUCTION

Uniaxial tensile test is the most commonly used method for determining the mechanical properties of the scaffold. Authors differ only in technical details of a particular test design. Studies have been conducted, in which the electron microscope is used to compare structure of scaffolds or to establish cooperation with biological material. Pavia, et al. used SEM to observe the cross section of the scaffold [1]. Shi et al. used SEM for detecting connection of cells and scaffold [2]. In this paper, we used SEM to detect change of the scaffold´s structure in connection with its mechanical loading in real time.

METHODS

The research subjects were nanofibrous scaffolds made of polylactic acid (PLA) with areal density of 16 g / cm2. Scaffolds were produced by the same procedure, while one of them was cross-linked for 30 seconds at 75 W. Quanta 450 scanning electron microscope from FEI company was used to detect the structure of scaffold. Samples were adjusted to the dimensions of 25x10 mm and sputter coated with gold (K55OX) before scanning.

Samples were scanned under high vacuum to 10-4 Pa, at an accelerating voltage of 10 kV, at a working distance 20 to 45 mm. A regime of secondary electrons was used, scanned by Everhart-Thornley detector.

We used open source software Fiji to identify the basic parameters of the samples.

Evaluated parameters were fibre directivity and the thickness of the scaffold fibres. Additionaly, comparison of these parameters was made on cross-linked and non-cross-linked scaffolds.

RESULTS AND DISCUSSION

A total of six samples of scaffold images were evaluated, with a magnification of 500x in four conditions. For non-cross-linked scaffolds, the evaluation was made in idle mode, at a relative elongation of 10%, 20% and 40%. For cross-linked scaffolds, the relative elongation was adjusted to 8%, 10% and 20%. Measurement results (figure 1) show, that the directivity of fibres increases with the relative sample elongation. All samples results were processed this way; and the comparison was made between scaffolds sequestered (cross-linked) and non-cross-linked.

Changes in the fibre thickness, was evaluated for all samples, histograms were created and average fibre thickness listed in the tables.

Although the values of average thickness fluctuate, it is only within the range of standard deviation. The standard deviation for all samples is relatively large for the measured value. Example shows the average thickness of the fibres for non-cross-linked sample: At elongation of 0%, the average thickness of the fibres is 480 ± 190 [nm], at elongation of 10%, the average thickness of the fibres is 510 ± 240 [nm], at an elongation of 20%, the average thickness of the fibres is 510 ± 230 [nm], at an elongation of 40%, the average thickness of the fibres is 520 ± 240 [nm]. This may be due to the large dispersion of fibre scaffold, which is evident from the histograms, or the optical observation image

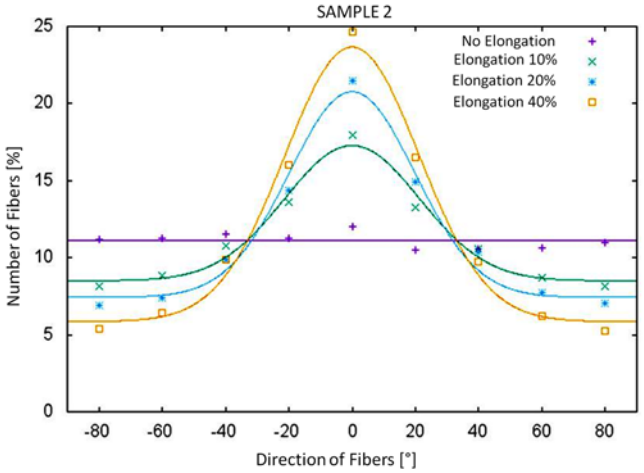

Figure 1: *Directivity of Fibres of Non-cross-linked Scaffold*

CONCLUSIONS

When the samples are elongated, the fibres of cross-linked scaffolds appear less directed/organized in the direction of the strain in comparison with the non-cross-linked scaffolds.

Due to the relative elongation of the scaffold, the trends in change of samples with varied thickness of the fibres was not established

P222 - *IN VIVO* SARCOMERE LENGTH DISTRIBUTION IN WHOLE MUSCLE TETANIC CONTRACTION

[1] **Eng Kuan Moo**, [1]Timothy R. Leonard and [1]Walter Herzog
[1]University of Calgary
Corresponding author email: ekmoo@ucalgary.ca

INTRODUCTION

The maximal, steady-state, isometric force produced by a muscle depends on its sarcomere length (SL) according to the classic 'cross-bridge' theory [1]. Previously, we found that i*n vivo* sarcomere lengths are non-uniform in muscle at rest [2]. Also, it was found in previous studies using single myofibrils that sarcomere length non-uniformities increase during activation and force production [3]. However, single myofibrils lack much of the structural proteins that provide stability to entire muscles, thus the observed SL non-uniformities in myofibrils might not occur in whole muscles. This study was aimed at investigating changes in SL distribution during tetanic contractions in intact muscles of live mice.

METHODS

Mice (N=4) were anaesthetized using isoflurane. The proximal femur and foot of the left lower limb were clamped. The skin over the left tibialis anterior (TA) muscle was opened and stretched to form a pool for a saline bath that allowed for imaging using water-immersion, multi-photon microscopy. The TA was supra-maximally stimulated using a nerve cuff electrode on the sciatic nerve using 0.1ms square wave pulses at 60Hz for 600ms. Two fluorescent markers that were 1mm apart were applied to the mid-belly of the muscle. Through the eyepiece lens and fluorescent light, displacements of the two fluorescent markers resulting from muscle contraction were determined. A location between these two markers was selected for sarcomere imaging using second harmonic generation (SHG) laser microscopy for short (90° ankle joint angle) and long TA length (180° ankle joint angle) under passive and active conditions. Using a custom-written MATLAB code, SLs were measured from the SHG images for passive and active conditions over an area of 160x3 μm^2 in the mid-belly of the TA. SLs were corrected for out of plane orientation.

RESULTS AND DISCUSSION

Consistent with our previous work [2], SLs for the passive TA at the short length were 2.26±0.07µm (mean±sd), and increased by 12% to 2.53±0.07µm when the TA was passively stretched to the long length (Figure 1A).

During contraction, sarcomeres shortened by <4% at the short TA length, and by <2% at the long length (Figure 1A). Similar observations have been made in single intact active fibres, in which SLs stayed relatively constant in the mid-muscle but shortened substantially at the two ends [4].

At short TA length, the coefficient of variation (CV) of the SLs almost doubled from 3.5±1.4% at rest to 6.5±1.5% during activation (Figure 1B). The range of SLs also increased from passive (2.06–2.45µm) to active (1.83–2.58µm) states. At long TA length, SLs were more uniform than at short TA length. As for the long TA length, the CV of SLs increased from passive 3.0±0.4% to active 4.3±1.1% (Figure 1B). The increase in non-uniformity in SLs during activation is consistent with previous studies using myofibrils [3].

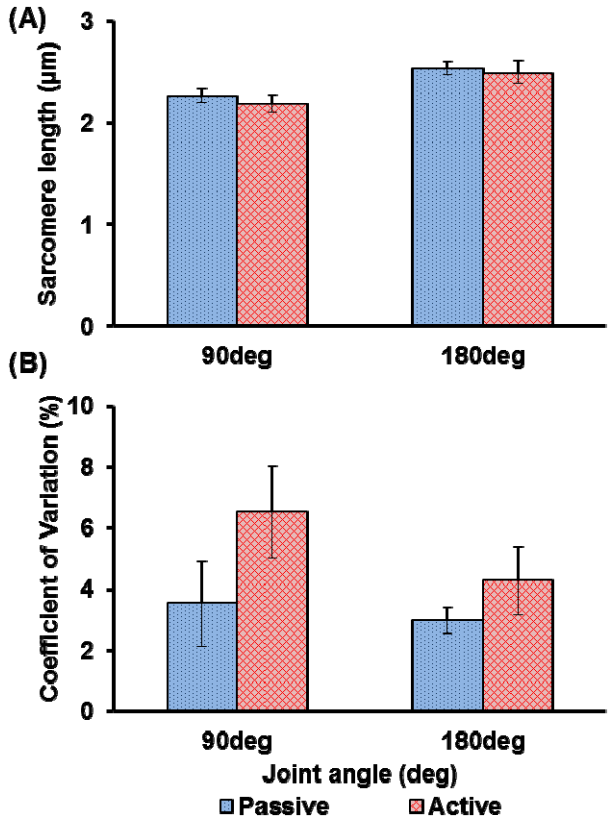

Figure 1: (A) Sarcomere lengths and, (B) coefficient of variation of sarcomere lengths in short (90deg) and long (180deg) TA lengths for passive and active conditions.

CONCLUSIONS

SL non-uniformity doubled during muscle activation and differed by more than 0.7 µm in a small area of the TA. SL non-uniformity is more pronounced at short compared to long muscle lengths. The functional implications of these substantial SL non-uniformities need to be explored, and the common practice of representing muscles with a single SL value needs to be reconsidered. Future studies will focus on investigating the SL re-distribution during active contraction at the proximal and distal ends of TA muscle.

INTRODUCTION

Regenerative medicine and medical transplantation using autologous cells have attracted attention as fundamental treatment methods for diseases. Regenerative medicine can circumvent the problems of conventional medical transplantation such as donor shortage, immune rejection, and harmful side effects of immunosuppressive agents. The potential for practical use of regenerative medicine or medical transplantation technology has been growing through intensive research efforts. One of the techniques put to practical use is skin transplanting made by the sheet-shaped patient's own cells [1]. In addition, cell assembly techniques were developed by several researchers for creating tissues [2-3]. Herein, we attempt to create heterocellular tissues using two-dimensional (2D) cell patterns comprising different types of cells. This technique is applicable to three-dimensional (3D) artificial tissue creation techniques such as multilayer laminated cell sheets [1] and cell origami [3].

MATERIALS AND METHODS

The alginate gel is used as a hydrogel material that inhibits cell adhesion. The alginate film is formed on a glass plate by a cross-linking reaction of sodium alginate. EDTA or alginate lyase was used to remove the alginate film. EDTA chelates bivalent metals and can dissolve the carboxylate and calcium ions of the alginate film. Alginate lyase is an alginate-degrading enzyme that cleaves the internal glycosidic bond of the alginate film. The cell micropatterns were created by gel micromachining process that developed by authors as shown below. The alginate gel was formed by spin-coating. A photoresist is patterned by general photolithography on the alginate film. Then, the alginate film pattern is fabricated by etching with alginate lyase or EDTA based on photoresist pattern. Cells ("A"Cell) are disseminated on the glass plate having alginate micropatterns. The various cell micropatterns are created along the alginate micropatterns. The alginate micropatternas are removed by alginate lyase during cultivation, and a different cell type was disseminated. The second type of cells ("B"Cell) could be patterned alongside the first within the same culture dish.

RESULTS AND DISCUSSION

The processing accuracy of alginate micropatterns was evaluated. When EDTA was used as the etching reagent, the corners of the formed micropatterns were rounded, and spaces between alginate coated regions were broader than designed (Fig.1(a)). The minimum widths of lines and spaces were 50 μm and 30 μm, respectively. When the alginate micropatterns were formed by alginate lyase etching, the micropatterns and spaces were precisely formed as designed (Fig.1(b)). The minimum widths of lines and spaces were 20 μm. The cells in linear and square islands of different sizes on the patterned substrates after 24 h cultivation were created by presented methods (Fig.1(c,d)). These results indicate that cell micropatterns at the single-cell level can be created by using islands with <20-μm wide cell-adhesive surfaces, and we can create cell micropatterns with widths >20 μm. The formation and configuration of cells were controlled by the fabricated alginate film micropattern. Moreover, we created a cellular micropattern comprising different types of cells. After forming the "A" cells micropattern, the alginate film was removed using alginate lyase, and "B" cells were added. The "B" cells adhered to the newly exposed regions. After 12 h of culture, the heterogeneous cell micropattern was successfully created (Fig.1(e,f)) and cells co-cultured on the same dish. This result indicates that multiple cell types could be patterned within the same culture dish to create functional tissues comprising heterogeneous cells.

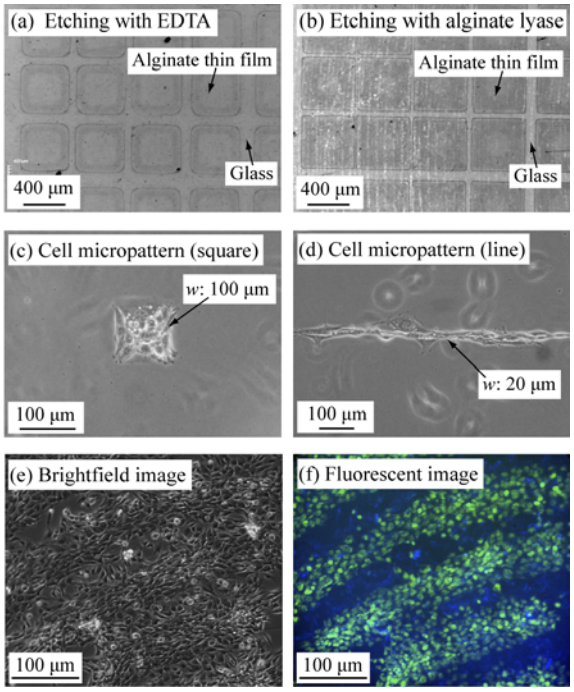

Figure 1: Photographs of created alginate patterns and cell micropatterns.

CONCLUSIONS

In this paper, we apply the general photolithography, has developed two types of cells micropatterning technique by patterning the alginate. This technique can create the multiple cell type pattern within the same culture dish to create functional tissues comprising heterogeneous cells.

P224 - NUMERICAL ANALYSIS OF A RED BLOOD CELL IN AN EXTENSIONAL FLOW

[1]**Stephanie Nix**, [1]Yusuke Oguma and [1]Yukitaka Ishimoto
[1]Akita Prefectural University
Corresponding author email: snix@akita-pu.ac.jp

INTRODUCTION

Rupture of red blood cells occurs under two types of conditions: when the cell is suspended in a shear flow with a large shear rate for even a short period of time; or when the cell is suspended in a shear flow with a small shear rate for an extended period of time [1]. Previous numerical studies on the dynamics of red blood cells in flow have mainly focused on the evolution of the cell deformation and membrane tension as a function of the shear rate when the cell is suspended in a simple shear flow or Poiseuille flow.

However, to induce the rupture of a red blood cell during a simulation, it is most straightforward to analyze the behavior of the cell in an extensional flow, in which the red blood cell is compressed along its minor axis while it is pulled along one of its major axes, as the mechanism of rupture is likely related to a forced increase in the surface area of the red blood cell membrane. In this study, we numerically simulate the behavior of an intact red blood cell in an extensional flow as a first step toward the understanding of the flow-induced rupture of red blood cells.

METHODS

The numerical method used in this study is based on the method developed by Walter et al. [2], in which the deformation of the red blood cell membrane is solved using the finite element method, and the velocity fields of the fluids both inside and outside the cell are solved using the boundary integral method.

The initial biconcave shape of the red blood cell is given by the function for the red blood cell resting shape first proposed by Evans and Fung [3]. The constitutive law of the cell membrane is given by the Skalak law [4], which was developed specifically to model the red blood cell membrane. The Skalak law has separate shear and area dilation terms, and in this study, we consider a membrane with a shear modulus of G_s and an area dilation constant of $C = 10$, where the area dilation modulus is given by $(1 + 2C)G_s$.

The inner and outer fluids are modeled as Newtonian fluids with viscosity μ. Though the interior of the red blood cell is considered to have a viscosity approximately five times that of blood plasma, the final shape of the red blood cell is unaffected by the viscosity of the solution inside the red blood cell. Thus, we consider the case of equal viscosities to simplify the computation.

The parameters in the simulation are non-dimensionalized as follows. Lengths are non-dimensionalized by the major axis a of the red blood cell. Velocities are non-dimensionalized by the characteristic velocity $\dot{\varepsilon}a$, where $\dot{\varepsilon}$ is the rate of strain of the flow. By non-dimensionalizing the governing equations, the simulation can be described by a single parameter, the strain capillary number, $Ca = \frac{\mu \dot{\varepsilon} a}{G_s}$.

RESULTS AND DISCUSSION

An example of the computational results are shown in Figure 1. The red blood cell undergoes compression in the z-direction and expansion in the x-direction. Initially, the concave portion of the red blood cell remains concave as it is stretched in the x-direction. Then, as the red blood cell is stretched further, the shape of the red blood cell becomes ellipsoidal, with sharp edges at the points of maximum extension. This shape is also observed in experiments on red blood cells in high shear [1].

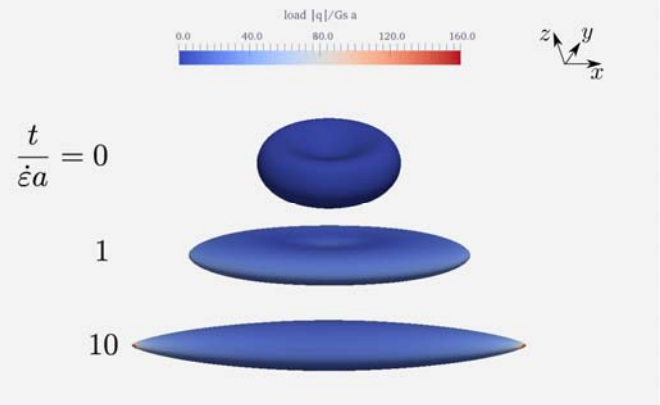

Figure 1: Superimposed snapshots from simulation of red blood cell suspended in extensional flow. The times at which the snapshots are taken are nondimensionalized by the characteristic extensional flow velocity and shown to the left of each cell.

CONCLUSIONS

In this study, the shape of a red blood cell in high shear was reproduced in simulations of a red blood cell in extensional flow. As the shape obtained resembles that of a red blood cell in conditions that lead to red blood cell rupture, we expect that this simulation can be used as a base for the investigation of flow-induced rupture of red blood cells.

P225 - EFFECTS OF VISCOELASTIC PROPERTIES OF PLAQUE WALLS ON LUMINAL DIAMETER VARIATION

[1] Tae Hun Noh, [2]Gon Khang and [1]**Kyehan Rhee**
[1]Myongji University
[2]Kyung Hee University
Corresponding author email: khanrhee@mju.ac.kr

INTRODUCTION

Viscoelastic properties of plaque wall tissues provide important biomechanical characteristics related to tissue composition and pathological process. Because viscoelastic wall properties change as the atherosclerotic disease progresses, estimation of wall viscoelasticity may provide a valuable assessment tool for plaque rupture prediction. Motivated by the hypothesis that wall viscoelastic property is related with plaque progression, the effect of plaque wall viscoelastic characteristics on lumen diameter variation was studied. Luminal diameter changes of coronary artery models under pulsatile pressure loading were analyzed using a finite element method for different plaque wall viscoelastic properties, and the effect of viscoelastic parameters of the plaque wall on wall stress and deformation was explored.

METHODS

Cross section of the stenotic coronary artery was modeled based on the IVUS (intravascular ultrasound) image obtained from a patient. Outside wall of the intima was fitted to the circle of the radius of 3.75 mm, and intimal wall was composed of the fibrous tissue and the necrotic lipid core regions, which were determined from virtual histology of IVUS. Three different viscoelastic properties were used to simulate the intima of the normal vessel (NV), the less viscoelastic vessel (LVV), and the elastic vessel (EV). NV model simulated the healthy intima tissue, and the Voigt viscoelastic model (elastic coefficient of 260 kPa, viscous coefficient of 3 kPa·s) was used. For LVV model, anisotropic elastic vessel model [1] was modified to include viscous effects using the Prony series as in the reference [2]. The Young's moduli for radial, axial and circumferential direction were 100 kPa, 1,000 kPa, and 1,000 kPa, respectively. EV model simulated the purely elastic wall with the same anisotropic properties as LVV. The lipid core was modeled as an incompressible elastic material with the Young's modulus of 1 kPa [3].

The two dimensional coronary artery cross section was modelled in Solid Works (Dassault System, Waltham, MA), and imported to the finite element analysis software (ANSYS Workbench 17.0, Cannonsburg, PA). Outer wall of the artery was fixed in all direction, and intramural pressure was applied to the inner wall. The physiological pressure wave had the period of 1 sec, and the pulse pressure was 6.3 kPa. Transient computational analysis was performed with the time step of 3.9 ms under the periodic pressure loading, and the stress and displacement values were converged within 5% of the previous step values within three periods of simulation.

RESULTS AND DISCUSSION

Vessel wall stress and displacements were calculated for three different models. The maximum equivalent stress (PCS: peak cap stress) was found near the thinnest fibrous tissue between the lumen and the lipid core (fibrous cap) at peak pressure. PCSs were 86.5 kPa, 73.3 kPa, and 131.7 kPa for NV, LVV, and EV model, respectively. The maximum displacements were found not at the fibrous cap with the minimum thickness, but at the outer boundaries between the lipid core and the intimal fibrous tissue. The displacement peak values and waveform changed for different models. The luminal wall displacement variations at the thinnest cap location were 0.103 mm, 0.115 mm, and 0.135 mm for NV, LVV, and EV model, respectively. The elastic models (EV) showed similar waveforms as the pressure waveform, and the peak displacement increased as the elasticity reduced. Waveform changed noticeably for the isotropic viscous vessel model (NV), and the displacement peak lagged the pressure peak by 0.04 s. The peak of displacement wave was slightly lagged for the LVV model, and there was no phase lag for the EV model.

Progression of the atherosclerotic disease changes the cellular function and composition of the plaque walls. Decrease of smooth muscle cells and increase of macrophage recruitment reduce the wall tissue integrity, which causes the plaque wall more susceptible to rupture. Because smooth muscle cells are important wall constituents contributing to viscoelasticity [4], estimation of wall viscosity based on the wall displacement waveform analysis may provide wall tissue composition information, which help diagnosing vascular wall diseases.

CONCLUSIONS

The effect of plaque wall viscoelasticity on lumen diameter variation was investigated in this study. Structural analysis was performed for the cross section of the atherosclerotic plaque wall tissues which had different viscoelastic properties. Decrease of viscous effect increased the deformation and stress, and decreased the phase angle between the pressure and displacement waveforms. Because viscous effect of tissue components could be identified using the phase angle difference, wall displacement wave analysis might be applied to predict plaque wall composition change and vascular wall disease progression.

P226 - DYNAMOMETRY RELIABILITY TESTING REVEALS FASTER PROGRESSION OF STRESS RELAXATION IN INITIAL ELONGATION OF PELVIC FLOOR TISSUES

[1] **Catriona S. Czyrnyj**, [2]Marie-Ève Bérubé and [2]Linda McLean

INTRODUCTION

Intravaginal dynamometry has provided invaluable insights into pelvic floor muscle (PFM) mechanics in women, where women with various disorders have demonstrated altered passive tissue resistance [1]. The interpretation of stiffness and stress relaxation characteristics of the pelvic floor tissues may be limited by the manual control of aperture opening [1]. The purpose of this study was to evaluate the reliability of measures of passive PFM characteristics made using a new servo-controlled automated dynamometer.

METHODS

Protocol approval was granted by our institutional research ethics board. Twenty nulliparous women attended a familiarization session (V1) during which they provided informed consent and underwent the study protocol. Women returned for a second (V2) and third (V3) visit, from which the data were analyzed for the purposes of this study. In the supine position, women inserted the lubricated arms (printed in ABS) of the servo-controlled dynamometer into their vagina. An initial antero-posterior (AP) diameter of 15mm was used, and once the baseline resistance force was stable and the woman was relaxed, elongation of the tissues occurred as the arms of the dynamometer opened to an AP diameter of 40mm at a constant velocity, either 18mm/s (fast) or 9mm/s (slow). The tissues were held at this elongation for 5s, and then returned to the original position (AP diameter =15mm). Three trials of each task (slow and fast) were performed with 60s of rest between trials.

Data were filtered using a fourth order, dual pass, low pass Butterworth filter (5Hz cutoff), and resistance forces at the baseline and peak (PRF), 1s (PRF1) after, and 5s (PRF5) after maximal opening were determined. All measures, except the baseline resistance, were calculated as change from baseline. Repeated measures, one-way analyses of variance (ANOVAs; α=0.05) tested between-trial and between-day differences, while intra-class correlations (ICCs; 95% confidence interval) and minimum detectable change (MDC) assessed within- and between-day reliability.

RESULTS AND DISCUSSION

Participants (N=20) had a mean (±SE) age of 35(±3) years and body mass index of 23(±1) kg/m^2 and exhibited a higher baseline resistance, and lower PRF1 and PRF5 in trial 1 with respect to trials 2 and 3 for many outcomes (Table 1). This indicated faster progression of stress relaxation in trial 1, thus between-trial reliability was calculated using trials 2 and 3 only. No significant between-day effect was found.

The between-trial effect, recently attributed to thixotropy [1], has been identified as a by-product of the short-range elastic component (SREC) of skeletal muscle to sarcomere elongation [2]. While we did not measure sarcomere length, thixotropy may be one of the factors underlying the faster progression of stress relaxation of the pelvic floor tissues in women.

CONCLUSIONS

Our custom, servo-controlled dynamometer yielded excellent between–trial reliability and moderate to very good between-day reliability. Further testing is required to investigate differences in the progression of stress relaxation between repeated trials of pelvic floor tissue elongation.

P227 - THE INFLUENCE OF CHRONIC ANKLE INSTABILITY ON LOWER EXTREMITY MUSCLE ACTIVIATION OF FEMALES DURING LANDING

[1] **Yumeng Li**, [2]Jupil Ko, [3]Marika Walker, [3]Julianne D. Schmidt, [4]Cathy N. Brown and [3]Kathy J. Simpson

INTRODUCTION

Chronic ankle instability (CAI) usually develops after an initial ankle sprain [1]. CAI may be related to knee injuries (e.g., ACL injury) due to the alterations of lower extremity biomechanics during high-impact movements [2]. One possible reason for the altered biomechanics is differences in neuromuscular control. However, much remains unclear that how CAI could affect knee muscle activations and interact with knee biomechanics and ACL loading. Therefore, the purpose of the present study was to assess the influence of CAI on lower extremity muscle activation during the landing onto tilted surfaces.

METHODS

A surface electromyography (EMG) system was used to collect lower extremity muscle activation of 21 young female individuals with CAI and 21 pair-matched control participants (CON) during a double-leg landing with test limb (CAI limb) landed on a 25° tilted force plate. The drop-landing height was 30 cm. The EMG electrodes were attached on the muscle belly of tibialis anterior (TIB-ANT), gastrocnemius lateralis (GAS-LAT), peroneous longus (PER-LON), rectus femoris (REC-FEM), vastus lateralis (VAS-LAT) and biceps femoris (BIC-FEM). The EMG data were filtered, rectified; and the linear envelope was generated using a low pass filter at 10 Hz and normalized to the linear envelope of the maximum voluntary isometric contraction (MVIC). The data were then averaged for the 50 ms before initial contact (IC) and for the first 100 ms after IC to represent the amplitude of muscle activation during the pre-landing and landing phases, respectively. Ten acceptable landing trials were analyzed for each participant. Comparisons of EMG variables between CAI and the CON group were using paired *t*-tests ($p < 0.05$).

RESULTS AND DISCUSSION

Compared to CON group, CAI group exhibited (~70% MVIC, $p<0.01$) less PER-LON activations in the pre-landing phase (Fig 1), which may result in an increased pre-landing ankle inversion angle for CAI group and reduce the ankle stability. In the landing phase, CAI group exhibited (~60% MVIC, $p<0.01$) greater TIB-ANT activation. This could be a strategy that employing active stabilizers (i.e., TIB-ANT muscle) to compensate for the limited ability of passive stabilizers (e.g., ligaments) of CAI group. CAI group also exhibited greater knee extensor activation (80% MVIC for REC-FEM and 53% MVIC for VAS-LAT, greater than CON) but reduced knee flexor activation (17% MVIC for BIC-FEM, less than CON). The greater knee extensor activity could increase the anterior shear force applied at the proximal end of the tibia, which is the primary contributor of ACL loading [3]. On the other side, the reduced knee flexor activity could reduce the forces that counteract the anterior shear force. Therefore, CAI group may undergo greater ACL loading, especially during the early landing phase (100 ms post IC).

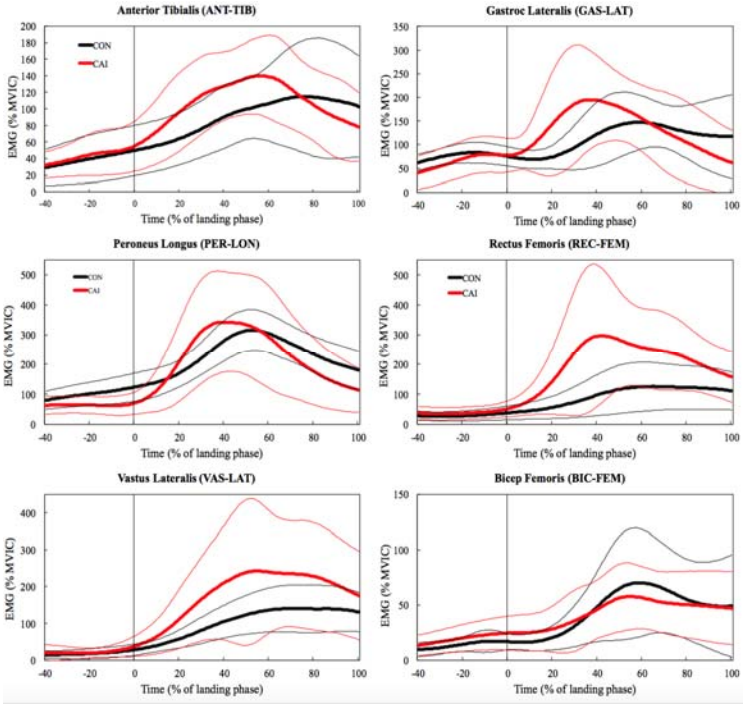

Figure 1: Group ensemble average curves of the linear envelope EMG (+/- SD) of lower extremity muscles. Initial contact = 0% and end of landing phase = 100%. A portion of the pre-landing phase is also shown.

CONCLUSIONS

Individuals with CAI displayed some differences of lower extremity muscle activation compared to CON during landing. We conclude that the muscle activity alterations may be related to ACL loading. Relevant training programs (e.g., increasing pre-landing peroneal activation, optimizing activation ratio of quadriceps to hamstrings) may help individuals with CAI improve ankle stability and reduce atypical knee loading. However, future study may need to confirm whether these altered lower extremity muscle activities could increase ACL stress.

P228 - BIOMECHANICAL COMPARISON OF WARM-UP PROCEDURES FOR ACHILLES TENDON

[1] **Ya Hsun Shen**, [2]Shuo-Ju Chiang, [1,2]Chih-Hwa Chen, [1]Hsiang-Ho Chen,

INTRODUCTION

With the development of the society, leisure activities and exercises, especially jogging, are becoming more popular. More and more females participate in sports, virtually evolving into a trend. However, many people are busy and warm up exercises can be ignored easily, which may result in sports injuries. Achilles tendon (AT), commonly known as the calcaneus tendon, is located in the back of the calf. At the end of the gastrocnemius, it tapers off and becomes tendon tissue connecting to the calcaneus, serving as the connection between muscle and bone. AT is the body's thickest, largest and strongest tendon, with an average length of 15 centimeters. Its flexibility is critical during exercise, as it can withstand 8 times the body's weight while running and jumping. Repeated stretching causes the AT to become fatigued, leading to rupture [1]. This study focuses on the effects of two different warm up routines on the AT of females who exercise regularly. We utilize jogging and hot compresses as the two warm up methods and then analyze the risk of injury posed to the AT.

METHODS

Ten untrained female amateurs, who regularly participated in recreational running and were able to comfortably run 2 kilometers, volunteered to participate in this study. Candidates with any history of AT injuries or other major injuries to the lower limbs that impeded normal gait were excluded from the study.

During the two-week period of the experiment, we conducted trials on the first, the fourth, and the eleventh day. The baseline test was performed on the first day. We marked Soles muscle-tendon junction (Soles MTJ) as point A and Gastrocnemius muscle-tendon junction (Gastrocnemius MTJ) as point B. A mechanical properties test and ultrasound scan were performed immediately. On the fourth day, we set the treadmills in Taipei Medical University's recreational center to 11.3-14.5 kilometers per hour (adjusted in accordance with each participant's height). After participants ran for 15 minutes, we immediately performed a mechanical properties test and ultrasound scan. On the eleventh day, we used heat padding on the participants. We set electric blankets (iLove, New Taipei City, Taiwan) to 45 degrees Celsius and covered participants' legs from the knees down until the calcaneus. Then we let participants run for 15 minutes, after that the same tests were performed.

We built spring pedals to perform the mechanical properties tests. The ankle torque was set at 27N-m (50% MVC, maximal voluntary contraction), and the spring pedal board was placed flat on the ground. Participants sat with their knees bent at 90 degrees and used their dominant foot to step on the board, affixed with a girdle, at 50% MVC in the plantar flexion position. To ensure accuracy, the two points underwent three isometric contractions and simultaneous ultrasound scans. Throughout the process, the probe remained at the same position for two seconds at a time.

We used the GE Vivid I ultrasonography machine, coupled with the GE linear probe 12L-RS to perform 2D ultrasonography manually, followed by tissue speckle tracking using Echopac software in order to determine movement of the MTJ, strain rate, mechanical parameters, etc. Data was analyzed by SPSS, a statistical software.

RESULTS AND DISCUSSION

Paired t-test was applied to compare tendon lengthening of the Soles MTJ and the Gastrocnemius MTJ in the control group, warm group and run group (Table 1). It was found that tendon lengthening in the warm group and the run group were significantly longer than the control group ($P < 0.05$), indicating that tendon elasticity was increased after the two warm-up routines. Tendon lengthening in the Soles MTJ and the Gastrocnemius MTJ were then compared. Results showed that there was no significant difference between the three groups. Therefore, we initially inferred that warming has opposite effects on muscle and tendon.

CONCLUSIONS

The contribution of warming up towards performance is still controversial. Numerous authors have attributed the protective benefits of warming up in increasing range of motion or body temperature to causing a decrease in AT flexibility [2]. However, there is no literature which can specify that muscle and tendon contractions lead AT to Stretch-Shortening-Cycle (SSC) during warmup exercises. If athletes could know more about this phenomenon, they will be able to better protect their AT and improve their performances.

P229 - DEPENDENCE OF ISCHIAL AND COCCYGEAL SHEAR STRESSES ON BODY INCLINATION

Amelia E Dyck, Visar Berki and Brian L Davis
The University of Akron
Corresponding author email: bdavis3@uakron.edu

INTRODUCTION

Bed sores, often called pressure sores, are a significant problem in the medical community [1]. Many elderly and bed-ridden patients suffer from these painful wounds that can progress to Stage 4 and become life-threatening. Since they most often develop during hospital stays, they drive up healthcare costs that must be paid by the provider instead of insurance.

There are several different stages and types of bedsores. According to the literature, these typically involve a situation where sustained pressure is placed on skin. As a result, skin and tissue may begin to break down and lead to an open wound, especially at and around bony ridges such as the ischial tuberosities, sacrum, and coccyx [2].

With the focus traditionally being on pressure, insufficient research has been performed on the contribution of shearing forces to the formation of sacral bed sores. Frictional forces have been tentatively linked to pressure ulcer formation, and the consensus is that sensors must be developed to gather as much data as possible in this area [3]. This study therefore focuses on measuring shear forces on the ischial and coccygeal areas at different angles to the supine position.

METHODS

A patented Surface Stress Sensitive Film (S3F) was first developed to provide skin friction (drag) measurements in wind tunnels. It is an elastic film that deforms in response to applied forces. Upon removal of the forces, the film returns to its original shape. The dynamic 3-D deformations are captured using digital imaging of probes incorporated in the film. The measured deformations can be analyzed directly since they are proportional to the applied forces. In addition, the deformations can be used as inputs to a finite element model of the film to quantify the pressure and shear forces that produced the measured deformations. A force plate provides traditional pressure measurements and an expanded capability for system calibration.

The S3F-based platform has been used in studies related to shearing stresses on the plantar surface of feet [4,5] but to date has never been used to assess interface mechanics under the ischial tuberosities and coccyx.

For the current study, data were collected on equal numbers of healthy male and female subjects ages 18 to 28 with no history of back injuries or skin ulcers. Data were sampled at 30 Hz for 1.6 seconds. Trials were collected at angles of 0, 22.5, 30 and 45 degrees, with four repeats at each angle. Seamless sports clothing was worn by each subject. For the purposes of assessing the dependence of shear on inclination angle, peak anteriorly directed shear stresses were quantified.

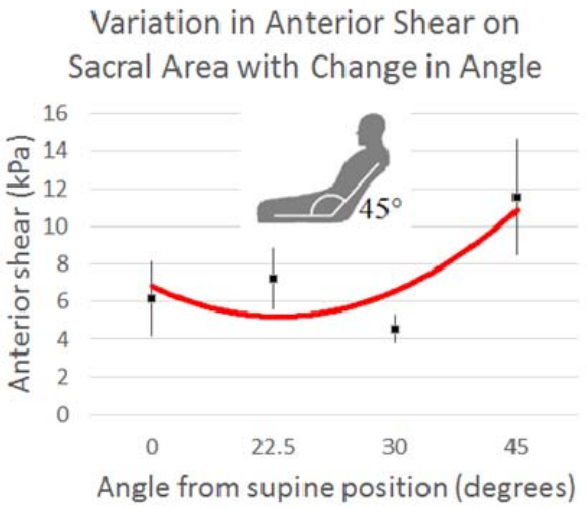

Figure 1. Typical results for one subject, showing the dependence of anterior shear stresses on inclination angle. At an angle of 0°, the subject was lying supine.

RESULTS AND DISCUSSION

Peak anterior shearing stresses showed a non-linear trend as a function of inclination angle (Figure 1). Variability of these stresses seemed to increase as subjects were positioned more upright, possibly due to the increasing influence of ischial geometries and the effect of small postural adjustments.

In terms of magnitudes, anterior shear stresses were, as expected, significantly higher than posterior shear stresses ($p < 0.05$). When compared with shearing stresses under the feet of healthy subjects, the values are about 40% of those previously reported [5]. The relative effects of (i) lower peak shear stresses versus (ii) prolonged application times is unclear. However, what is apparent is that changing a patient's body inclination can significantly lower shear stresses under the ischial tuberosities and coccyx.

CONCLUSIONS

Prolonged application of shear stresses on skin may predispose a bed-ridden patient to chronic wounds. This study shows that the inclination of a patient has significant effects on these shear stresses.

P230 - NOVEL CHARACTERISATION OF BONE GROWTH ON IMPLANT SCAFFOLDS THROUGH INTEGRATING NEURAL NETWORKS AND COMPUTATIONAL SIMULATION

INTRODUCTION

Predicting cell responses on implant scaffolds, given its architecture and material, can be useful in evaluating different scaffold designs. Nevertheless, successful predictions need to address two challenges. The first is to quantify uncertainty in the observations of cell processes. Cell processes have a stochastic element which leads to variability in growth, death, and migration of cells. To model these processes, Fick's law (governing equation of bone diffusion) [1] is used to quantify the uncertainty, because Fick's law is deterministic. The second challenge involves identifying Fick's law coefficients which cannot be obtained directly from experiments.

In this work we propose a novel pipeline integrating neural networks and population-based computational simulation to predict growth, death, and migration of bone osteoblast cells on porous polymer scaffolds between given days. This work advances on previous studies that have three shortcomings: (i) solely modelling cell migration; (ii) considering only specific cell concentration patterns, and (iii) matching only general spatial patterns between simulation and experiment. The improved pipeline therefore examines not only migration but also growth, death and various cell patterns, and increases classification accuracy of the responses at a population level.

METHODS

Our dataset consists of the intensity of alamarBlue (general indicator for cell population) and live/dead fluorescent stain images on parts of the top of implant scaffolds in a 21-day experiment. The intensity on unobservable days was regressed and the parameters of the linear regression were inferred. Thus, the cell population could be drawn from the intensity. Cell spatial concentrations were sampled using a random walk algorithm [2] on the digitized images.

For modelling cell responses, finite element simulations approximate concentrations in a representative cube from initial concentrations after 1 day. Cell growth and death were imposed as a concentration-dependent flux on randomly sampled locations. It had a flux gradient of 50000/ mL day for growth and -50000 for death. Heavily occluded pores were assigned a diffusivity of $1x10^{-4}$ while open pores 0.01. A convolutional neural network was trained and tested on the above cases [3]. Afterwards, it predicted cell responses one day apart in the experiment. See Figure 1 for an overview of the modelling pipeline.

RESULTS AND DISCUSSION

The first finding shows the expected populations and cell concentration patterns could be drawn from Bayesian inference. The second finding shows the network classifies "element-wise" cell responses highly accurately. Otherwise, the network predicts responses with low probability for both cases of Fick's law and the cell concentration patterns from the experiment due to the current limited training sets.

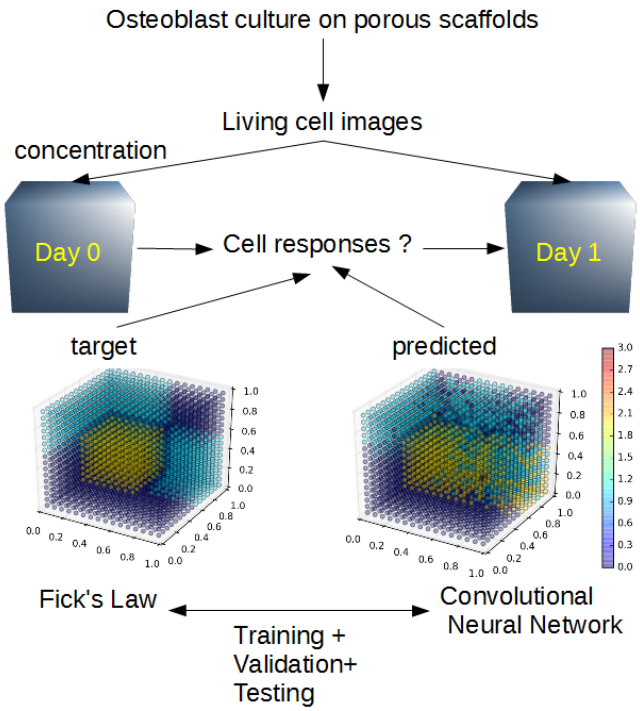

Figure 1: Modelling pipeline.

CONCLUSIONS

The neural network pipeline was shown to approximate the inverse function of Fick's law by its high classification accuracy. However, the current low prediction probability reflects that the network needs more training, which is currently being done using GPU simulations. Finally, while cases of Fick's law provide the ground-truth to measure the accuracy and probability of prediction, the cell patterns in the experiment do not have labels. This combination of continuum modelling and statistical inference does not provide evidence of the specific biological responses but rather homogenized behaviors of simulated populations, which may be more useful when designing implant scaffolds.

INTRODUCTION

This paper focuses on the calcaneal nail "C-NAIL" produced by the Czech company Medin a.s. The C-NAIL was developed via Czech-German cooperation. The C-NAIL is an intermedullary calcaneal nail used in the treatment of intraarticular/extraarticular fractures of the calcaneus (heel bone). Fixation with this nail is mini-invasive, based on the principle of stabilizing the bone fragments by means of the nail and fixing screws [1]. Heel fractures occur most frequently as a result of falls from height. They are serious injuries, and patients may experience difficulties even under qualified treatment. On impact after a fall, the entire weight of the body is transferred via the shank (crus) and the ankle (talus) to the heel bone (calcaneus), which meets resistance from the ground, causing it to fracture partially or to break into two or more fragments.

METHODS

The C-NAIL is an intermedullary calcaneal nail used for the mini-invasive fixation of intraarticular/extraarticular fractures of the calcaneus (heel bone). The principle is the stabilization of the calcaneus fragments by the nail in conjunction with seven fixing screws, with which it forms an angularly stable fixation. Maximum stability is achieved by fixing the sustentacular fragment via the nail using two locking screws that are introduced by means of a targeting device. The success of treatment also depends on the strength of the screws and nails used; if these fail, it is necessary to repeat the entire osteosynthesis procedure. Despite all efforts by operators, treatment is not always successful, but the optimization of these implants reduces the occurrence of their failure.

This biomechanical research of the C-NAIL is based on multidisciplinary collaboration among medical professionals and engineers; see Fig. 1.

The use of numerical methods brings quicker and simpler options for optimizing the design of current devices (plates and nails) used in calcaneal osteosynthesis. Numerical modelling of the C-NAIL is described in [2]; the interaction of the nail with the bone is substituted via the theory of beams on an elastic foundation [3], which gives a suitable approximation of the mounting of the nail in the bone. This process offers a quick and elegant method of determining maximum stress values.

A far more accurate, realistic and demanding method is to conduct a contact numerical analysis of the nail mounted in the actual bone. However, for this purpose it is necessary to create a high-quality CAD model of the bone itself. This was done using Materialise Mimics software. In order to create an accurate model of the bone, it was necessary to separate the dense bone tissue from the other soft tissues in the individual CT sections.

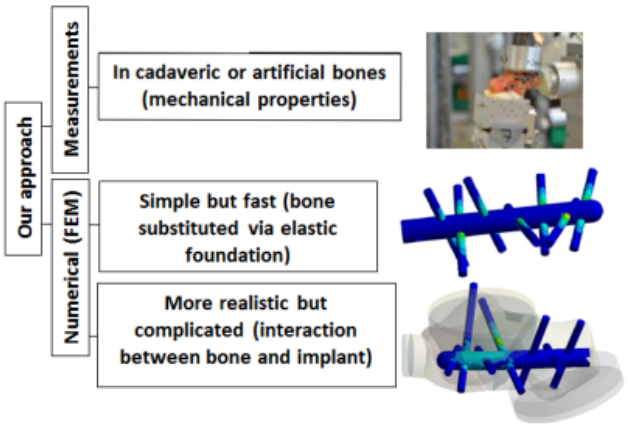

Figure 1: Approaches to calcaneal osteosynthesis

Experimental methods (static, dynamic and fatigue testing of the bone/nail system) are also important; see [1].

RESULTS, DISCUSSION AND CONCLUSIONS

Complex calculations and laboratory experiments were conducted for a C-NAIL applied to the calcaneus. The results verified and recommended correct design parameters for the structure, strength, stiffness and reliability of the C-NAIL. The nail meets the requirements of modern medical practice.

INTRODUCTION

The article proposes and verifies a new model of the interaction of bones and screws; see Fig. 1 and references [1] and [2]. A screw mounted in a bone is subjected to tensile/compressive loading until the limit state is reached (the screw is pulled out of the bone). The results give information on the behaviour of the screw in a bone and can be used to optimize the design of implants for post-fracture osteosynthesis in traumatological or orthopedic practice.

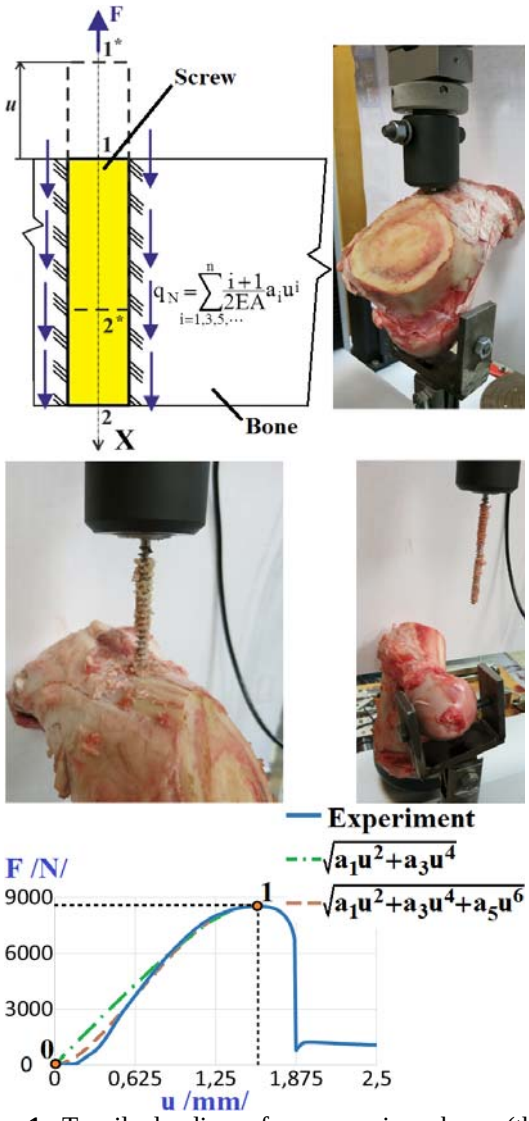

Figure 1: Tensile loading of a screw in a bone (theory, experiment and approximation)

METHODS

The model for the tensile/compressive loading of a screw in a bone is described by the nonlinear differential equation

$$EA\frac{d^2u}{dx^2}=\sum_{i=1,3,5,\cdots}^{n}\frac{i+1}{2EA}a_i u^i, \quad \text{or} \quad F\frac{dF}{du}=\sum_{i=1,3,5,\cdots}^{n}\frac{i+1}{2}a_i u^i,$$

where F is axial force, u is axial displacement, E is the modulus of elasticity of the screw, A is the cross-sectional area of the screw, and a_i is the nonlinear dependence constant of the continuously distributed reaction force in the bone; see Fig. 1. A result (a solution of the above differential equation) fulfilling the boundary conditions requires the dependence $F=\sqrt{\sum_{i=1,3,5,\cdots}^{n}a_i u^{i+1}}$, where the constants a_i can be determined experimentally; see Fig. 1. The constants a_i must fulfil the conditions at point 1, where the extreme situation (pulling the screw out) occurs (i.e. the approximation passes through this point and the extreme is $\frac{dF}{du}=0$). If more than 2 constants a_i are required, the least squares method may also be used. An acceptable approximation is $F=\sqrt{\sum_{i=1,3,5}^{n}a_i u^{i+1}}$, and sufficient accuracy is given by approximations $F=\sqrt{\sum_{i=1,3,5,7}^{n}a_i u^{i+1}}$ or higher. The experiments to pull the screws out of the bones were conducted repeatedly using not only cadavers, but also wooden and plastic blocks; the results always gave good agreement.

RESULTS, DISCUSSION AND CONCLUSIONS

The proposed original model (nonlinear differential equation and its solution) gives very good agreement with experiments conducted using cadavers, wooden and plastic blocks. The results give an adequate picture of the behaviour of a screw in bone under tensile/compressive loading, including the extreme situation in which the screw is pulled out. The results can be used to optimize the design of implants for post-fracture osteosynthesis in normal medical practice.

P233 - GENETIC ALGORITHM APPROACH FOR ERROR OPTIMIZATION WITH 2-DIMENSIONAL DIRECT LINEAR TRANSFORMATION

INTRODUCTION

Methodologies for field based motion capture are somewhat limited, particularly for motion capture duirng competitive sporting events. Capture situations utilising large areas and difficult space, as found in athletics compititions, are still mostly reliant upon two-dimentional (2D) caputre combined with manual digitising techniques. The 2-D DLT method is a commonly employed technique of quantifying 2D coordinates prior to motion analysis in such situations. However, this methodology is prone to errors. Two specific errors that arise are human errors incured during manual digitising and error due to image resolution during the DLT process.

Genetic algorithm (GA) is a computational method based on a natural selection process designed to mimic biological evolution [1]. It is utilized for solving both constrained and unconstrained optimization problems through successive generations of random population data until a solution evolves. The purpose of this study was to examine the utility of GA as a technique for reducing reconstruction errors in manually digitized 2D DLT method.

METHODS

This study targeted 2D DLT on 1200×1080-pixel image. The image consisted of 135 manually digitized points in a gridded plane. 15 points in the left corner of the grid were selected (Figure 1b, right) as calibration points for the DLT. To simulate maximal digitizing error firstly all the digitized coordinates were randomly shifted ±0-3 pixels (four significant digits) toward U and V components. The number of population and generations was set to 1000 with a bellowing GA crossover rate of 70% with one-point crossover and a mutation rate of 30%. The first GA technique utilized 15 randomly selected points over ten iterations (e.g., Figure 1b left) from here on called RANDUM. The second GA technique used only the 15 calibration points (Figure 1b, right), from here on called FIXED. The best technique RANDUM or FIXED is the one with the least error in the DLT image reconstruction.

RESULTS AND DISCUSSIO

Reconstruct error of RANDUM was smaller as compeared with normal DLT without GA process (x, 0.307±0.191%; y, 0.155±0.099%). It is suggested that shifting the image coordinates is a beneficial method after manual digitizing. Additionaly, x component error was bigger than x component error in both of RUNDAM and normal DLT. It is suspected that this defference is caused that a coordinate system of object is arranged in the x coordinate direction in a coordinate system of image (Figure 1a). On the other hand, FIXED showed larger reconstruction errors. It is inferred that the increase of errors results in the arrangement of calibration points, because reconstruction errors are larger as they move away from the calibration area (Figure 1b, left).

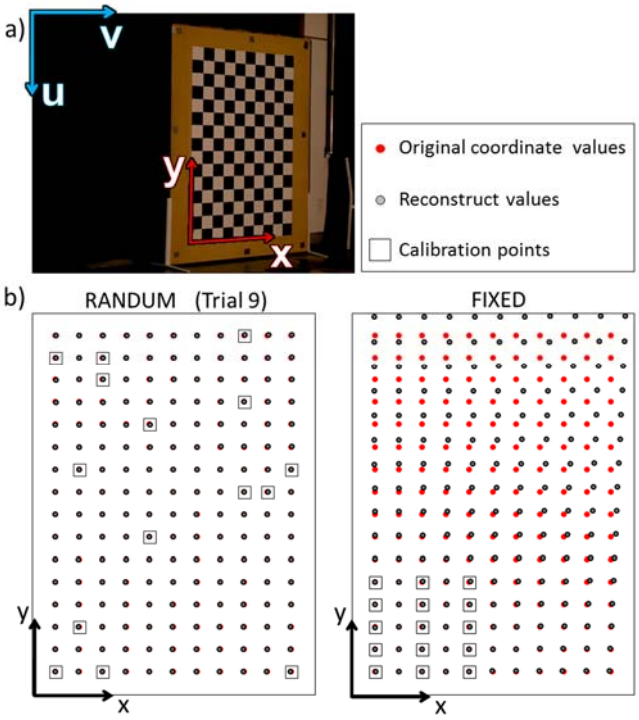

Figure 1: a) Test image written two coordinate systems. Coordinate system of image was u and v components and coordinate system of object plane was x and y components. **b)** Reconstruction values after DLT of RANDUM (left) and DIXED (right). RUNDAM shows trial 9 in ten trials as a sample. The rates of reconstruction errors for the analysis area (x,10; y, 15) were that RANDUM was 0.159±0.120% and 0.149±0.121%, and FIXED was 1.417±1.484% and 1.762±1.781%.

CONCLUSIONS

The results of this analysis suggest that using the RANDUM GA method of optimizing the image coordinates is a beneficial analysis technique when the reference points are arranged evenly throughout the image coordinate system. Moreover, we note that the potential exists for the reconstruction error to surmise zero or unlimitedly close to zero when the using the RANDUM technique. Therefor we believe it is necessary to review GA parameters and other optimization methods for use with 2D DLT reconstruction in future.

P234 - SURFACE TEXTURING OF CO-CR-MO ALLOY TO PROLONG SERVICE LIFE OF ARTIFICIAL JOINTS

[1] **Takuro HONDA**, [1]Shin Sakuraba, [1]Riku Yoshioka, [1]Yuta Nakashima, [1]Yukio Fujiwara, [1]Yoshihiro Komohara, [1]Motohiro Takeya, [2]Hiromasa Miura, [3]Hidehiko Higaki, [1]Yoshitaka Nakanishi

INTRODUCTION

The service life of artificial joints is affected by their tribological characteristics. Wear particles of the bearing materials, such as ultra-high-molecular-weight polyethylene (UHMWPE) are considered as a major factor in osteolysis and loosening of total joint replacements. Macrophage activation and production of cytokines are influenced by total volume and sizes of wear particles. Some studies have indicated that small particles with sizes less than 1.0 μm exhibit the most biological activity [1]. In order to control the volume and sizes of wear particles, it requires a high-quality geometric surface with nano-scale roughness and micro-scale waviness [2]. In this study, a micro-wet blasting technique was proposed for creating a variety of surface profiles on a Co-Cr-Mo alloy counterface. The effects of the profiled surface on polyethylene wear characteristics were investigated experimentally.

METHODS

Micro-wet blasting (MWB) technique was applied to produce the textures on Co-Cr-Mo alloy. Water solution containing 1.2 μm alumina particles (3.2 wt%; WA #8000) was used as the slurry. The slurry was injected through a nozzle having a diameter of 1.0 mm under compressed air. A surface profile was created by adjusting the feed speed and feed pitch of the nozzle.

A pin-on-disc wear test was conducted to compare the performance of MWB processed and conventional Co-Cr-Mo alloy surfaces. A pin was made of UHMWPE (GUR1050) and the disc material was a Co-28Cr-6Mo alloy (ASTM F75). The pin with 9 mm in diameter was pressed against the disc at a contact pressure of 6.0 MPa. The testing machine provided multi-directional sliding motions. The wear track on the disc had a diameter of 20.0 mm, and the sliding speed was 20.0 mm/s. Fetal calf serum was used as the lubricating liquid. The total protein concentration (20 g/L) in the lubricating liquid was adjusted by adding distilled water. Each test involved a total of 500,000 cycles.

After wear test, the gravimetric wear of the pin was measured to calculate the specific wear rate of the UHMWPE. The used lubricant was also collected to obtain wear particles using 0.1 μm cellulose membrane filters. 100 particles on the membrane were examined using a scanning electron microscope in order to evaluate the morphological features of the wear particles.

RESULTS AND DISCUSSION

Figures 1 shows surface images of each Co-Cr-Mo alloy disk for wear test obtained by three-dimensional optical surface profiler (NewView 7000, Zygo Corp., USA). Some smooth surface patterns were prepared by MWB, and the roughness in the actual contact area (Pa) was reduced to 1-2 nm in compared to conventional one (11 nm). The wave surface had a waviness curve with a horizontal pitch of 1.0 mm and a peak-to-valley height (Dpv) 0.187 μm.

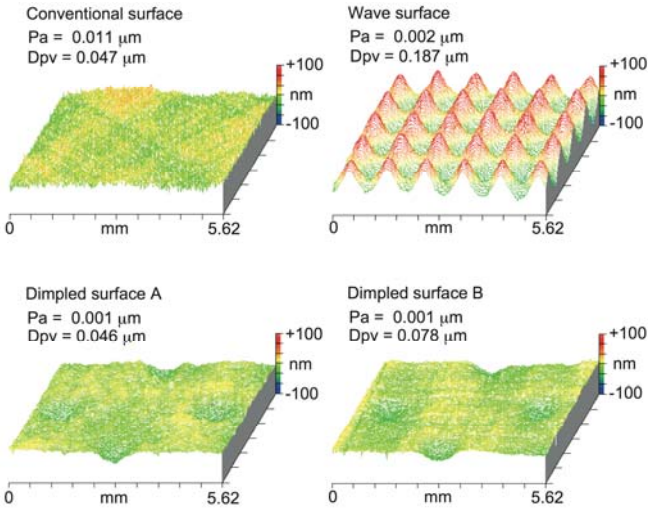

Figure 1: Surfaces of Co-Cr-Mo alloy discs used for the wear tests.

The specific wear rate with the wave surface was lower than that with conventional one, while the wear rate was increased in case of dimple surfaces. The equivalent circle diameter of the particles derived from the wave surface was 1.62 mm, and larger than that from the conventional surface (1.30 mm). The aspect ratio of wear particles from the wave surface was also larger than that from the conventional surface.

CONCLUSIONS

A variety of surface profiles on Co-Cr-Mo alloy were produced by MWB technique. A wave surface with very smooth roughness in actual contact area was useful to reduce the specific wear of polyethylene and make the wear particles large size.

P235 - EFFECT OF ROBOT SUIT HAL FOR LUMBAR SUPPORT ON REDUCTION OF LUMBAR LOAD IN REPETITIVE SNOW SHOVELING MOVEMENT

[1] **Hideki Kadone**, [1]Kousei Miura, [1]Tetsuya Abe, [2]Hirooki Endo, [2]Hideki Murakami, [2]Doita Minoru,

INTRODUCTION

Repeating snow shoveling movement is physically demanding and can be a cause of lower back pain. In an aged society such as the one of Japan, elderly people tend to live in county side without accompaniment of young people, which is not exception for snowy areas where the inhabitants have to manually shovel snow away at least for private areas in front of their own houses and parking lots. In such situation, some device that can facilitate the shoveling movement is wanted.

Robot suit HAL (Hybrid Assistive Limb, Cyberdyne, Japan) is a wearable exoskeleton type robot. It can assist joint motion according to the user's motion intention detected using skin surface electrodes attached on relevant muscles. It has been applied for motion improvement in patients with limb paresis [1]. The version of HAL for lumbar support [2] consists of a lumbar attachment, bilateral thigh attachments and two electric motors that assist hip and lumbar extension according to activation of electric potential detected by the electrodes attached on the lower back corresponding to the erector spinae muscles.

In this work, we analyzed the effect of using HAL for lumbar support on reduction of lumbar load and efficiency improvement in repetitive snow shoveling movement to investigate the possibility of it becoming a support for the elderly in snowy regions.

METHODS

Nine healthy subjects (age: 26-44y, mean 31y, height: 161-180, mean 171 cm, weight: 59-76, mean 66 kg) participated in the experiment. They were asked to continuously repeat snow shoveling movement as much as possible in the two conditions; without using HAL and with using HAL (Figure 1). In the snow shoveling task, shoveling movement consisted of lowering a shovel, picking up a full scoop of snow, bringing it up to a certain height by coming back to a natural standing position, throwing it and then stepping sideways along a straight line toward an indicated target. Between the trials of the two conditions, they took a rest until they felt that they had recovered from fatigue.

For each condition, number of times of shoveling movement, length of cleared area, duration of continuously repeated work and subjective perception of fatigue in lumbar by VAS (visual analog scale) just after finishing the shoveling task were recorded. Muscular usage during the shoveling task was recorded using a Trigno Lab wireless measurement system (Delsys) which had EMG and three axis acceleration sensor in each wireless sensor unit.

Figure 1: In the experiment, healthy participants repeated snow shoveling movement as much as possible with the aid of robot suit HAL for lumbar support. They also performed the task without HAL. Results were compared between the conditions.

RESULTS AND DISCUSSION

By averaging among the subjects, the number of times of shoveling was 50 without HAL and 144 with HAL, the duration of continuous shoveling was 145s without HAL and 366s with HAL, the length of cleared area was 9.6m without HAL and 35.4m with HAL, the fatigue VAS was 75 without HAL and 39 with HAL. All of these evaluations showed statistically significant difference. From the EMG analysis, activation of erector spinae muscles during lowering of a shovel tended to gradually increase through time in the condition with HAL but not in the condition without HAL.

CONCLUSIONS

While there exist some reports on the reduction of lumbar load during snow shoveling by refinement of shovel design, there is no other reports on the use and effectiveness of assistive robots for this purpose as far as we know. Our experiment showed that using HAL for lumbar support was effective in reducing lumbar load and improving work efficiency. Further analysis of the EMG data is expected to elucidate the biomechanical mechanism behind it.

P237 - PLANTAR PRESSURE DISTRIBUTION ANALYSIS IN HIGH PERFORMANCE ATHLETES

José de Jesús Mayagoitia-Vázquez, Israel Miguel-Andrés & Sergio Luis Orozco Villasenor
Biomechanical department of CIATEC A. C. Mexico
Corresponding author email: imiguel@ciatec.mx

INTRODUCTION

Plantar pressure distribution measurements have been used to detect several pathologies of the foot, such as excessive mechanical pressure on the plantar region which can lead to foot ulceration [1]. In addition, it has been used in footwear design, sport performance analysis, injury prevention, improvement in balance control and diagnosing disease [2-4]. It is know that the abnormal plantar pressure distribution can produce injures in the soft tissue of the foot. This is an important factor for high performance athletes where competitions take long period of time and for diabetic people, especially those with neuropathy [1]. Wireless in-shoe plantar pressure sensors have the potential of measure the pressure distribution of the foot during normal walking with great accuracy [4]. This research aimed to scrutinise the plantar pressure distribution in four high performance athletes in order to detect foot pathologies and be able to prevent future damages.

METHODS

Four high performance athletes, two males and two females, mean body mass 55.25 ± 4.03 kg, with no history of neuro-musculoskeletal disease were considered in this study. An in-shoe F-Scan system (TEKSCAN, Inc. Boston MA USA) was used to record the plantar pressure distribution. The thickness of the F-Scan sensor is 0.15mm and it has 25 sensels™ per square inches. The insole sensors were placed inside of the shoes of each subject to record the plantar pressure. During the trials, the participants wore the same shoes that they wear during normal training. The gait cycle was evaluated in each subject at normal walking speed with a sampling frequency of 100 frames per second. Data were acquired by the F-Scan device and sent via wireless to the workstation to be saved and analysed. The participants walked three times in a ten metres track. The first and the last gait cycle were discarded from the analysis. Before the trials began, the participants were allowed to walk during 15 minutes in order to be familiar with the sensors.

RESULTS AND DISCUSSIONS

The plantar pressure distribution of the four participants is shown in Figure 1a-d. The plantar pressure distribution of the first participant was higher on the left foot. In addition, the big toe displayed high pressure during the take-off, Figure 1a. Subject number 2 illustrated higher plantar pressure in the right foot as shown in Figure 1c. Similarly, subject 3 displayed higher contact pressure in the right foot. Finally, subject 4 showed higher contact pressure in the left foot, Figure 1d. After reviewing the plantar pressure distribution in all participants, it was clear to observe the asymmetry on both feet. Clinical feedback was given to the participants for rehabilitation. Plantar pressure measurements indicates how the muscle forces interact with the ground surface. This information is useful to detect some abnormalities which can lead to foot disorders.

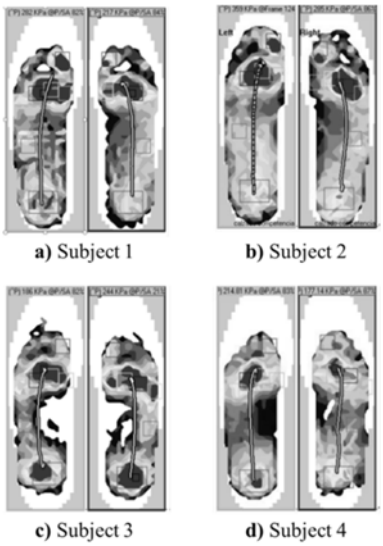

Figure 1 Plantar pressure distribution of four high performance athletes. Black colour shades indicate the highest pressure and the line in the middle shows the contact pressure pattern during the gait cycle.

CONCLUSIONS

The plantar pressure distribution of four high performance athletes was analysed during normal walking. It was found that all the participants have issues in the plantar region of the foot. This could produce damage in different regions of the lower limbs. It was recommended to them acquire insoles to correct the abnormality and avoid future damage.

ACKNOWLEDGEMENTS

P238 - MICRO SLURRY-JET PROCESSING FOR BIOMATERIAL SURFACE

[1] **Yoshitaka Nakanishi**, [1]Takashi Baba, [1]Yuta Nakashima and [2]Hidehiko Higaki
[1]Kumamoto University
[2]Kyushu Sangyo University
Corresponding author email: yoshi@mech.kumamoto-u.ac.jp

INTRODUCTION

Surface texturing on a material is useful, because this can change of the wettability, adhesion and wear characteristics on the surfaces. A variety of the processing methods have been proposed. Laser processing, electrical/chemical etching and nanoimprint technology are representative methods.

In this research, the micro slurry-jet, which is a kind of wet blasting, has been proposed to improve the surface characteristics on a glass and a prosthetic material [1]. For the glass plate, the relationship between the surface profile and the change of wettability were discussed. For the Co-28Cr-6Mo alloy disc, the influence of wear characteristics of artificial joint was discussed [2].

METHODS

The micro slurry-jet is a wet blasting which uses alumina particles as abrasive media, along with compressed air and water to create a textured surface. The mean diameter of the alumina particles was 1.2 μm. 3.2 wt% of slurry was prepared by adding distilled water. The slurry was injected through a nozzle having a diameter of 1.0 mm under compress air of 0.36 MPa. This powerful stream removed the material surface with high accurately. The injection nozzle was mounted on a stage that could be mechanically controlled to move parallel to the material surface. A textured surface was created by adjusting the feed speed and feed pitch of the nozzle. The materials tested were a glass plate and a Co-28Cr-6Mo alloy disc.

The textured glass surface was visualized using a three-dimensional optical surface profiler. A contact angle of water on the material surface was also measured.

The textured Co-Cr-Mo alloy disc was used for a pin-on-disc wear testing, where an ultra-high molecular weight polyethylene (UHMWPE, GUR1050) was used for the counterface material. The polyethylene pin was pressed against the Co-Cr-Mo alloy disc at a contact pressure of 6.0 MPa. The center of the wear track on the disc had a diameter of 20.0 mm, and the sliding speed was set to 20.0 mm/s. The bearing surfaces were lubricated by a foetal calf serum, in which the protein concentration was 20 g/L. The specific wear tare of polyethylene and morphological features of the polyethylene debris were measured.

RESULTS AND DISCUSSION

Figure 1 shows the processed surface on glass. Smooth surface with dimples, concave lines or convexo-concave profiles was able to be created by the micro slurry-jet. The processing accuracy in vertical direction of surface (depth from top surface to bottom surface) was less than 50 nm. The depth could be controlled by the feed speed. It was confirmed that there was a limitation of reducing the feed pitch, which was less than 0.25 mm. The contact angle of water on the glass without the processing was 28.3 degree (S.D.: 2.70). The convexo-concave surface with the depth of 50 nm and the pitch of 0.25 mm (orthogonal axes) recorded the contact angle of 25.6 degree (S.D.: 3.81), and the surface with the depth of 50 nm and the pitch of 0.50 mm had 41.0 degree (S.D.: 3.41). These results supported that the surface processing by the micro-slurry-jet could change the hydrophilic or hydrophobic character on a glass.

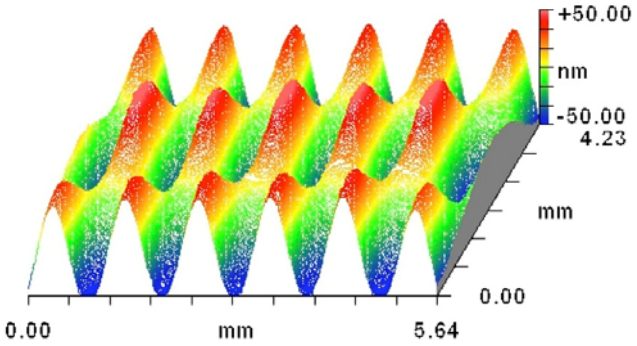

Figure 1: Example of textured surface on glass. Convexo-concave surface was observed. Feed speed of injection nozzle was 0.5 mm/s. Feed pitch was 1.0 mm with oblique axes.

The convexo-concave surface of Co-Cr-Mo alloy, in which the depth of 200 nm and the pitch of 1.00 mm (orthogonal axes), was obtained by the micro slurry-jet. The surface roughness was reached to Ra of 2 nm. By using the textured surface, 75% of reduction in the specific wear rate of polyethylene was recorded in comparison with the conventional surface (Ra of 20 nm with flat surface and the specific wear rate of 0.887 mm^3/Nm). The equivalent circle diameter of polyethylene debris was enlarged from 1.30 to 1.62 μm. The lower wear and larger debris of polyethylene suggested that the surface processing by micro slurry-jet was useful for prolongation in service life of artificial joint.

CONCLUSIONS

The wettability on the glass surface could be changed by the micro slurry-jet processing. The specific wear of polyethylene could be reduced by using the processed Co-Cr-Mo alloy as the counterface material.

P239 - UPSTREAM SWIMMING OF A SPERM CELL IN SHEAR FLOW

[1] **Toshihiro Omori** and [1] Takuji Ishikawa
[1]Tohoku University
Corresponding author email: omori@pfsl.mech.tohoku.ac.jp

INTRODUCTION

Mammalian sperm cells must maintain the correct orientation throughout their journey from ejaculation to potential fertilization. The overall distance typically exceeds 10 cm, while the length of the sperm cell is between 50-100 μm. In such a long distance, how do sperm cells find a correct swimming direction? Recently, a possible mechanism used in long-distance navigation, rheotaxis, was found experimentally. In the experiments, sperm cells were subjected to shear flow or Poiseuille flow and the sperm cells actively swam against the flow. Although the rheotaxis is important for the fertilization process, the mechanism was not clear at all. We then numerically investigated sperm cell locomotion in shear flow near a plane wall, and clarified the stability of the rheotaxis in the parameter space of shear rate and flagellum beat chirality [1]. In this paper, we show the results of upstream swimming of the sperm cell in shear flow.

METHODS

For the numerical analysis, a sperm cell is considered to be immersed in an incompressible Newtonian liquid, adjacent to a 2D plane of infinite dimensions. Due to the small scale of a sperm cell, the flow field can be assumed as the Stokesian regime, and is described by the boundary integral equation:

$$\mathbf{v}(\mathbf{x}) = \mathbf{v}^{\infty}(\mathbf{x}) - \frac{1}{8\pi\mu}\int \mathbf{J}(\mathbf{x},\mathbf{y})\cdot\mathbf{q}(\mathbf{y})\,dS(\mathbf{y}), \tag{1}$$

where $\mathbf{x}$ is a observation point, $\mathbf{y}$ is a material point on the sperm cell surface, μ is the viscosity, $\mathbf{v}$ is the velocity at $\mathbf{x}$, $\mathbf{v}^{\infty}$ is the background shear flow, $\mathbf{q}$ is the surface traction, and $\mathbf{J}$ is the Green's function, respectively. We also assumed force-free and torque-free swimming of a sperm cell:

$$\int \mathbf{q}\,dS(\mathbf{y}) = 0, \quad \int \mathbf{q}\wedge(\mathbf{y}-\mathbf{X}_0)\,dS(\mathbf{y}) = 0, \tag{2}$$

where $\mathbf{X}_0$ is the body frame origin, head-tail junction of the sperm cell. To accurately describe the motions of the flagellum, an orthonormal body frame is defined as ξ^i. Then, time-dependent flagellum beat can be given by following formula of centerline of the flagellum:

$$\begin{aligned}\xi^2 &= A\cos\left(k\xi^1/L - 2\pi ft\right),\\ \xi^3 &= -\alpha A\sin\left(k\xi^1/L - 2\pi ft\right),\end{aligned} \tag{3}$$

where L is the flagellum length, k is the wave number, A is amplitude of flagellum beat, f is the beat frequency, and α is the chirality parameter. Once flagellum motion was given, the velocity at the cell material point $\mathbf{v}(\mathbf{y})$ can be decomposed as:

$$\mathbf{v}(\mathbf{y}) = \mathbf{V} + \mathbf{\Omega}\wedge(\mathbf{y}-\mathbf{X}_0) + \mathbf{V}^{fla}(\mathbf{y}), \tag{4}$$

where $\mathbf{V}$ and $\mathbf{\Omega}$ are translational and angular velocity of the cell. The last term $\mathbf{V}^{fla}$ is the velocity flagellum with respect to the body frame, which is given by time-derivative of (3). In order to express a sperm cell locomotion, we solve following linear system with respect to unknown variables $\mathbf{V}$, $\mathbf{\Omega}$ and $\mathbf{q}$.

$$\begin{bmatrix} J & V \\ F,T & 0 \end{bmatrix}\begin{bmatrix} \boldsymbol{q} \\ \boldsymbol{V} \\ \boldsymbol{\Omega} \end{bmatrix} = \begin{bmatrix} -\boldsymbol{v}^{\infty} + \boldsymbol{V}^{fla} \\ 0 \end{bmatrix}. \tag{5}$$

Matrix component J, F, T and V are computed from Equations (1), (2) and (4), respectively.

RESULTS AND DISCUSSION

Typical results of the sperm cell in shear flow (α =0.4, shear rate = 1 s^{-1}) are shown in Fig.1. The cell is initially aligned parallel to the direction of flow. When the cell is swimming downstream, it gradually approaches the surface, as shown in the Figure. Then, the background vorticity causes the cell to change direction and move against the flow, which effect is called as the weather vane effect. After the reorientation, the sperm cell remains near the wall and continuously swims upward against the shear flow.

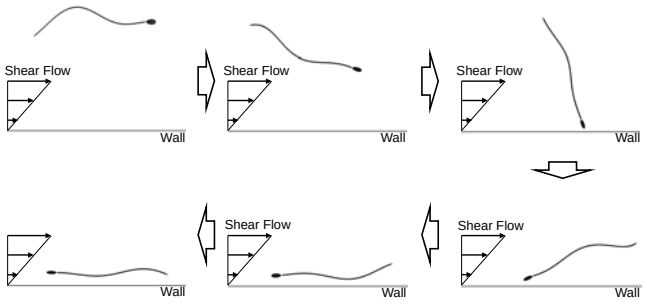

Figure 1: Upward swimming of a sperm cell.

CONCLUSIONS

In this study, sperm cell behaviors in shear flow were investigated numerically using a boundary element method. The swimming direction was hydrodynamically changed, with a number of cells showing stable upward swimming. These results indicated that sperm cell navigation could be controlled using the background shear flow, even in the absence of any biological or biochemical factors.

INTRODUCTION

Based on the Global Status Report on Road Safety 2015 from the WHO, Thailand has the second-highest road fatality rate in the world [1]. Traumatic brain injury (TBI) is found to be a common consequence of car crashes. TBI patients require the pressure in the skull to be measured namely the intracranial pressure (ICP). A pressure greater than 15 mmHg is considered harmful to the patient. Conventional techniques include the wired system which consists of a catheter connected to a bedside monitoring unit such as an epidural transducer and ventriculostomy etc. However, these catheters initiate many problems e.g. they are invasive to brain tissue, high risk of infection and blood clotting [2]. Therefore a minimally invasive technique is desirable.

A minimally invasive wireless ICP sensor is proposed to address these aforementioned problems. The sensor consists of three main units; pressure sensing unit, telemetry unit and power unit. In this paper, the biocompatible pressure sensing unit is presented, namely its design, fabrication and characterization. The sensor is fabricated from Liquid crystal polymer (LCP), this material is chosen for its biocompatibility, low moisture absorption and flexibility, these characteristics make it suitable for biomedical application [3].

METHODS

The LCP pressure sensor is designed to operate in the pressure range of 0-50 mmHg. The design and fabrication of the pressure sensor is based on MEMS technology. The piezoresistive concept is applied to simplify both the design and fabrication. The LCP pressure sensor is designed and fabricated into 8x8 mm^2 and is 100 µm thick membranes. The 2x2x0.05 mm^2 sensing membrane is situated on the middle of the membrane. Four strain gauges are placed and connected to the contact pads for the measurement.

When pressure is applied to the top of the membrane, the sensing membrane deflects and changes the resistivity of the sensor. This operation is tested in a hydrostatic environment to study the feasibility of the fabricated sensor. The LCP pressure sensor is packaged with glass using adhesive epoxy. A 3V DC input voltage is supplied to the sensor and measured by using a National Instruments NI-DAQ 6289 data acquisition card.

RESULTS AND DISCUSSION

The resistances of LCP pressure sensor is ~300 Ω. The sensor can be immersed in the water and operated in the pressure range from 0-30 mmHg. The experimental results show the linearity of the sensor. The average sensitivity is approximately 48 µV/mmHg. The proposed sensor does not reach the requirement of the intended application (0-50 mmHg), this work does however show feasibility for the sensor to operate in a moist environment.

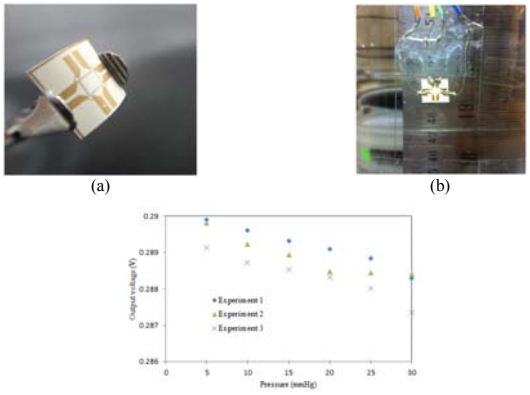

Figure 1: Experiment and Results of LCP pressure sensor (a) a fabricated LCP pressure sensor (b) LCP pressure sensor in the water tank (c) Output voltages of three experiments versus the pressure at 0-30 mmHg.

CONCLUSIONS

The proposed LCP pressure sensor is shown to operate in the required pressure range for ICP measurement. MEMS fabrication offers benefits of low manufacturing cost and mass productivity compared to conventional ICP measurement approaches. The proposed wireless LCP pressure sensor has the potential to improve the treatment of TBI patients in Thailand.

P241 - VIRTUAL 3D ARRAY FOR BILATERALLY CONTROLLED SURGICAL ROBOT

INTRODUCTION

Bilateral control systems can be used in surgeries [1]. If the bilateral control is used in a surgery, ideally the doctor should perceive the sensation of both the body tissue and the reaction force of the surgical tool. Many researchers have attempted to improve the operationality of the surgical tool using virtual models [2]. However, limited researches have carried out to control surgical tool movement in the surgery area. In this paper, a virtual three dimensional wall with vision [3] to protect body tissues and organs around the surgery area is proposed. In a bilateral tele-operation based robot surgery, master (doctor) and slave (surgical tool) may be placed at a distance as shown in Figure 1(a). In a usual robotic surgery, the doctor always has to pay his attention to protect the nearby body tissues and organs from the surgical tool. With the proposed virtual 3-D space created at the surgery area, doctor is able to conduct the surgery easily with a little consideration about the surrounding organs

METHODS

The modeling and development of the robot arm is carried out by applying kinematics and dynamics theories as shown in Figure 1 (b).The force sensation expected at this bilaterally controlled robot arm with the sensorless sensors. The research proposes to use DOB and RTOB based sensors and observers to improve the robustness of the system [1], [4]. Further, the system is modified to the slave robot arm to operate in a 3-D virtual space to protect the surrounding organs of the surgery area.

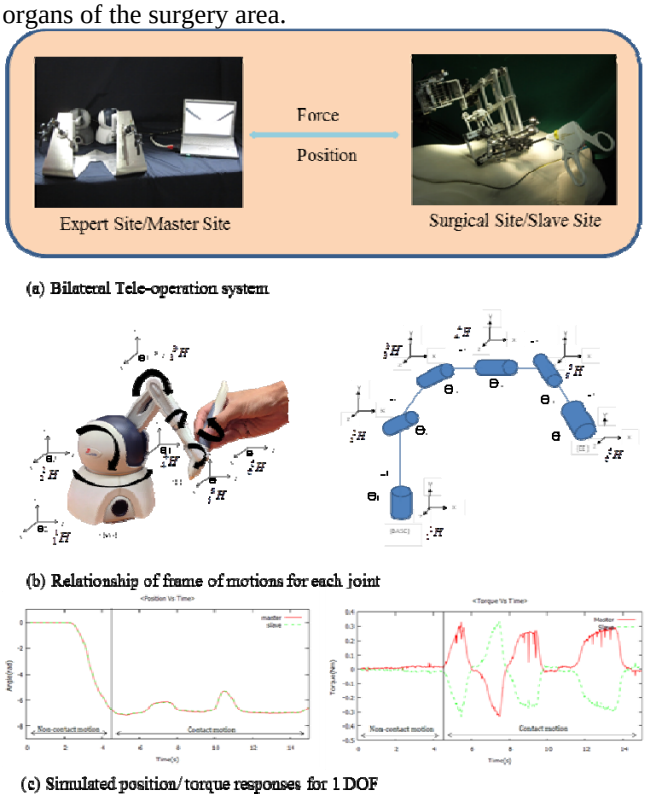

Figure 1: Overview of BART LAB Tele-surgical system

Advanced image processing techniques are used to incorporate the vision to the slave robot arm and it is seen by the surgeon at the master device. Figure 1(b) shows the relationship between homogeneous transformation matrixes of ${}^{EE}_{BASE}H$. It is computed to show the position and orientation of the end effector with respect to the base frame as (1).

$$ {}^{EE}_{BASE}H = {}^{1}_{7}H = {}^{1}_{1}H\,{}^{1}_{2}T\,{}_{2}^{2}H\,{}^{2}_{3}T\,{}_{3}^{3}H\,{}^{3}_{4}T\,{}_{4}^{4}H\,{}^{4}_{5}T\,{}_{5}^{5}H\,{}^{5}_{6}T\,{}_{6}^{6}H\,{}^{6}_{7}T \qquad (1) $$

In actual application, the disturbance observer is effective not only for the disturbance compensation but also for the reaction force estimation. That is, the disturbance observer is able to estimate the reaction force without using a force sensor by identifying the internal disturbance of the system. The transmission of force sensation by Bilateral Tele-Operation is based on the action and reaction relationship. The disturbance observer calculates and estimates the reaction force as quickly as possible by increasing the cut-off frequency [4]. For our experiment, Motoman HP3RX 100 proposed as a surgical Robot. Figure 1(b) shows the relationship of frame of motions for each joint and the workspace measurements. The equation of motion for the Motoman HP 3 is shown in equation (1). It shows the position and orientation of the end effector with respect to the base frame.

RESULTS AND DISCUSSION

Figure 1(c) shows the simulated position and torque responses of the proposed system were one DOF was considered. This response proves that the proposed method performs satisfactorily when the estimated position and orientation of the end effector with respect to the base frame are close to actual system. The proposed research will be a great assistant for the existing bilaterally controlled robotic surgeries. The authors expect to research this technique with the aid of existing BART Lab Tele-surgical system. The outcome of this research will be verified with the help of medical surgeons by testing this tool in real world applications.

P242 - DEVELOPMENT OF CELL CULTURE SUBSTRATE FOR ES CELLS WITH SURFACE MODIFICATION USING UV/OZONE AND ATMOSPHERIC PRESSURE PLASMA TREATMENTS

INTRODUCTION

Culturing pluripotent stem cells effectively requires a culture substrate coated with feeder cell layers or cell-adhesive matrixes. However, it is difficult to apply the pluripotent stem cells as resources for regenerative medicine because of the risk of contamination in culture system by animal-derived factors or the large cost of adhesive matrixes. Therefore, it is imperative for safety and low-cost culture system to remove the feeder cell layers or the matrixes. To enable a coating-free culture system, we focused on UV/ozone and atmospheric pressure plasma surface treatment of polystyrene substrates to improve adhesion and proliferation of pluripotent stem cells. These treatments modify the hydrophilic property and molecular structure of polystyrene surface by oxidation and energy of plasma. The purpose of this study is to develop the coating-free cell culture substrate for ES cells using UV/ozone-plasma combined treatment to realize a similar proliferation rate compared with that on the feeder layer or the matrix-coated substrate.

As a fundamental study for pluripotent stem cells, human induced pluripotent stem cells (hiPSCs) were cultured on the surface-engineered substrates modified by UV/ozone treatment [1]. That study indicates the UV/ozone surface-modified substrates improved the stem cell culture efficiently. However, vitronectin was used as the matrix for a coating. Previously, we reported that mouse embryonic stem cells (mESCs) could be cultured on UV/ozone surface-modified substrates under feeder-free condition [2]. However, the proliferation rate of mESCs on the substrates treated by only UV/ozone modification could not reach the rate on the matrix-coated substrates.

MATERIALS AND METHODS

The polystyrene used as conventional cell-culture substrates was modified by UV/ozone-plasma combined treatment. For UV/ozone treatment, the polystyrene substrates were irradiated for 600 s by UV lamps at the wavelength of 185 and 254 nm. The distance between the substrates and UV lamps was set to be 40 mm. For plasma treatment, the plasma was generated from nitrogen gas. The substrates were exposed to the plasma for 5 s. The distance between the substrates and plasma torch was set to be 10 mm. Two kinds of combinational processes, the UV/ozone treatment followed by plasma treatment (UV/ozone-plasma) and the reversed process (plasma-UV/ozone), were tested.

To analyze the surface structure of the modified polystyrene substrates, X-ray photoelectron spectroscopies (XPS) using monochromated Mg Kα radiation (1,253.6 eV), a 10-mA emission current, and a 4-kV anode potential were performed.

Virgin polystyrene, surface-modified polystyrene, and polystyrene coated with gelatin were used as culturing substrate. The mESCs were cultured on these substrates during 3 days. The phase-contrast images of cells were acquired during the culture. The DNA amount of cultured cells per dish was measured after the 3-day culture to evaluate the adhesion and proliferation.

RESULTS AND DISCUSSION

From the XPS measurements, two chemical bonds derived from carbon chains and benzene rings were detected in a virgin polystyrene substrate. In addition, a single bond -C-O- or a carboxyl bond were found from the substrate treated with the UV/ozone or the plasma single process. Moreover, an imino group was detected from the substrate treated by UV/ozone-plasma process, and an amide group was found from the substrate treated by plasma-UV/ozone process. It was suggested that each combinational process of surface treatments introduced different chemical bonds into the polystyrene substrate.

The DNA amount of cultured cells on the modified substrate at day 3 were larger than that on the virgin polystyrene substrate (Figure 1). The DNA amount of cells cultured on the substrates modified by combined UV/ozone-plasma treatment were much larger than those on the substrates modified by the single process. Moreover, the substrate treated by the combinational process radiating UV before the exposure of plasma showed the improvement of cell proliferation compared to the substrate coated with the adhesive matrix.

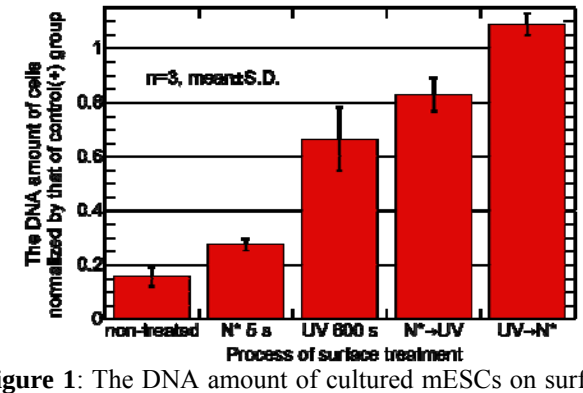

Figure 1: The DNA amount of cultured mESCs on surface-modified polystyrene dishes.

CONCLUSIONS

Combinational process, especially the UV/ozone followed by plasma treatment, improved the adhesion and proliferation of mESCs with maintaining their pluripotency compared with the single treatment.

INTRODUCTION

In-vitro and computational studies have investigated Bone Tissue Engineering (BTE) scaffold design parameters such as material stiffness, total porosity, pore size and pore shape and concluded on the importance of such parameters for implant mechanical integrity and tissue growth [1]. Native bone structure and loading environment vary from region to region. However, most studies neglect these aspects and only report investigations conducted on homogeneous cellular structures, with a fixed simplified outer shape. Their designs routinely rely on arbitrary parameter selection and decisions are made based on a trial and error approach. In addition, the vast majority of the proposed models require great computational power. Furthermore, it should be noted that a large gap still exists from bench to bedside, with restricted clinical and commercial applications of BTE research.

The main objective of this work is to implement and evaluate a digital tool for parametric optimisation of printable scaffold designs for BTE, accounting for heterogeneous mechanical properties and porosity. It is expected that in addition to increasing bone repair performance compared to existing designs, this tool will simplify and encourage the use of optimal designs in practice by relieving the end-user of the computational modelling burden.

METHODS

Digital design: The 3D design software *Rhinoceros 3D* and its algorithmic modelling plugin *Grasshopper* are used for the scaffold design, via the implementation of a plugin to *Grasshopper* written in C#. This novel piece of software incorporates functionalities of the open-source plugin *IntraLattice* [2], used in the initial design phase to populate an arbitrary scaffold outer shape with homogeneous cells of chosen topology.

The in-house plugin then supports automatic optimisation of thicknesses of the individual cell struts based on Finite Element (FE) simulations of the expected loading scenario, building on a strain-based algorithm previously derived by the authors [3]. Porosity constraints can be applied at reduced computational cost thanks to integrated generation of topology-specific cell porosity models.

Fabrication: For initial validation, the CAD model resulting from the digital design is manufactured in biodegradable poly(D,L-lactide) (PDLLA)-based resin using a stereolithography 3D printing process. Micro-CT is used to characterise the printed geometry and its fidelity to the design.

Characterisation: Compression and shear mechanical tests are conducted to assess the overall mechanical properties of the scaffolds. In-vitro test set-ups are currently being designed to allow mechanical characterisation of the scaffolds in more complex physiological loading conditions.

RESULTS AND DISCUSSION

An example of heterogeneous scaffold design adapted to combined loading is displayed in Figure 1. Characterisation of print geometry and mechanical properties are ongoing. Initial results indicate that a good fidelity to the design geometries will be obtained for structures of characteristic length > 100 µm. Material properties of the resin are expected to vary with strut thickness, which is to be taken into account in the FE simulations conducted in the design phase.

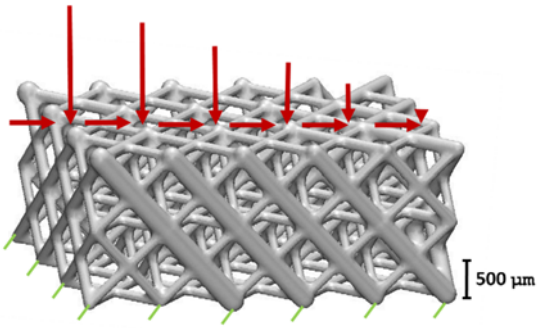

Figure 1: Example of high porosity, cross topology scaffold optimised for a combination of linearly distributed compression and homogeneous shear (red) with fixed bottom (green).

Future work includes functional characterisation focusing on bone growth within the scaffolds.

CONCLUSIONS

A user-oriented digital tool for parametric design of printable BTE scaffold is developed which supports novel efficient structural and topology optimisation methods for heterogeneous constructs. Its capabilities are confirmed by thorough assessment of selected printed structures' geometry and mechanical properties.

P244 - DOES DISTAL FEMORAL EXTENSION OSTEOTOMY WITH PATELLAR TENDON ADVANCEMENT IN INDIVIDUALS WITH CEREBRAL PALSY HELP IN THE LONG-TERM?

[1]Elizabeth R. Boyer, [1]Jean L. Stout, [1]Jennifer C. Laine, [1]Sarah M. Gutknecht, [2]Lucas Henrique Olivera, [1]Meghan E. Munger, [1]Michael H. Schwartz, and [1]Tom F. Novacheck

INTRODUCTION

Short-term gait improvements are achieved after a distal femoral extension osteotomy with patellar tendon advancement (DFEO+PTA) in individuals with cerebral palsy (CP) who walk in crouch [1], but long-term outcomes are unknown. We measured long-term outcomes (body structure, function, activity, participation, and pain) in individuals who had a DFEO+PTA (cases) compared to baseline and individuals who did not have a DFEO+PTA (controls). Secondly, we ascertained if short-term gait improvements are maintained at long-term.

METHODS

This was an IRB approved cohort study. Baseline visits were identified retrospectively from a clinical database. All participants had CP, walked in crouch (knee flexion angle >2 SDs above typically developing at contact and minimum flexion) and had knee flexion contracture(s) ≥10° at baseline, were ≥20 years old at long-term, and ≥8 years post-DFEO+PTA (cases). Controls had no or alternative treatments to DFEO+PTA. At long-term, all participants completed questionnaires (quality of life, satisfaction with life, functional assessment questionnaire, frequency of participation, functional mobility scale, pain) and a subset completed a full gait analysis, 5-times sit-to-stand (5xSTS), and timed-up-and-go (TUG). The primary outcomes were knee flexion at initial contact and minimum flexion. Wilcoxon rank sum, signed rank, and chi-square tests were used, as appropriate ($p<0.05$).

RESULTS AND DISCUSSION

Of the 65 participants, 28 cases (40 limbs) and 24 controls (34 limbs) returned for an analysis. The remainder only completed questionnaires. An additional short-term gait analysis was available for 13/28 cases. At baseline, cases had more abnormal gait and higher oxygen consumption than controls (Table). Between baseline and long-term, knee flexion angles did not change for controls, whereas they improved for cases. From short- to long-term, cases lost 6° of knee extension at initial contact ($p=0.004$) and minimum flexion ($p=0.007$). Among case and control limbs, 36% and 61%, respectively, were in crouch at long-term ($p=0.045$). The 5xSTS was completed by 42% of each group. Controls tended to perform it faster ($p=0.17$). There were no differences in TUG or most questionnaire responses. The controls reported slightly more general pain (not specific to the knee) during select activities.

CONCLUSIONS

A DFEO+PTA improves knee extension during gait into young adulthood for most individuals, which is superior over no or alternative treatment(s). On average, however, the superior knee kinematics did not affect life satisfaction, activity, participation, or knee pain relative to controls. Knowledge of these comprehensive long-term outcomes will allow more comprehensive for counseling patients who walk in crouch and aid pragmatic post-surgical goal setting.

ACKNOWLEDGEMENTS

Thank you to the Gillette Children's long-term outcomes fund for supporting this study.

P245 - CHANGED CERVICAL KINEMATICS IN RADICULOPATHY PATIENTS

Erik Cattrysse, Martine Van Onna, and Luca Buzzatti
Vrije Universiteit Brussel, Belgium, KIMA-Department, Experimental Anatomy Research Group
Corresponding author email: Erik.Cattrysse@vub.ac.be

INTRODUCTION

Cervical radiculopathy is a pathological process that affects the cervical spinal nerve root. It is the results of an impingement and inflammation of a cervical nerve root induced by a space occupying lesion that reduces the size of the cervical intervertebral foramen. The patients can experience pain in the cervical spine, radiating pain in the upper limb, neurological symptoms such as a numb feeling or paresthesia with dermatomeric distribution, loss of strength of one or more muscles in the upper limb, reduced reflexes, a decrease in cervical range of motion (ROM), stiffness in the neck and neck-muscle tension [1-2].
At this moment no information is available about the difference in kinematics of the cervical spine in patients with a cervical radiculopathy compared to healthy subjects. Therefore, the objective of this research was to assess the difference, with the aim of improving the understanding and treatment of the 3D kinematics of the cervical spine in patients with cervical radiculopathy.

METHODS

The design was a cross-sectional study with two groups aged between 18 and 65. Subjects in the symptomatic group had to be diagnosed with a cervical radiculopathy with a positive cluster of Wainner [3] and had an objective loss of sensory and/or motor function of the same segment (definition according to the classification of the International Association for the Study of Pain). Motions were registered using an electromagnetic tracker (Polhemus Liberty TM). The subjects were positioned against the backrest of a wooden chair to eliminate thoracic compensation. The sensors were placed on the subject, one on the forehead above the nose and one on the sternum. These sensors were related to two local reference frames based on the following anatomical points: the most lateral point of the acromion right and left, the deepest point of the incisura jugularis, the most caudal aspect of the mastoid process right and left and the dorsal aspect of the protuberantia occipitalis externa. Three active movements were registered twice in a fixed order: axial rotation, lateral bending and flexion-extension. Quantitative kinematics were extracted using Cardan-angles for main and coupled motion components, ratio and cross-correlation between axial-rotation and lateral bending as well as qualitative aspects like jerkiness and deviation from a 6^{th} polynomial smoothing [4]. Data were analyzed using ANCOVA, Mann-Whitney U and t-tests ($P < 0,05$).

RESULTS AND DISCUSSION

A group of 80 subjects was examined: 15 in the symptomatic group and 65 in the asymptomatic group. The number of subjects within subgroups differ due to technical errors in the registration. The time in which subjects in the symptomatic group experienced complains varied from one month to 180 months. The Flexion-extension subgroup had a mean pathology duration of 30 months (SD 55,8). The rotation subgroup had a mean duration of 32,4 months (SD 58,3). The lateral bending subgroup had a mean of 33,58 months (SD 56). Subgroups show a significant difference in the main flexion-extension motion component during forward bending and extension of 22,8°. In the rotation subgroup the ROM shows a significant difference of 24,7° compared to controls. In the lateral bending subgroup the ROM of the main lateral bending motion component was the only significant parameter showing a difference of 14,8° (table 1). The post hoc power analysis showed that eventually the preset power of more than 80% was only achieved for the ROM of the main motion component during active rotation and flexion–extension.

Kinematics parameters	Flexion-extension		Axial rotation		Lateral bending	
	Asymptomatic	Symptomatic	Asymptomatic	Symptomatic	Asymptomatic	Symptomatic

Table 1: Kinematics of radiculopathy patients and controls

CONCLUSIONS

The observed kinematic differences between radiculopathy patients and healthy controls are reflected on the main motion components of classical so-called planner movements. This may be due to increased pressure on the nerve root by reducing the size of the intervertebral foramen during the movement in combination with an already reduced lateral foramen or an irritation of the nerve root. Qualitative aspects of cervical kinematics did not show significant group differences. There might be two reasons for this observation. On the one hand subgroups may have been too small to detect significant differences considering small mean values and SD's. On the other hand patients may have avoided the painful motion allowing them to move with normal smoothness. It can be expected that forced movements within the painful range of motion might have a strong influence on the quality of cervical kinematics. Further research may reveal whether these hypotheses hold. From this first study on cervical kinematics one might conclude that changes in the clinical status of the patient can be reflected in their kinematics. As such this registration approach might also be used to evaluate treatment outcomes.

P246 - PAIN DOES NOT INFLUENCE KINEMATICS OF WOMEN WITH PATELLOFEMORAL PAIN DURING STAIR ASCENT: A PILOT STUDY

[1]**Danilo de Oliveira Silva**, [1]Marcella Pazzinatto, [1]Amanda Ferreira, [1]Maira Coura, [1]Deisi Ferrari [1]Ronaldo Briani and [1]Fábio Azevedo

INTRODUCTION

Patellofemoral pain (PFP) is a common problem, especially among young women, which usually present kinematic alterations at proximal (hip), local (knee) and distal (ankle and foot) levels [1]. Pain is usually described as peri or retropatellar aggravated during activities requiring high levels of knee flexion such as stair ascent [2]. Women with PFP have intermittent periods of pain, which means that a fluctuation in the level of pain exists making difficult to obtain the same level of pain across different days [2]. The fluctuation regarding the levels of pain may influence the kinematic behavior of individuals with PFP, which might lead to potential misunderstandings about PFP kinematic alterations and compensation strategies [3]. Therefore, the intermittent characteristic of pain could be a confounding factor during clinical assessments and data collections if women with PFP change their movement pattern in the presence of pain. Thus, the aim of this pilot study was to investigate the kinematics of proximal, local e distal factors during stair ascent before and after a patellofemoral joint loading protocol in women with PFP.

METHODS

Ten women (mean (SD) age 22.3 (3.4) years; body mass 60.9 (10.7) kg; height 1.61 (0.05) m; worst pain in the last month (58.8 (14.5) VAS mm) with PFP were recruited. Inclusion criteria were: aggravation of pain during at least two of the following activities (squatting, stair negotiation, kneeling, jumping, quadriceps isometric contraction); and worst pain in the last month higher than 30mm in a 100 mm VAS. Each participant underwent 3-D kinematic analysis during stair ascent using a 9-camera Vicon motion analysis system in a 7-step staircase (day 1). Participants were asked to climb the stairs 5 trials; the mean values were used. Peak angles for hip internal rotation, knee flexion and rearfoot eversion were measured using standardized marker sets (Oxford Foot Model combined with Plug-in Gait). Then, the participants returned to the laboratory to perform a patellofemoral joint (PFJ) loading protocol designed to increase patellofemoral joint pain (day2) [2]. After performing the protocol, they repeated the kinematic data collection in the same way of the first day. Participants were asked to report pain in a VAS scale before and after the first day of kinematic data collection as well as before and after the patellofemoral joint protocol. Paired-samples t tests were performed to identify possible differences between days in pain and kinematics during stair ascent, the level of significance was set at $p < 0.05$.

RESULTS AND DISCUSSION

Findings indicate that the PFJ loading protocol used by this study was able to increase pain in women with PFP (VAS mean difference = 33.7 mm; $p = 0.001$). On the other hand, ascending stairs without performing the PFJ loading protocol (day 1) did not increase pain (VAS mean difference = 6.1 mm; $p = 0.786$). However, the kinematics of women with PFP did not change in the presence of pain (Table 1).

Table 1 – Pain and kinematic variables in women with PFP.

Variables	Day 1 (without PFJ loading protocol)	Day 2 (with PFJ loading protocol)	p
Pain before data collection	13.7 (14.3)	53.5 (30.3)	0.004
Peak hip internal rotation (degrees)	13.2 (7.7)	13.2 (7.2)	0.965
Peak knee flexion (degrees)	66.6 (8.3)	66.5 (8.6)	0.951
Peak rearfoot eversion (degrees)	4.5 (2.4)	5.04 (2.3)	0.432

Our findings indicate that regardless the presence of pain proximal, local and distal peak angles maintain similar behavior during stair ascent. Similar to our findings, Noehren et al. reported that runners with PFP do not or are unable to adapt their hip mechanics in the presence of pain but rather they remain constant. It could be argued that the constrained range of motion of the participants of our study had over the course of the PFJ loading protocol would then likely stress the same location and structures of the patellofemoral joint, which resulted in pain. In addition, we demonstrated that all joints related to PFP, not just hip, do not change kinematics in the presence of pain. Therefore, a strong clinical implication of this study is that targeting excessive peak angles at first could not be the best option to treat pain in women with PFP. Giving support to this recommendation, a recent systematic review [4] reported that proximal strengthening exercise in the management of PFP reduced pain and improved function. However, no significant differences were observed for any of the kinematic variables, including hip internal rotation, knee abduction and rearfoot eversion.

CONCLUSIONS

Proximal, local and distal kinematics were not altered in the presence of pain in women with PFP. Perhaps, giving the first focus of the treatment to the correction of excessive peak angles in proximal, local and distal factors could not be the best option.

INTRODUCTION

Measurement of spine curvatures is mainly obtained from medical imaging techniques; however various tools are currently available to determine similar parameters from external measurements [1]. These non-invasive tools are of interest for estimating clinical outcomes and follow-up in various clinical conditions.

The present work focused on developing a protocol for determining spinal profiles in stereophotogrammetric environment often used in gait analysis laboratory. Previous work has shown the feasibility of using the A-palp to digitize anatomical landmarks from manual palpation and has shown a good accuracy and reproducibility [2]. The present work used a similar jig in order to estimate accuracy and repeatability of lordosis and kyphosis parameters from various computation methods.

METHODS

Forty-two asymptomatic subjects (AS) and 20 patients with low back surgery (LBS) were included. Reflective markers were placed on each subject for further estimation of both static and dynamic parameters (e.g. pelvic orientation…). Anatomic manual digitization was performed on the entire spine from the external occipital protuberance to the sacrum at S2 spinous process to allow computing cervical and lumbar lordosis and thoracic kyphosis. Digitization was performed with successive stops at Th1, Th7 and Th12 spinous processes to allow spine regionalization. Three measurements were performed on each subject in standing position. A regional best-fitting polynomial approach was used to estimate regional spine profile (i.e. lordosis and kyphosis). Tangential [3], Taubin best-circle fit [4,5] and trigonometric [6] methods were then applied on adjusted spine profiles, at inflection points or at the stops points. Repeatability assessment was performed using intra-class coefficients while the Bland & Altman graphical method for limits of agreement was used to compare methods. A mixed model of ANOVA for repeated measurement was also used to determine the influence of method, session and group.

RESULTS AND DISCUSSION

For repeatability lordosis and kyphosis angle computation, ICC were above 0.75. Trigonometric method displayed significant difference with others.

ANOVA showed difference between groups (Table 1); no significant difference for the repetition of spine profile measurement; significant difference between angle calculation methods; no interaction between method * Repetition; GROUP * Repetition and GROUP * method.

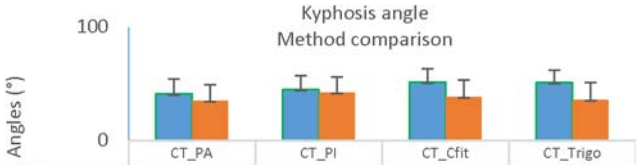

Table 1: Kyphosis angle measured by 3 different methods (CT_PA: tangential using stop points; CT_PI: tangential using inflection points; CT_Cfit: Taubin circle fit; CT_Trigo: trigonometric method) in both groups

CONCLUSIONS

A novel approach for spine curvature digitization using the pulp of the index finger as a probe has been developed and tested in a control group and in patients. The method is noninvasive and may offer a method of reducing the need for multiple radiographs. The technique is repeatable without group effect (Control – Patients), but spine angle estimations are method-dependent.

This palpatory approach offers new interesting perspectives in spine curvature profile appreciation in upright standing but also during forward and/or lateral bending.

The method allows to appreciate graphically modification of spine shape (Figure 1).

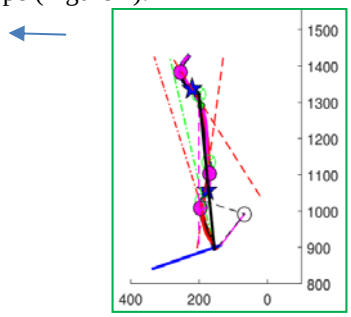

Figure 1: Cervical and lumbar hyperlordosis associated with a loss of thoracic curvature

P248 - IN VIVO 3D KINEMATICS OF CERVICAL SPINE MANIPULATION: INFLUENCE OF PRACTITIONER EXPERIENCE AND OCCURRENCE OF CAVITATION NOISE

[1] Bernard Van Geyt, [1] Pierre-Michel Dugailly, [3] Benoît Beyer, [2] Paul Klein, [2] Yves Lepers and [1,3] **Véronique Feipel**

INTRODUCTION

Investigations on 3D kinematics during spinal manipulation are widely reported for assessing motion data [1-4], task reliability [5-7] and clinical effects [8,9]. However the link between cavitation occurrence and specific kinematics remains questionable.

The objectives of the present study were 1) to assess 3D head-trunk kinematics during high velocity low amplitude (HVLA) manipulation between four different practitioners, 2) to analyze influence of expertise (years of practice) on ROM, velocity and acceleration and 3) to investigate the occurrence of cavitation and its link with kinematics.

METHODS

Twenty asymptomatic volunteers (9 females and 11 males, mean age 25 (SD 2.7) years (19–31 years), without previous cervical or thoracic disease, cervical manipulation red flags; history of pain or Whiplash associated disorders; sign of radiculopathy; history of spine fracture) were recruited. Four practitioners with different years of experience in cervical spine manipulative therapy (1, 10 and 20 years) were enrolled to perform HVLA technique on each subject.

A 6-degree of freedom instrumented spatial linkage (CA 6000 Spine Motion Analyzer, OSI, USA) was attached to the subject using an adjustable helmet and a harness fixed at the level of the first thoracic spinous process. This device provides good measurement accuracy and reliability [10,11] for the assessment of active motion. Prior to the procedure, a reference neutral position and active ROM (AROM) in each anatomical plane were sampled. Head-trunk 3D kinematics was sampled during HVLA manipulation by an independent operator at 100 Hz. Four target levels were selected (C3 and C5 on each side), and were randomly allocated to the different practitioners for each subject. Each practitioner was allowed a maximum of four trials per subject to produce a cavitation noise.

Maximal ROM, relative ROM (ROM%, in % of AROM) peak velocity and acceleration in each plane were computed. A repeated-measures ANOVA (analysis of variance) was used to explore the influence of side, level and practitioner on kinematic parameters. In case of significance, a LSD post hoc test was applied. Also, an ANOVA and a LSD post hoc test were used to compare kinematics when a cavitation occurred or not.

RESULTS AND DISCUSSION

Results are presented in Figure 1 and Table 1. The manipulation task was performed using extension, ipsilateral side bending and contra-lateral axial rotation independent of side or target level. The displayed angular motion magnitudes did not exceed normal active ROM. Regardless cavitation occurrence, wide variations were observed between practitioners, especially in terms of velocity and acceleration. Cavitation occurrence was related to several kinematics features (i.e. frontal ROM and velocity, sagittal acceleration) and practitioner experience. In addition, multilevel cavitation was observed regularly.

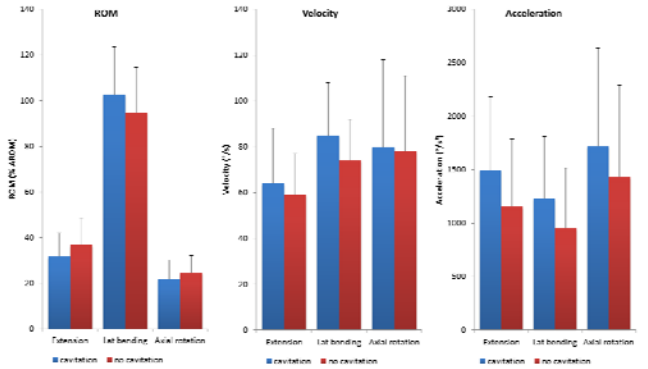

Figure 1. ROM, velocity and acceleration during HVLA manipulation.

Table 1. Effect of (p – ANOVA) of practitioner and cavitation on HVLA kinematics.

	Extension		Lat bending		Axial rotation	
	Pract.	Cavit.	Pract.	Cavit.	Pract.	Cavit.
ROM%	0.292	0.271	**<0.001**	**0.008**	0.058	0.630
Velocity	**<0.001**	0.103	**0.002**	**0.045**	**<0.001**	0.351
Acceleration	**<0.001**	**0.039**	**<0.001**	0.087	**<0.001**	0.090

CONCLUSIONS

Kinematics of cervical manipulation is dependent on practitioner and years of experience. Cavitation occurrence could be related to particular kinematics features. These aspects should be further investigated in order to improve teaching and learning of cervical manipulation technique.

P250 - MORPHOLOGIC ANALYSIS OF THE THREE COLUMNS OF THE SCAPULA: SURGICAL IMPLICATIONS IN REVERSE SHOULDER ARTHROPLASTY

[2,3] **Ashish Gupta**, [1,2] Nikolas K. Knowles, [2] George S. Athwal, [1,2] Louis M. Ferreira
[1]The University of Western Ontario, Biomedical Engineering Graduate Program, London, ON, CANADA

INTRODUCTION

Glenoid baseplate fixation for reverse shoulder arthroplasty relies on sufficient bone stock and quality. Glenoid bone may be deficient in cases of primary erosions or due to bone loss in the setting of revision arthroplasty. In such cases, the best available bone for primary baseplate fixation usually lies within the three columns of the scapula. The purpose of this study was to characterize the relationship of the three columns of the scapula with and without respect to the glenoid, and to determine if sex differences exist.

METHODS

Fifty cadaveric scapulae (25 male, 25 female) were analyzed using three-dimensional CT-based imaging software. The surface geometries of the coracoid, acromial scapular spine and lateral pillar were delineated in the sagittal plane. A linear best-fit line was drawn to establish the long axis of each column independent of the glenoid. The width of the glenoid was measured and points marked at the midpoint of each measurement. A best-fit line starting at the supra glenoid tubercle passing through the midpoints was chosen as the superior inferior (SI) axis of the glenoid.
An orthogonal (sagittal) plane to the scapular plane was used to project each axis representing the three columns of the scapula and the SI axis of the glenoid. The angle between each column was calculated with respect to each other and to the SI glenoid axis. Thus, measurements gave the relationships of the three columns of the scapula (independent of the glenoid) and to the long axis of the glenoid (dependent on the glenoid). Comparisons were made by sex using independent t-tests. Institutional review board approval was received for this cadaveric study.

RESULTS AND DISCUSSION

The mean angles between the three columns of the scapula and between each column and the glenoid SI axis are presented in table 1. There was no significant difference in the angle between the acromial spine and coracoid in males and females (p=0.29), but were significant differences between sexes in the angle between the lateral pillar and acromial spine (p=0.030) and coracoid (p=0.009). No significant sex difference was found between the acromial spine (p=0.260) and inferior scapular pillar (0.27) with respect to the SI glenoid axis. However, the female coracoid was found to be more horizontal than the male coracoid in relation to the SI axis of the glenoid (p=0.037).

Table 1: Angle relationships between the three columns of the scapula

	Male (n=25)	Female (n=25)	Total (n=50)	p-value
Acromial Spine/ Coracoid	91 ± 15º	95 ± 10º	93 ± 13º	*p=0.290*
Acromial Spine/ Lateral Pillar	128 ± 11º	134 ± 10º	131 ± 11º	*p=0.030*
Coracoid/ Lateral Pillar	141± 15º	131 ± 12º	136 ± 14º	*p=0.009*
Acromial Spine/ Glenoid SI	50 ± 10º	47 ± 8º	48 ± 9º	*p=0.260*
Lateral Pillar/ Glenoid SI	3 ± 9º	-0.4 ± 11º	1 ± 10º	*p=0.270*
Coracoid/ Glenoid SI	41 ± 13º	48 ± 9 º	45 ± 11º	*p=0.037*

This study demonstrates that the relationship between the scapular spine and coracoid is independent of sex. However, sex has a significant effect on the positions of the scapular spine and coracoid columns with respect to the inferior column. The inferior scapular column is positioned more anterior (closer to the coracoid) in females than in males. Sex variations may be important for screw placement in reverse shoulder arthroplasty baseplate fixation in bone deficient glenoids.

CONCLUSIONS

An understanding of the orientation of the columns of the scapula may aid in the design of reverse shoulder arthroplasty baseplates, and assist surgeons in the most effective screw placement for sufficient baseplate fixation.

P251 - TASK SPECIFIC MAXIMAL ELBOW TORQUE MODEL FOR ERGONOMIC EVALUATION

INTRODUCTION

In industrialized and developing countries, musculoskeletal disorders (MSD) represent the principal cause of working day loss. Most of them affect the upper limb. Risk factors identified include load, repetition, and postures [1]. While distinct indices exist to assess independently these factors none account for their interaction.

In production lines, some operations remain manual because of reduced workspaces and require workers to adopt unnatural postures while producing efforts. Since loads and postures management are dependent within the musculoskeletal system, measures able to relate them are required.

Isokinetic measurements were proposed to assess the maximal load capacity within joint. The purpose of this study was to evaluate the physical demand during an overhead manipulation task. A ratio between elbow flexion torque during the task and maximal isokinetic torques obtained in a similar posture was computed. Our hypothesis is that the ratio will be higher than 10% (i.e. 2 on Borg scale), meaning that fatigue related to the task should be considered for task management planning [2].

METHODS

Task measurement

The task consisted in holding and pushing up a screw-gun with the arm in 90° flexion to reach a point located 2 meters above the ground. A set of 47 anatomical markers put on the entire body as in [3] were recorded during the task using a 16 cameras motion capture system at 100 Hz. Simultaneously, ground reaction forces and moments were measured using two AMTI 120x60 cm force platforms at 1000 Hz supporting each foot. Inverse kinematics and inverse dynamics were performed using a full body model in Anybody to obtain joint angle, velocity and torque during the task. The model is available at the AnyBody Managed Model Repository[1].

Isokinetic measurements

The dynamometer was set up with the participant laying on the table and his dominant arm elevated in 90° flexion. Maximal isokinetic elbow flexion measurements included concentric and eccentric cycles at 60°.s^{-1}, 120°.s^{-1}, and 180°.s^{-1}. Three maximal isometric measurements were also recorded at varying elbow angles. Between trials, 1-minute rest was respected. Using the method in [4] based on Hill muscle model, parameters of the elbow flexion torque-angle-velocity relationship were optimized to fit the isokinetic data.

RESULTS AND DISCUSSION

The maximal torque model (Fig.1a) obtained elbow parameters values in coherent with those found in the literature [2]: maximal torque 38 N.m^{-1}, optimal angle 60°, range of motion 222°, 50% at 720°.s^{-1}, 75% at 585°.s^{-1}, concentric/eccentric ratio 0,13. With the arm in 90° flexion, the elbow flexion optimal angle and maximal torque of the participant seems smaller than in a more natural posture.

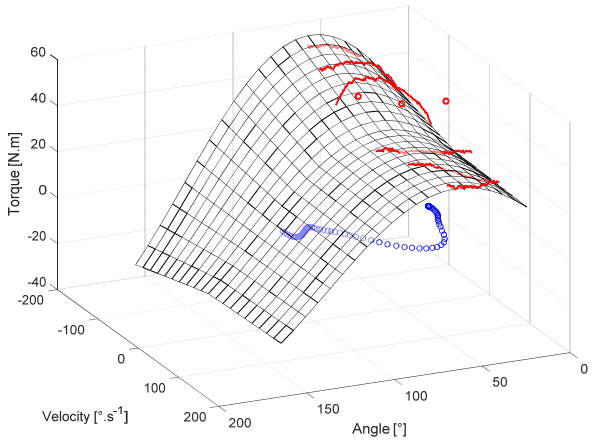

Figure 1: The torque-angle-velocity relationships during the task (dots) compared to the maximal torque model (mesh) fitted to the isokinetic experimental data (bold lines).

With regard to the limits defined by this model, the elbow flexion torque during the task varies about 10% of maximal torque in average with a maximal peak at 20% (Fig.1b). This peak seems to be obtained at the moment the screw-gun reaches the pushing position. These ratios refer to a "somewhat hard effort" [2]. Therefore, a proper task management planning should take this information into account. In addition, the task can be expected to impose higher loads on the shoulder joint. The same protocol might require to be applied on shoulder flexion and

CONCLUSIONS

Overhead manipulation tasks could be considered as "a somewhat hard effort" for elbow flexion. However further research is required on the shoulder to complete this evaluation. In the future, the present method could easily be applied to various type of tasks.

P252 - THE EFFECTS OF ELASTIC TAPING ON GAIT BIOMECHANICS OF STROKE PATIENTS

[1] **Konstantinos Kaliarntas**, [2]Mark Smith, [1]Susan Brown and [3]Anne Rowat
[1]Edinburgh Napier University, School of Applied Sciences
[2]NHS Lothian
[3]Edinburgh Napier University, School of Nursing, Midwifery and Social Care
Corresponding author email: k.kaliarntas@napier.ac.uk

INTRODUCTION

Elastic therapeutic taping (ETT) is a technique commonly used with athletes in order to increase joint stability potentially through the enhancement of kinesthetic feedback. Evidence suggests that tactile stimulation correlates with motor recovery in stroke patients (1).

The evidence regarding stroke rehabilitation and taping is limited and inconclusive and needs further research (2). Specifically for gait rehabilitation after stroke, ETT reported to significantly improve waking velocity, balance and decrease in spasticity (3,4). However, there is no evidence regarding biomechanical characteristics of gait and functional parameters as well as subjective self-reported experiences of patients from the use of taping.

Aim

To investigate the use of ETT application on chronic stroke patients as an alternative method to improve gait quality and function and to explore patient perceptions.

METHODS

This is a pilot experimental study. Three male and three female participants (n = 6) with stroke were recruited, with a mean age of 63 (16) years, mean height 165 (9) cm and mean body mass of 84 (21) Kg. All patients were > 3 months post stroke and with median Barthel Index score of 18 (interquartile range (IQR) 5) and median Functional Ambulatory Category score (FAC) of 5 (IQR, 2).

Study participants attended the laboratory twice, 3-5 days apart. After initial assessment and familiarizations participants fitted with lower body retroreflective markers and performed the outcome activities. Each activity repeated 3 times. Thereafter, the tape was applied, reflective markers were re-fitted and the outcome activities were performed once again. In the follow up assessment, 3-5 days later, the same outcome activities were measured without the tape.

Outcome Measures:

- Time Up and Go Test (TUG)
- 8m walking test, walking velocity
- temporal/spatial gait parameters
- Lower body kinetic parameters (Kistler force plates, Switzerland)
- Lower body kinematic parameters (Qualisys Oqus, Sweden)
- Balance/coordination during forward lunges and forward stepping activities
- Post-trial interview

Data Analysis:

Kinematic/kinetic data were processed with Visual3Dv5 software (C-Motion). Upon completion of the trial appropriate descriptive and inferential statistics will be used through IBM SPSSv20 to statistically analyse different outcome variables.

RESULTS AND DISCUSSION

The qualitative evidence of this pilot study suggests that ETT can affect confidence levels of stroke patients. This could potentially improve their capacity to perform physical activity, which is suggested to be beneficial after stroke (5).

Table 1. Temporal-spatial & functional walking parameters (median & interquartile range)

Participants n =6	Walking Velocity (m/s)	TUG (sec)	Spatial sym/try	Temporal sym/try
Baseline	1 (0.8)	20 (27)	0.89 (.3)	0.92 (.1)
Post Taping	0.85 (.8)	21 (26)	0.89 (.7)	0.92 (.2)
Follow up	0.75 (.6)	20 (28)	0.84 (.6)	0.92 (.2)

Some trends were observed suggesting improvements in walking velocity and TUG (Table 1). A clinical significant increase in walking velocity has been suggested previously to be around 0.2 m/s in stroke (6). More detailed analyses of the kinematic and kinetic variables could reveal further improvements in balance, coordination and general quality of gait.

However, the absence of control/placebo groups in this study and additional measures (i.e. EMG) cannot confirm or explain underlying mechanisms of any observed effects.

CONCLUSIONS

Initial analysis showed some improvement trends with respect to temporal and spatial as well as functional parameters. Biomechanical analysis will reveal possible changes in global lower body segment orientations which affect the quality of gait i.e. shank to vertical angle. Taping received very positive comments from stroke patients with particular references to their perceived confidence levels.

ACKNOWLEDGEMENTS

The authors would like to thank all participants for their contribution in this study.

P253 - LOWER-LIMB MUSCULAR STRENGTH IN PERIPHERAL ARTERIAL DISEASE/ INTERMITTENT CLAUDICATION: A SYSTEMATIC REVIEW & META-ANALYSIS

[1] **Stephanie L King**, [2]Amy E Harwood and [1]Sean Carroll
[1]Sport, Health and Exercise Sciences, University of Hull, Hull, UK [2]Academic Vascular Unit, Hull Royal Infirmary, Hull, UK
Corresponding author email: Stephanie.King@hull.ac.uk

INTRODUCTION

Peripheral arterial disease and intermittent claudication symptoms (PAD-IC) are atherosclerotic in origin. Reduction in blood supply to contracting lower limb skeletal muscles often presents as IC pain during physical activity, which negatively impacts on walking capacity and physical function. Supervised exercise therapy is recommended by NICE; however, exercise prescription varies and consensus on the most effective exercise programme components for PAD-IC is lacking [1]. Given that poorer levels of lower limb muscular strength are predictors of all-cause mortality [2] and faster functional decline [3] in those with PAD-IC, interventions targeting improvements in strength seem warranted. However, better evidence is required on the specific impairments of 'muscular strength and function' in PAD-IC patients.

METHODS

A literature search using MEDLINE and Elsevier databases were performed with the following search terms "intermittent claudication" [OR] "peripheral arterial disease" [AND] "muscle" [AND] "strength". Searches were limited to empirical full-text articles with adult PAD-IC cohorts, published in English language journals between 1947- June 2016. Studies were excluded if relevant outcome data were not presented together with a comparison group or the study did not clearly classify PAD-IC. Effect sizes (with 95% confidence intervals) were calculated using standardized weighted mean differences for measures of strength in those with PAD-IC compared to healthy controls or asymptomatic limbs. Publication bias was examined through funnel plot inspection and I^2 statistic were used to assess heterogeneity between studies.

RESULTS AND DISCUSSION

The search yielded 432 articles, of which 202 were duplicates. Of the remaining 230, a total of 203 did not meet the inclusion criteria. Twenty-seven articles were included in this review. Highly variable muscular strength testing methodologies were employed in the studies analysed including; isometric, concentric and eccentric strength, power, and endurance. Furthermore, multiple muscle groups were assessed within and between studies; including, hip flexors/extensors, knee flexors/extensors, and plantarflexors/dorsiflexors.

Overall strength, regardless of contraction form was reduced in claudicants compared to healthy controls (ES -0.41[-0.56, -0.26]) but with a substantial I^2 (56%) indicating wide heterogeneity between studies. The variation between strength measures primarily originated from four studies employing ten measures of isometric strength (ES -0.33[-0.56, -0.09], I^2; 63%). In contrast, four studies reporting seven measures of concentric strength were homogenous and showed a moderate-large effect compared to healthy control participants (ES -0.48[-0.60, -0.36], I^2; 8%). Comparable effects were also seen in two study designs, comparing symptomatic to asymptomatic limbs with heterogeneous reductions in overall strength stemming from wide variation in isometric strength (ES -0.23[-1.01, 0.62], I^2; 94%). These reductions primarily stemmed from impaired plantarflexor and knee extensor strength (ES -0.47[-0.76, -0.17], I^2; 38% and ES -0.26[-0.44, -0.07], I^2; 43%, respectively).

The reduction in concentric strength measures was evident from seven different measures of strength conducted, primarily in both knee and ankle musculature. However, it must be emphasized that these findings were restricted to measurements from only four published studies in PAD-IC patients. It is clear that an increase in both the quantity and consistent methodological quality including approaches to the assessment of muscular strength is needed for more definitive conclusions to be drawn. Nonetheless, the meta-analysis indicates that the effects of PAD-IC on isometric strength appears highly variable and not reduced in claudicants. Whereas concentric strength is more consistently reduced within PAD-IC groups. This finding is supported by previous functional reports during level walking [4] and stair ascent [5]. These findings suggest targeted exercise interventions should focus on improving lower-limb concentric strength and power. Whether eccentric strength has been compromised or maintained is unknown and, given its importance during a multitude of functional tasks, should be strongly considered for future investigation. The heterogeneity and lack of effect observed within isometric strength measures is of note and may be due to the following a) PAD-IC symptoms and underlying physiological responses to maximal isometric voluntary contractions in the affected limbs; b) measurement validity/reproducibility with isometric protocols c) PAD-IC effects on muscle characteristics, including neuromuscular and motor unit recruitment, between muscular contractions. Isometric strength testing may be of limited value as a primary outcome measure in PAD-IC patients, especially studies examining exercise interventions.

CONCLUSIONS

The present study has revealed that lower limb concentric strength is impaired in patients with PAD-IC and should be the focus for future targeted exercise interventions.

INTRODUCTION

The implantation of the acetabular component has a strong effect on the clinical outcome of the total hip arthroplasty [1-3]. Additive three-dimensional printed, patient specific templates (PSI) are promising tools which could prohibit a potential misalignment of the acetabular cup. The objective of our study was therefore to build PSIs with various dimensioned reference surfaces, followed by in-vitro investigations to examine the inter- and intra-operator reliability as well as the overall precision of these PSIs. We hypothesized that a template design could be found that guarantees practical usability and positional repeatability acceptable to be useful in THA surgery.

METHODS

Seven macroscopically normal human hemi-pelvis specimens were used for this study. After medical imaging with a 64-row MDCT scanner, the bony structure of each specimen was segmented using a combination of different algorithms with manual post processing by one operator. The segmented pelvic specimens were then further processed to PSIs with three different imprint heights (T1-T3) and manufactured using a Fused Deposition Modeling based 3D rapid prototyping system. Three volunteers were then asked to place the manufactured templates in the prepared acetabulum. They were requested to repeat this procedure 10 times for each template. For the recording of a repeated positioning of the PSI relative to the acetabulum an optical tracking system was used. Overall precision of the PSIs were calculated. Intra-class correlation coefficients (ICC) were determined to evaluate the intra- and inter-operator reliability.

RESULTS AND DISCUSSION

The inter- and intra-operator reliability of template T1 showed better results than the other templates, with excellent reliability in all orientations (Rx, Ry, Rz) ranging from 0.93 to 0.98. The intra-operator agreement was mixed with excellent to poor reliabilities (Table 1).

A strong difference in precision between the PSI designs could be observed. Our study has shown that by use of a PSI, the desired orientation of the acetabular shell can be adjusted with an overall precision of up to 1.55°, depending on the template design: The averaged deviation from the mean pose was 1.55° (SD 1.1°) for T1, 2.45° (SD 1.68°) for T2, and 4.09° (SD 2.04°) for T3. The mean values as well as SD in the single direction increased steadily from T1 to T3.

The precision was significantly different between T1 and T3 (Figure 1).

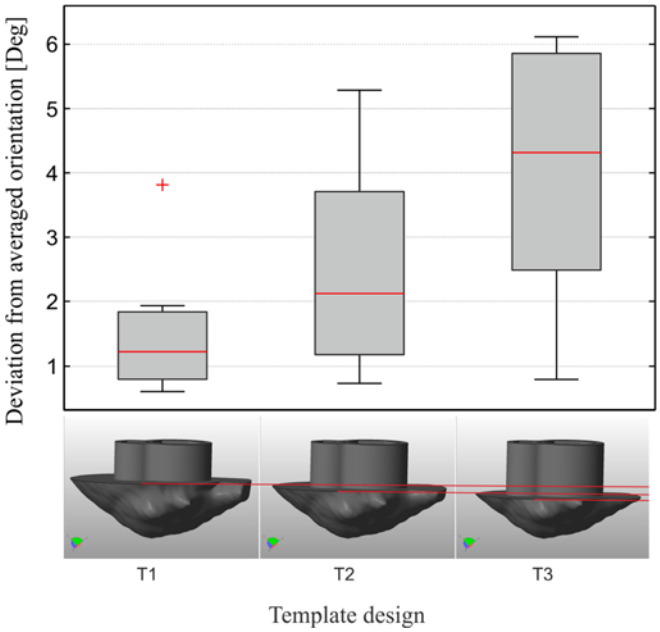

Figure 1: Deviation from averaged orientation of the used PSIs T1-T3.

CONCLUSIONS

This study provides further insight into the application of a PSI based approach for the implantation of the acetubular shell. The precision of the PSIs depends on the height of the template. The PSI with the largest contact surface showed good precision values with overall excellent inter- and intra-reliabilities. Based on our results, we believe that an application of the PSI based acetabular shell positioning in total hip arthroplasty procedures can potentially increase the precision of implant component placement.

INTRODUCTION

Traumatic brachial plexus injury is a severe peripheral nerve palsy resulting in upper limb dysfunction. Intercostal nerve transfers represent one method of elbow flexion reconstruction, and allow approximately 60 to 90% of patients to actively flex their elbow against gravity after surgery for brachial plexus injury [1, 2]. However, some patients have poor voluntary elbow flexion and shortening of the duration of muscle contraction even when able to perform voluntary elbow flexion after surgery.

The upper limb single-joint HAL (upper limb HAL-SJ) is a wearable robot that can support elbow flexion and extension motion (Figure 1). The features of the upper limb HAL-SJ enable real-time voluntary elbow motion by the wearer through muscle action potentials that are detected by surface electrodes on the anterior and posterior skin (biceps and triceps brachii) of the upper arm.

We report the effectiveness of electromyography (EMG) of biofeedback therapy for 3 cases in which elbow flexion exercises using the upper limb single-joint Hybrid Assistive Limb (upper limb HAL-SJ) were implemented postoperatively following elbow flexion reconstruction with intercostal nerve transfer and nerve grafting after a traumatic brachial plexus injury.

METHODS

The 3 patients (men 2, woman 1, mean age 36.0) were undergone elbow flexion reconstruction with intercostal nerve transfers (two cases) and nerve grafting (one case) after a traumatic brachial plexus injury. The 3 patients initiated elbow flexion exercises using the upper limb HAL-SJ as outpatients at mean 18.7 months (13, 38, and 5) after surgery. The patient's elbow flexion powers were the manual muscle testing (MMT) 3, 1, and 1 just before the initiation of treatment with the upper limb HAL-SJ.

Exercises using the upper limb HAL-SJ supported weaner's elbow motion by detecting surface muscle action potentials through surface electrodes on the biceps and triceps brachii. Elbow flexion exercises using the upper limb HAL-SJ were performed 50–100 times per session in a seated position. A therapist operated the controller and supported the device during performance of the elbow exercises. Clinical evaluation included the MMT without use of the upper limb HAL-SJ at the before and after HAL-SJ training. The patients also were asked to report any adverse events during treatment with the upper limb HAL-SJ at every session. A Trigno Lab wireless electromyography (EMG) system (Delsys, USA) was used to evaluate muscle activities of biceps and triceps brachii muscles at injured side. We instructed the 3 patients to perform elbow flexion and extension with maximum effort for five seconds three times at every session while equipped with the EMG system. Activities of the biceps brachii were evaluated by the ratio of its antagonist activation during extension to its maximum voluntary agonist activation during flexion.

RESULTS AND DISCUSSION

All patients completed the sessions of treatment with the upper limb HAL-SJ with no serious adverse events. Treatment using the upper limb HAL-SJ was administered once or twice a week for mean 10.7 sessions (10, 7, and 15) from mean 18.7 months (13, 38, and 5 months) after surgery. The MMTs of the 3 patients for elbow flexion changed from 3 to 4, 1 to 1, and 1 to 3 after the upper limb HAL-SJ sessions, respectively. By the EMG analysis, gradual decrease in the activities of biceps brachii during elbow extension, from 74 to 38, 198 to 95, 51 to 17 (%MVC), was observed respectively. In other words, the antagonistic muscle activation decreased. It suggested that upper limb HAL-SJ training have the potential to improve separated control of biceps and triceps brachii.

Figure 1: Exercises using the upper limb HAL-SJ.

CONCLUSIONS

Treatment with the upper limb HAL-SJ can be performed safely and effectively in a patient with elbow flexion reconstruction by intercostal nerve transfer and nerve grafting after a traumatic brachial plexus injury. No serious adverse events were observed during treatment with the upper limb HAL-SJ. We anticipate that treatment with the upper limb HAL-SJ has the potential to be an effective rehabilitation tool in elbow flexion reconstruction after traumatic brachial plexus injury.

P256 - THE CORRELATION OF NECK POSITION SENSE AND POSTURAL CONTROL AFTER PROLONGED TABLET COMPUTER USAGE

[1]Jen-Chieh Liao [2]Siang-Hua Hua [2]Cheng-Feng Lin
[1]Department of Neurosurgery, Chi Mei Medical Center, Chiali, Tainan, Taiwan
[2]Department of Physical Therapy, College of Medicine, National Cheng Kung University, Tainan, Taiwan

INTRODUCTION

Neck pain, or cervical spinal pain, is one of the most frequent musculoskeletal disorders; with an annual prevalence of around 30~50% among the general and work populations [1]. Despite the widespread use of tablet computers, the potential for use-related injury is not yet fully understood. Young et al. [2] found that the head and neck flexion angles during tablet computer use are greater than those for desktop and notebook computing, respectively. Previous studies have shown that muscle fatigue, inflammation, ischemia and pain alter the sensitivity of the human muscle spindles, and therefore disturb the proprioceptive input. Notably, impaired proprioceptive information from the cervical region affects the whole body via the proprioceptive chain, and hence may have a negative effect on balance control [2, 3]. Therefore, the purpose of this report was to evaluate the relationship between neck position sense and balance control after prolonged tablet computer usage.

METHODS

Twenty participants with chronic neck pain (14 women, 6 men, 24.1 ± 3.4years) and twenty pain-free controls (14 women, 6 men, 23.7 ± 3.3years) participated in this study. The cranio-cervical flexion test were measured in neck pain group and control group. The craniocervical flexion test was used to assess the endurance and movement control of deep neck flexor. The test required the subjects to perform precise upper cervical flexion and hold for 10 seconds. There was an inflatable pressure sensor (Stabilizer, Chattanooga Group Inc.) behind the neck and inflated to 20 mmHg. Then the subjects were guided to perform gentle head-nodding (craniocervical flexion) for 5 incremental stages from 22mmHg to 30 mmHg, and hold for 10 seconds in each stage. The highest pressure level was defined as the maximal pressure level where the subjects could achieve and hold for 10 seconds without *sternocleidomastoid muscle contraction.*

The neck pain group received a pain reproduced protocol in a sustained neck flexed posture by using tablet computer. The reflective spherical markers were put on head and neck to calculate the joint position error during cervical kinesthetic sensibility test and were collected with the motion capture camera (Qualysis Motion Capture System). The markers attached including bilateral tragus of the ears, the inferior orbit of the right eye, the bilateral acromion process and the sternum to define the location of the head and neck. The participants were also asked to perform balance tasks that included Romberg stance, Tandem stance and single-leg stance on two forceplates (Type 9281B, Kistler Inc., Switzerland) for ground reaction force measure and COP parameters. The head repositioning accuracy was defined as the absolute error (AE) over three repeated tests , i.e.,

$$AE = \frac{|\text{raw error trial 1}| + |\text{raw error trial 2}| + |\text{raw error trial 3}|}{3}$$

RESULTS AND DISCUSSION

In cranio-cervical flexion test, patients with neck pain showed lower pressure score as compared with healthy controls (neck pain: 24.2 ± 2.7mmHg, control: 28.3 ± 3.2 mmHg). There were some significant correlations between joint position error and balance performance (COP sway area) in neck pain group after pain-induced. The absolute errors (AE) in the frontal plane during flexion to initial were negatively correlated with COP sway area during majority of single leg stance tasks (r=-0.458 ~ -0.588). The AE in sagittal plane during extension to initial were positively correlated with COP sway area during right single leg stance tasks with and without eyes closed (r=0.609 ~ 0.732), but AE in the frontal plane were negatively correlated with COP sway area instead (r=-0.505 ~ -0.548). Besides, AE in the sagittal plane during right rotation to initial were positively correlated with COP sway area during Romberg stance with eyes open (r=0.489). Overall, participants after prolonged tablet computer using had decreased muscle endurance and had poor balance performance during standing.

Figure.1 The balance tasks: Romberg stance, Tandem stance and single leg stance

CONCLUSIONS

The insufficient endurance of deep neck flexor may lead to position error in the sagittal plane, and thus contribute to balance impairment. That is, the mechanical receptors of cervical spine play important roles in providing proprioception inputs and affecting the postural control.

P257 - DOES THE ADJUSTABLE DYNAMIC RESPONSE ANKLE-FOOT ORTHOSIS GIVE CHILDREN A POWER BOOST?

[1]**Anna Murphy**, [2]Rhiannon Campbell, [1]Stella Kravtsov and [1]Corey Joseph
[1]Clinical Gait Analysis Service, Monash Health, VIC, Australia.
[2] Australian Sports Commission, ACT, Australia.
Corresponding author email: annat.murphy@monashhealth.org

INTRODUCTION

The use of articulated ankle-foot orthoses (AAFO) is common in the management of children with lower limb spasticity [1]. They are used primarily to restrict ankle plantarflexion through the gait cycle while allowing full dorsiflexion through stance phase. AAFO can also assist in controlling knee motion and providing ankle/foot stability [2]. The Adjustable Dynamic Response (ADR) ankle-foot orthosis (AFO) is a new design that incorporates an ankle joint which can be tuned to control both plantarflexion and dorsiflexion to suit a child's available ankle range of motion. Such a device was recently shown to produce significantly more ankle power than the dynamic AFO in a small group of children with cerebral palsy [3]. The aim of this study was to quantify and compare the spatio-temporal characteristics, and lower limb kinematics and kinetics during gait of children with neurological and developmental conditions between two different orthoses; 1) a standard-issue AAFO; and 2) an ADR AFO.

METHODS

Fourteen children (8.2±2.5yrs, 130.5±15.3cm, 28.4±8.3kg) with a hemiplegia already using an AAFO daily have been recruited to date. Each participant was cast and fitted for their new ADR AFO by an orthotist at least three weeks prior to presenting for gait analysis testing. A minimum of 10 trials of 10 metre walks in each AFO were collected. Three-dimensional lower limb kinematics and kinetics were captured using an eight camera VICON motion analysis system (100 Hz) and two in-ground Kistler force plates (1000 Hz). The primary outcome measures were peak knee flexion and extension, sagittal plane knee and ankle range of motion (ROM), peak ankle dorsiflexion and plantarflexion, and ankle joint power of the AFO limb. Standard spatiotemporal outcome measures were output. This study was a within-subjects repeated-measures design using paired t-tests ($p<0.05$) to determine any differences in outcome measures between the two AFO types.

RESULTS AND DISCUSSION

Data analysis is on-going. Kinetic data from two participants was excluded due to equipment failure during testing. A total of 112 trials was included in the kinematic analysis and 56 trials in the kinetic analysis.

In this preliminary analysis, there were no significant spatial-temporal changes when wearing the ADR AFO. Double support time was shorter in the ADR AFO but only approached significance ($p<0.06$). Six kinematic variables were significant and are listed in Table 1. There were no differences in peak power generation at any lower limb joint, and the analysis to date suggests increased work done at the ankle joint through single support only when wearing the ADR AFO.

Table 1: Significant ($p<0.05$) sagittal plane kinematic findings

Mean kinematic angles (degrees)	ADR AFO	AAFO
Hip flexion at initial contact	40.2 ± 8.6	38.6 ± 6.9
Knee flexion/extension ROM	62.9 ± 12.2	64.2 ± 11.5
Ankle dorsi/plantarflexion ROM	20.1 ± 5.9	18.3 ± 4.0
Peak ankle dorsiflexion swing	2.9 ± 4.2	1.8 ± 4.3
Peak ankle plantarflexion stance	-6.4 ± 5.2	-3.9 ± 4.3
Peak ankle plantarflexion swing	-3.5 ± 4.9	-2.3 ± 4.2

The kinematic data supports the hypothesis that the ADR AFO increases ankle range of motion compared to an AAFO. This was particularly evident during late stance and swing phase where there was an increase in plantarflexion. This increase in ankle range of motion (ROM) was associated with a significant increase in work done at the ankle during the single support phase. This may suggest that the development of the positive ankle work period (A2) commences earlier in the gait cycle with the increased available range into plantarflexion when wearing the ADR AFO. This necessitates further exploration of the data.

Of note, a review of all data was done by the clinical team to assess and discuss orthotic alignment. Of the 14 children assessed, 10 were recalled to optimize alignment of the knee and ankle joints in the ADR AFO. This may account for the increased variation in the population when wearing the ADR AFO and have some impact on the findings of this study.

CONCLUSIONS

In this preliminary analysis of data, the ADR AFO was found to improve ankle joint kinematics, enabling better use of available ankle range which appears to allow the development of more positive work at the ankle joint. Data analysis continues and the full dataset will be prepared for presentation.

P258 - CHARACTERISTICS OF SPINAL MOVEMENT DURING GAIT IN DEGENERATIVE LUMBAR SCOLIOSIS AND THOSE ASSOCIATIONS WITH CLINICAL SYMPTOMS AND SPINAL DEFORMITY

[1]Nakamura H, [1]Urakawa S, [2]Tanaka N, [1]Kuwahara W, [3]Asaeda M, [1]Abe T, [4]Deie M and [2]Adachi N
[1]Graduate School of Biomedical & Health Sciences, Hiroshima University, Hiroshima, Japan

[4]Department of Orthopaedic Surgery, Medical Department, Aichi Medical University, Aichi, Japan

INTRODUCTION

Degenerative lumbar scoliosis (DLS) is defined as a spinal deformity in elderly people with a Cobb angle of more than 10°. The DLS patients often complain of clinical symptoms such as low back and leg pain during gait and these symptoms were occurred by walking [1]. However, few studies have shown the gait characteristics of segmental spinal movement in the DLS patients and relationship with clinical symptoms. The DLS patients also complain of their spinal deformity. However, the relationship between spinal deformity in the DLS patients and segmental spinal movements during gait remains unclear.

The purpose of this study was: (1) to clarify kinematics of segmental spinal movements during gait and relationship with clinical symptoms in the DLS patients, and (2) to investigate the relationship between spinal deformity and segmental spinal movements during gait in the DLS patients.

METHODS

Sixteen patients with DLS (DLS group) and age-matched healthy volunteers (Control group) were included. This study was approved by the Ethics committee of our institute and conformed to the Declaration of Helsinki.

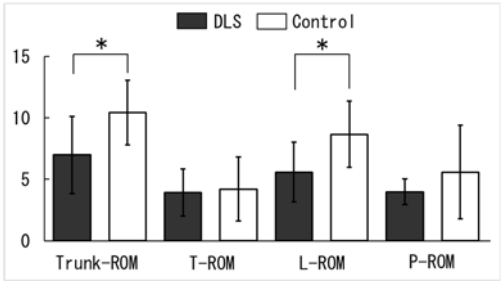
Spinal movements during gait were captured using the three-dimensional motion analysis system with 16 cameras and 8 force plates. We placed 38 reflective markers in reference with Plug-in-gait model and a previous study [2]. Trunk, thoracic, lumber, and pelvic angles were defined as interactive movements between the segments as follows, trunk angle: thoracic-pelvic segments, thoracic angle: thoracic-lumbar segment, lumbar angle: lumbar-pelvic segments, and pelvic angle: pelvic-global segments, respectively. The amount of lateral bending during one gait cycle in the coronal plane was calculated as trunk, thoracic, lumbar, pelvic ROM (Trunk-, T-, L-, and P-ROM, respectively).

As clinical outcomes, the Visual Analogue Scale (VAS) was used and low back pain, leg pain, and leg numbness for the DLS group were evaluated.

As assessments of spinal deformity for the DLS patients, Cobb angle (CA), sagittal vertical axis (SVA), and coronal imbalance (CI) were evaluated using radiographs.

RESULT AND DISCUSSION

In gait kinematics, Trunk- and L-ROM were significantly smaller in the DLS group. Many studies reported the smaller trunk movement in scoliosis patients. However, few studies revealed the segmental spinal movements during gait in the DLS patients. Therefore, smaller Trunk-ROM and newly L-ROM were the characteristics of segmental spinal movements during gait in the DLS patients.



*: $p < 0.05$ with independent *t*-test

Figure 1: The amount of lateral bending in each angle

In clinical outcomes, Trunk-ROM was negatively correlated with VAS score for low back pain (R = -0.50). Nerve root symptoms in the DLS patients were occurred at the convex side by compressing or at the convex side by overstretching a nerve root [1,3], resulting in low back pain or radiating pain. Summarizing the above, the decrease of Trunk- and L-ROM were the characteristics and coping strategy of DLS patients so as not to induce their low back pain during gait.

Whereas, there was no correlation between spinal deformity and segmental spinal movements during gait. Many studies reported the no correlation between spinal deformity and gait kinematics in the AIS patients [4,5]. Therefore, spinal deformity might not influence to the spinal movements during gait in the DLS patients.

CONCLUSIONS

These results suggested that the kinematic analysis could result in further understanding of clinical symptoms of DLS in a different way from the spinal deformity.

P259 - EVALUATING EFFECTS OF HIGH AND LOW FREQUENCY DEEP BRAIN STIMULATION ON GAIT PERFORMANCE OF ADVANCED PARKINSON'S DISEASE PATIENTS

[1] **Ching Nien,** [1,2]***Bing-Shiang Yang, [3] Kai-Hsiang Chen
[1] Department of Mechanical Engineering, National Chiao-Tung University, Hsinchu, Taiwan
[2]Institute of Biomedical Engineering, National Chiao-Tung University, Hsinchu, Taiwan
[3]Department of Neurology, National Taiwan University Hospital, Hsinchu Branch, Hsinchu, Taiwan

INTRODUCTION

Deep brain stimulation (DBS) is an invasive therapy that can control the symptoms of Parkinson's disease (PD). Setting the stimulation frequency at 130 Hz has been verified that it can control patient's symptoms. However, the efficacy of DBS decreases by time and could not control gait disorder like freezing of gait (FOG) properly. A previous study claimed that the number of freezing episodes during the stand-walk-sit test (SWS test) was significantly lower during 60 Hz DBS among PD patients who developed FOG [1]. When PD patients developed FOG during 130 Hz DBS, clinicians switched DBS frequency to 60 Hz and determined whether the patients had better gait performance based on complete time of SWS test or subjective freezing of gait questionnaire (FOG-Q) scores. However, only part of patients who developed FOG satisfied with 60 Hz DBS and we did not know what objective gait parameters were improved. Also, it is controversial whether the gait parameters of patients without FOG during 130 Hz DBS could be improved by 60 Hz DBS. Therefore, the purpose of this study was to observe stride time and swing time duration of one patient with FOG who satisfy with 60 Hz DBS and one patient without FOG during 130 Hz DBS.

METHODS

We recruited two subjects: Subject One (68-year) with FOG who implanted 130 Hz DBS for 6 months. Also, subject one whose complete time of SWS test reduced from 92 to 58 second (average of three SWS test) when switching stimulation frequency from 130 Hz to 60 Hz. Subject Two (61-year) who implanted 130 Hz DBS for 8 months and did not develop FOG. Two subjects were asked to execute gait-evaluating experiment in three conditions order: 1) with 60 Hz stimulation 2) without stimulation (off stimulation) 3) with 130 Hz stimulation. Besides, DBS voltage decreased while frequency increased in order to maintain total electrical energy delivered (TEED) constant. In the gait-evaluating experiment, subjects walked through a 75-meter route including four 90-degree turnings and four 180-degree turnings.

We attached four inertial measurement units on subject's shanks and thighs. Angular velocity on sagittal-plane of shank was used to determine the timing of toe off (TO) and heel strike (HS) [2]. Furthermore, we defined time duration between two consecutive HS points as the stride time, and the ratio of the time duration between TO and HS to stride time as swing time duration. Repeated measures two-way ANOVAs were used to compared variables among conditions and patients. Post-hoc analyses were completed using repeated measures one-way ANOVAs to compared variables among conditions. Also, paired t-tests were used to determine statistically different level of stride time and swing time duration between conditions (set p value at 0.05).

RESULTS AND DISCUSSION

Figure 1 shows two subjects' gait parameters, collected by each condition with at least 30 gait cycles, were observed. There was a significant interaction between subjects and conditions to stride time ($p < 10^{-10}$) and swing time duration ($p = 10^{-5}$). For subject one, there was an effect of conditions on stride time ($p < 10^{-10}$) and swing time duration ($p < 10^{-10}$). Post-hoc comparisons showed a significant reduction ($p < 10^{-10}$, 193.66 ms) in stride time and a significant increase ($p < 10^{-10}$, 10.83%) in swing time duration during 60 Hz compared with 130 Hz stimulation condition.

For subject two, there was an effect of condition on stride time ($p < 10^{-10}$) and swing time duration ($p < 10^{-10}$). However, post-hoc comparisons showed that the stride time and swing time duration were not significantly different between 60 Hz and 130 Hz stimulation conditions.

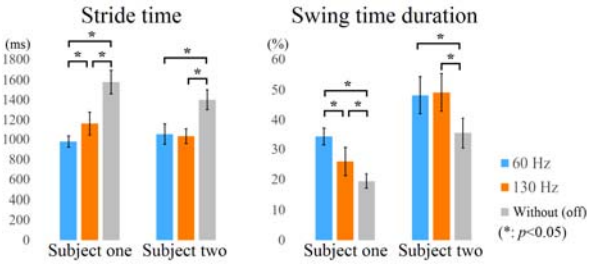

Figure 1: Two subjects' stride time and swing time duration parameters of right legs during 60 Hz, 130 Hz and without stimulation conditions. * represented p value < 0.05.

CONCLUSIONS

For the patient with FOG, we observe that stride time and swing time duration are significantly different between 60 Hz and 130 Hz stimulation conditions. On the other hand, stride time and swing time duration of the patient without FOG are not significantly different between 60 Hz and 130 Hz stimulation conditions. Future work is adding more subject results to verify the phenomenon.

P260 - CLINICAL ANALYSIS OF THE POSTERIOR TIBIAL TENDON AND THE RELATIONSHIP WITH THE FLATFOOD DEFORMITY

INTRODUCTION

The posterior tibial tendon (PTT) tenosynovitis was described for the first time by Kulowski in 1936 [1]. At the beginning, this abnormality was considered as a discrete clinical entity. However, several studies have demonstrated that the PTT tenosynovitis can lead to partial or total rupture of the tendon [2-3]. The causes of the rupture of the PTT are related with hypertension, diabetes mellitus, obesity and lack of blood supply to the tendon caused by the degenerative process of aging [2]. Furthermore, the dysfunction of the PTT is related with the collapse of the medial arc of the foot and others deformities, such as valgus foot. Nevertheless, there is no clear evidence to support that the rupture or dysfunction of the PTT produces the collapse of the medial arch of the foot. Basmajian and Stecko performed an EMG study of standing patients and found that there was no loss of the medial arch of the foot when the tibialis posterior muscle was inactive [4]. Therefore, this research aimed to investigate the relationship between the PTT and the flatfoot deformity, analysing the structure of the tendon in cadavers, with the aim of getting a better understanding of the origin of the flatfoot deformity.

METHODS

Seven right feet with flatfoot deformity were dissected from the posteromedial part of the ankle. Five females (71.4%) and two males (28.6%) were involved in the study with an average age of 73.28 years (range 58-85 years). The whole structure of the PTT was removed from the posteromedial part of the ankle and measurements of its length and thickness were taken.

RESULTS AND DISCUSSIONS

The whole structure of the posterior tibial tendon is shown in Figure 1a. The tendon presented a soft texture and white colour. It is clear upon inspection of Figure 1b that there was a significant reduction of the thickness of the tendon. Although there was no total rupture of the ligament, its thickness was less than 1mm in all the cases. This abnormality maybe related with the posterior tibial tendon insufficiency. Figure 1c shows the length of the tendon part and the muscle segment. Both structures integrate the total length of the PTT, mean length 24.71 ± 1.60 cm. It is known that the rupture of the PTT can lead to the flatfoot deformity [2-3]. However, other studies have shown that the structure of the arc remain the same when the tibialis posterior muscle is inactive [4]. The current study support the idea that the stability of the arch is given by passive (ligaments and bones) and active (muscles) components and failure of one of these will produce the collapse of the whole structure. The results of the present investigation cannot be applied to the overall population due to the small amount of participants. However, it is clear to observe that the atrophy of the PTT could produce the flatfoot deformity.

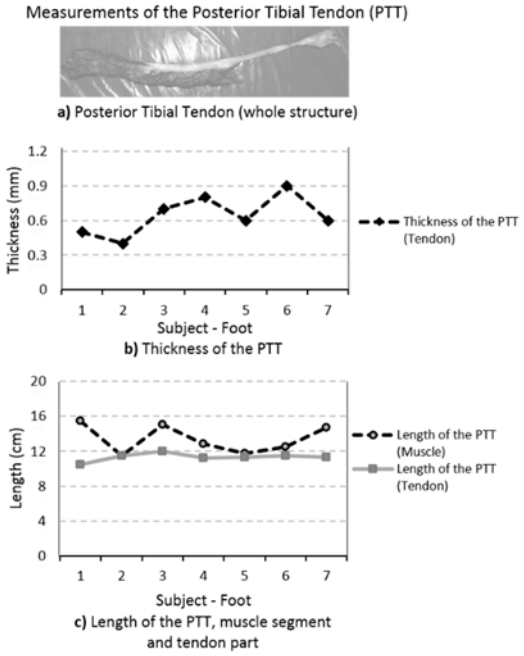

Figure 1 Measurements of the posterior tibial tendon; a) whole structure, b) Thickness of the tendon and c) Length of the tendon and muscle part.

CONCLUSIONS

There is a clear relationship between the atrophy of PTT and the collapse of the medial arc of the foot. Rehabilitation or surgery of the PTT should be considered in order to avoid the flatfoot deformity, which affects the biomechanics of the foot and the body structure.

ACKNOWLEDGEMENTS

The authors would like to thank the department of biomechanics at the Centre of applied innovation in competitive technologies (CIATEC A. C. in Spanish) for supporting the research.

P261 - THE EFFECTS OF A FLAT THORACIC SPINE CURVATURE ON SCAPULAR KINEMATICS DURING ARM ELEVATION IN CLASSICAL BALLET DANCERS

[1] **Augusto Gil Pascoal**, [1]Cátia Cascais and [1]Vanessa Costa
[1]University of Lisbon, Faculty of Human Kinetics, CIPER, LBMF, P-1499-002 Lisboa, Portugal

INTRODUCTION

The acute effect of an augmented thoracic kyphosis on scapular posture was previous analyzed comparing changes in scapular positions when subject switches between the "normal" trunk posture and the adoption of a slouched posture [1, 2]. No information exists about the changes on scapular kinematics imposed by "*flat thoracic spine*", particularly during arm elevation, and in asymptomatic subjects with a flat thoracic curvature resulting from a task-dependent morphological adaptation, e.g. classical ballet dancers. The purpose of the study was to compare scapular kinematics during arm elevation regarding the magnitude of thoracic spine curvature on the sagittal plane (kyphosis). We hypothesized that less thoracic kyphosis scapula induce a more upward, external and posterior tilting position.

METHODS

Thoracic kyphosis (TrK) was measured in a resting standing position using a Flexible Curve (Faber-Castell, Germany), a malleable band of metal covered by plastic with approximately 60 cm length, following a previously [3]. The percentage ratio between TrK height and length, the *kyphosis index* (KI) was also calculated [3]. The higher scores of KI indicate greater degrees of TrK. A cut-off value of 8.5 for the KI was used as postural criteria to distinct 2 groups of participants: "*Flat Thoracic Spine*" (FTS) group (N=25; Age = 19.8 ± 5.5 years; Height = 169.6 ± 6.3 cm; Mass = 49.6 ± 8.1 Kg); and "*Kyphotic Thoracic Spine*" (KTS) group (N=25; Age = 20.6 ± 3.6 years; Height = 168.6 ± 8.6 cm; Mass = 60.6 ± 7.8 Kg). The study was approved by the university ethics committee. The FTS participants were recruited among a classical ballet dancers population (practice time = 12.7 ± 2.4 years). A 6DOF electromagnetic device (Hardware: "*Flock of Birds*" Ascension Technology; Software: Motion Monitor v7.0) was used to record humeral and scapular 3D kinematics, according to according to the shoulder ISB standardization protocol [4], in 3 arm positions: rest (±15º elevation), 90º abduction and maximum elevation. An independent-samples *t*-test was run to examine differences in KI and scapular rotations in each arm positions. Person product-moment correlation coefficients were calculated to examine the relationship between KI and each scapular rotation. Specific software (SPSS 19) and a significantly level of $p<.05$ was used for statistics.

RESULTS AND DISCUSSION

Differences between both groups of subjects with respect to the thoracic spine curvature were confirm [$t(28) = 10.9$; $p = 0.0$; Mean difference: 1.9; 95CI: 2.3 – 1.6]. The FTS group displayed smaller KI [FTS Mean (SEM): 7.7 (0.7); KTS group: 9.7 (1.2)]. Significantly differences ($p<0.5$) were found between groups of subjects on all scapular rotations and arm positions. In the 3 arm positions, the FTS group (dancers) displayed significantly greater scapular upward rotation (Sx) and smaller internal rotation (Sy). Dancers also showed more posterior tilting (Sz), at 90º, and anterior tilting at rest and maximum arm elevation (Table 1). A significantly negative correlation was found between KI and upward and spinal tilt, except for upward rotation at maximum arm elevation. A positive correlation was found for scapular protraction at rest and 90º arm positions. These results are according with previous studies which found a scapular resting position more in the medial rotation, upward rotation, and anterior tilt, in subjects with higher TrK [2]. Finley et al. [1] also found that in a slouched posture (increased TrK) the scapular posterior tip and lateral rotation there were significant decreases, with no change in upward rotation angles.

Table 1: Scapular rotation angles [Mean (SEM)].

		Groups of Participants		M.D.	95%C.I.
		FTS *(Dancers)*	KTS *(Non-Dancers)*		
REST	Sx	1.5 (1.2)	-6.2 (1.5)	4.7 (0.5)	3.5 to 5.8
	Sy	35.4 (1.5)	42.6 (1.4)	-7.3 (0.7)	-8.6 to -5.9
	Sz	-14.7 (1.2)	-18.1 (1.3)	3.5 (0.4)	2.6 to 4.3
90º	Sx	19.7 (1.3)	13.4 (1.7)	6.2 (0.8)	4.6 to 7.8
	Sy	40.5 (1.3)	46.4 (1.6)	-5.9 (0.7)	-7.3 to -4.6
	Sz	6.9 (1.4)	2.9 (1.3)	4.0 (0.5)	3.0 to 5.0
Max	Sx	45.3 (3.1)	40.8 (3.2)	4.5 (3.0)	-1.6 to 10.6
	Sy	43.0 (1.7)	48.8 (3.3)	-5.8 (2.4)	-10.7 to -1.0
	Sz	3.5 (1.6)	13.2 (1.9)	16.7 (1.1)	14.5 to 18.9

SEM.: Standard Error of Mean; **FTS:** Flat Thoracic Spine group**;** **KTS:** Kyphotic Thoracic Spine group; **M.D.:** Mean Difference; **95%C.I.** : 95% Confidence Interval of the Difference; **S**x: Scapular Upward Rotation; **Sy:** Scapular Protraction; **Sz:** Scapular Spinal Tilt

CONCLUSIONS

A significant relationship was found between thoracic spine curvature and scapular posture, at rest and 90º arm elevation: smaller KI values are associated with an upward and anterior tilt scapular position. Females with flat thoracic spine displayed greater upward, external rotation angles and anteriorly tilted in all arm positions (rest, 90º and maximum), with the exception at 90º, where scapula assume a posterior tilting position.

P262 - CHANGES IN ANKLE POWER GENERATION FOLLOWING RESISTANCE AND ENDURANCE TRAINING IN MULTIPLE SCLEROSIS

[1]Rosie Richards, [1]Martin Heine, [2]Bibi Geurtz, [2]Felicia Los, [1]Marc Rietberg, [1]Jaap Harlaar, [2]Karin Gerrits, [1]Heleen Beckerman, and [1]Vincent de Groot.

INTRODUCTION

Multiple sclerosis (MS) is considered an immune-mediated progressive disorder of the CNS and is associated with a wide range of symptoms including motor, sensory, brainstem, cerebellar, visual, bowel/ bladder, fatigue and cognitive symptoms [1,2] and may experience reduced walking ability. During walking, ankle plantarflexor muscles generate power to initiate the next step [3]. In people with MS, the power generation can be reduced by up to 30% compared to healthy controls [4], potentially leading to a decline in walking performance. Exercise therapy is one option to improve walking performance through building muscular strength and endurance. In this pilot study, we investigated the effect of a sequential exercise program (8 weeks of resistance training followed by 8 weeks of walking-specific treadmill training) on the peak ankle push-off power during a twelve minute walk test. We also investigated changes in the total distance walked during the 12 minute walk test before, at the mid-point and after the exercise intervention. We hypothesized that patients with MS would show increased power generation post-training and that this would be consistent with an increase in the distance walked during the 12 minute walk-test.

METHODS

Ten patients with MS (mean age 48.8 ±8.9, six female) were recruited for this study through the local rehabilitation physician (VGR). Inclusion criteria were aged between 18 and 70, definite diagnosis of MS, ability to walk for 12 minutes without a walking aid but complaints of a decline in walking performance during continuous walking. Exclusion criteria were serious co-morbidities, an MS relapse in the 3 months prior to participation or medical conditions affecting gait. Ten age and gender matched controls were recruited and performed the 12 minute walk test as described below.

Prior to the exercise program, at the mid-point and post-training patients attended for gait analysis in the VUmc Virtual Reality Laboratory, where they undertook the twelve minute walk test on an instrumented, self-paced treadmill. Marker position data (based on the standard ISB recommendations for analysis of the lower limbs) and analog data from the force plates were recorded for 30 seconds during every minute of the 12 minute walk test using a 10 camera Vicon motion capture system. Ankle joint power was calculated from the force data and marker position data using in-house software, BodyMech, and was normalized to bodyweight.

The first 8 weeks of the training program consisted of progressive resistance training (PRT) of 30 to 60 minutes, 3 times per week aimed at the lower extremities. Following this, patients had one week of rest and one week of measurements (mid-point of the program). The program concluded with 8 weeks of treadmill training; high-intensity walking at 70-90% maximal heart rate interspersed with resting periods at slower walking speed.

Non-parametric tests were used to assess differences between results in patients with MS and healthy controls (Mann-Whitney U test). Friedman's two-way ANOVA was used to assess the preliminary effect of the sequential training intervention. Due to a small sample size and limited power, results should be interpreted with caution. All tests were conducted in IBM SPSS statistics 22 with α=0.05.

RESULTS AND DISCUSSION

Compared to healthy controls, patients walked with reduced power generation Fig.1. At the mid-point of the training program, patients with MS (n=9) improved their ankle push-off power, although this change was not significant. The change was maintained but not further improved after the walking-specific treadmill training (end of training). After the PRT (mid-point of the training), the walking distance increased significantly from 729±188m to 842±146m ($p<0.05$), likely as a result of an increased step length (although this change did not meet statistical significance) generated by increased ankle push-off power. Changes in hip power generation may also provide insight into the increase in distance walked.

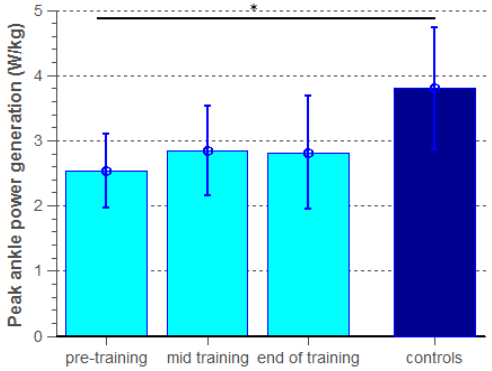

Figure 1: Peak ankle power generation at three time points for patients with MS, with comparison to controls. Note data is presented for the more affected leg only.

CONCLUSION

This pilot study indicates that progressive resistance training may be beneficial in improving ankle power generation in patients with MS, leading to an increase in walking speed/ distance. The added value of the walking specific treadmill training is not evident in the results presented here, but it may have contributed to improved walking performance through other mechanisms.

P263 - FINITE ELEMENT ANALYSIS SHOWS FUNCTIONAL BONE STRAIN AND CAPSULE COMPRESSION ACCOUNTS FOR MANDIBULAR CYST EXPANSION AND CORTICATION

Babak Sarrafpour[1], Charbel El-Bacha[1], Qing Li[2], Hans Zoellner[1]

INTRODUCTION

Numerous diseases result in pathological cavities collectively defined as cysts, usually but not always containing fluid and lined by epithelium. Cyst expansion in bone involves bone resorption, but is often accompanied by adjacent bone formation with cortication, and the mechanisms for these two apparently opposite processes remain unclear. Functional strain drives bone remodeling, which involves both bone formation and resorption. We explore the role of functional strain in cyst expansion and cortication using a three-dimensional finite element analysis (FEA) model of a simulated cyst in mandible.

METHODS

A 3D model of a mandible from an eight year old child constructed for our previous report [1] was modified for the current study. For cyst simulation, a spherical cyst cavity mask with a diameter of approximately 8mm was created around the apex of the mesial root of the lower right first permanent molar. The solid mesh model was imported into ABAQUS CAE 6.11 for FEA and three loading conditions were modelled, representing biting on the right molar, left molar and incisors. Strain Energy Density (SED) and Biological Response Units (BRU) were calculated and comparison was made with an identical finite element model, lacking the simulated cyst.

RESULTS AND DISCUSSION

We earlier described a role for soft tissue compression in bone resorption for tooth eruption [1], using Biological Response Units (BRU) to evaluate the net biological effect of soft tissue tension or compression, in driving either formation or resorption of adjacent bone respectively. Analysis of BRU for the simulated cyst capsule demonstrated overall compression in all loading conditions, indicative of surface bone resorption.

In all loading conditions studied, FEA demonstrated greater strain energy density within the bone lining the cyst, compared to the non-cyst containing model (Figure 1) , consistent with bone formation and cortication.

Cortication is a feature not limited to cysts, but may occur about any expansile bone lesion, including solid masses. We have chosen to model a dental radicular cyst, primarily because of the high prevalence and clinical significance of these bony lesion. However, our model is independent of the specific pathophysiology of the cyst, so that we further believe our findings are applicable to expansion and cortication of all bone cysts, and any solid lesion of the bone that has a well-developed capsule.

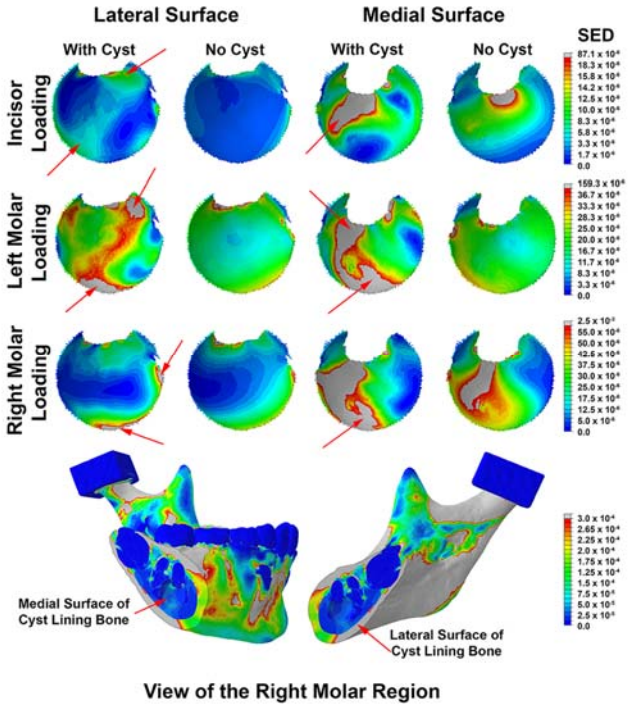

Figure 1: Color plots showing bone SED under incisor, left molar or right molar loading, with and without the presence of the simulated cyst. Red arrows indicate zones of particularly high SED relative to controls, while color scales are optimized for each view shown.

CONCLUSIONS

We conclude that functional stress results in dominant compression of the soft tissue capsule of bony cysts, and that this contributes to cyst. We further conclude that functional stress becomes concentrated in the bone immediately adjacent to the soft tissue cyst capsule, with the effect of driving bone formation and cortication. Our view is that this is a general mechanism applicable to any bone cyst or solid lesion.

P264 - FEMORACETABULAR IMPINGEMENT KINEMATICS AND KINETICS: A SYSTEMATIC REVIEW AND META-ANALYSIS

[1]**Matthew G King**, [2]Peter R Lawrenson, [2]Adam I Semciw, [1]Kane J Middleton, [1]Josh J Heerey, [1]Kay M Crossley
[1]La Trobe University
[2]University of Queensland

INTRODUCTION

Femoroacetabular impingement (FAI), specifically cam morphology, is a frequent source of hip and groin pain in young active individuals. The prevalence of cam morphology in semi-professional soccer players has been shown to be as high as 60% [3], however, presence of these findings on imaging does not necessarily conclude that the individual will go on to develop FAI [1]. Therefore, the identification of altered movement patterns may provide indications for treatment strategies to address symptoms and/or prevent further joint degeneration.

METHODS

A systematic search was conducted in Medline; CINAHL, EMBASE; Scopus and SPORTDiscuss. Studies were included if they investigated the biomechanics of activities of people with FAI and compared them to controls and/or the asymptomatic limb OR pre/post intervention studies where the study included pre-intervention data and an asymptomatic control group for analysis. Methodological quality was assessed using the Epidemiological Appraisal Instrument (EAI) [2]. Data extraction was conducted on demographics, kinematics and kinetics, standardised mean differences (SMD) were calculated and a meta-analysis was performed on data from studies with sufficient clinical homogeneity using a random effects model.

RESULTS AND DISCUSSION

Ten studies fulfilled the inclusion criteria (2 surgical pre/post intervention and 8 cross-sectional) with none investigating FAI in soccer players. Methodological quality varied between 41% and 68.5% using the EAI [2]. A total of 151 controls and 153 symptomatic were included. The included studies investigated the effects of pathology on walking, squatting, landing and stairs.

During the stance phase of gait, people with FAI had lower; peak hip extension (-0.40, -0.71 to -0.09; I^2= 0% p=0.60), total sagittal plane (-0.51, -0.93 to -0.08; I^2= 0% p=0.66) and, peak hip internal rotation (-0.67 -1.19 to -0.16; I^2= 47% p=0.15) range of motion (ROM). Pooled external joint torque data also showed that people with FAI had lower peak hip external rotation moment (-0.71, -1.07 to -0.35; I^2= 0% p=0.82).

People with FAI squatted to a lesser depth (0.92, 0.46 to 1.38; I^2= 0% p=0.77) but qualitative analysis showed no difference in hip kinematics and conflicting results for total sagittal plane pelvic ROM during a squat. Insufficient evidence was also found that people with FAI had lower peak external rotation torque (-0.13, -0.21 to -0.05) while squatting. No differences were observed in drop landing and there was insufficient evidence that people with FAI had a lower; peak hip extension angle (-0.83, -1.54 to -0.13), total hip sagittal plane ROM (-1.23, -1.97 to -0.49) and peak hip internal rotation angle (-0.90, -1.61 to -0.19) during stairs.

Data presented in this review demonstrated that individuals with FAI walk with lower total sagittal and peak extension ROM. This may be due to extension being the only movement that gets close to end of range while walking. The clinical relevance for this finding is unclear, however this kinematic finding has also been shown to be present in hip osteoarthritis and total hip replacement populations. Furthermore, the inability to squat to a lower depth despite no difference in hip joint kinematics may be caused by maladaptive movement strategies as a result of the condition, not a lack of hip ROM. This information may provide a target for future treatment strategies and interventions for FAI.

CONCLUSIONS

Further research into the effects of more provocative sport specific tasks are required, as these results show that individuals with FAI may benefit from task specific functional retraining to address maladaptive movement patterns as a result of FAI.

P265 - INVESTIGATING POTENTIAL MECHANISMS OF OVERUSE DURING DANCE LEAPS IN A DANCER WITH FLEXOR HALLUCIS LONGUS TENDINOPATHY

[1]**Hai-Jung (Steffi) Shih**, [1]Lindsey Trejo, [1]K. Michael Rowley, [2]Danielle N. Jarvis, and [1]Kornelia Kulig

[1]University of Southern California, Los Angeles, CA, USA
[2]California State University, Northridge, Northridge, CA, USA
Corresponding author email: haijungs@usc.edu

INTRODUCTION

Flexor hallucis longus (FHL) tendinopathy is so prevalent in female ballet dancers that it is also known as dancer's tendinitis. This condition may be attributed to the extreme range of motion and overuse of the toes in typical ballet training and performance [1]. The *saut de chat* leap is a common dance leap that places biomechanical demands on the toes because of the extreme range of motion during push off, which may contribute to the overuse of FHL.

In a previous work, we have established typical kinematics and kinetics during *saut de chat* leaps performed by 30 healthy dancers [2]. Therefore, the purpose of this study is to characterize kinematics and kinetics of the *saut de chat* leap takeoff in one dancer with FHL tendinopathy compared to 30 healthy dancers.

METHODS

A female professional dancer, aged 23, with FHL tendinopathy confirmed with a clinical and imaging examination participated in the study. Following warm-up and instrumentation, the participant performed *saut de chat* leaps taking off of her involved limb. Participant was pain-free during testing.

Ground reaction force (GRF) data were collected at 1500 Hz, and synchronized with kinematic data collected at 250 Hz. A full-body marker set was used to define body segments and track 3D segment motion. Additional markers were placed on the 1st and 5th metatarsal heads as well as the distal hallux to define the toe segment [3].

Marker and GRF data were low-pass filtered with cutoff frequencies at 12 and 50 Hz, respectively. Takeoff phase was defined from initial contact through toe-off of the takeoff limb. Range of motion of the hip, knee, ankle, and metatarsal phalangeal (MTP) joints were determined by the orientation of each segment relative to the proximal. Net joint moments were calculated using standard inverse dynamics equations, normalized to body mass, and expressed as internal moments. Data from the participant were time-normalized to 100% takeoff and superimposed on data from 30 healthy dancers described in our previous publication [3]. Weight acceptance and push off sub-phases were defined based on peak vertical GRF to aid interpretation.

RESULTS AND DISCUSSION

Upon visual examination, the dancer with FHL tendinopathy had prolonged weight acceptance compared to healthy dancers as evident by the delayed peaks in vertical GRF, ankle angle, ankle moment, and knee moment. This buffering of weight acceptance appears to be predominantly controlled by a notable increase in flexor moment of the MTP joint during this phase (Figure 1). In order to achieve sufficient height demanded by the task, the loss of vertical impulse during weight acceptance was compensated by an increase in vertical GRF during push off, which is attributed to increased ankle plantarflexor moment and knee extensor moment during the same phase.

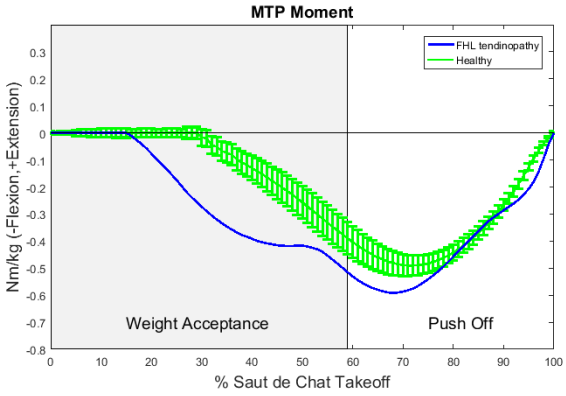

Figure 1: MTP internal joint moment during *saut de chat* takeoff for one dancer with FHL tendinopathy superimposed on data from 30 healthy dancers (95% confidence interval).

In addition, we found that the MTP joint angle was shifted approximately 10 degrees towards extension throughout 0-80% of takeoff for the dancer with FHL tendinopathy. This was caused by not fully lowering the heel to the ground following an elevated heel height at initial contact, as confirmed by additional analysis on the heel marker.

These results suggest a potential mechanism of overuse in a dancer with FHL tendinopathy. An alternative prediction that, given the injured state, the dancer would avoid loading the MTP, was not seen in this case. Higher demands were also placed on the ankle and knee during propulsion due to inter-joint compensation.

CONCLUSIONS

Our findings demonstrate phase-specific excessive loading of the MTP joint during *saut de chat* takeoff in a dancer with FHL tendinopathy, potentially caused by inadequate lowering of the heel. We are continuing this work in a larger sample size to identify potential rehabilitative and preventative strategies towards FHL tendinopathy.

P266 - AN IMPOSED FASTER WALKING SPEED ON GAIT PARAMETERS IN PARKINSON'S SUFFERERS

[1]Matthew Sweeney
[1]Australian Catholic University, Queensland, Australia
Corresponding author email: matthew.sweeney@acu.edu.au

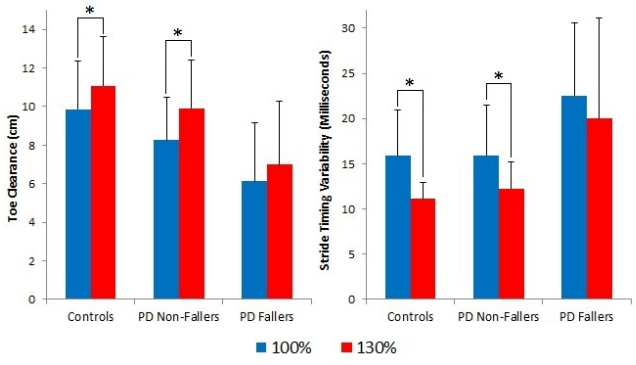
INTRODUCTION

Treadmill-based gait retraining is a common form of therapy amongst PD sufferers with evidence indicating participants can achieve significant increases in stride length, and ultimately walking speed [1]. These results are encouraging as decreases stride length and walking speed are both strongly associated with an increased risk of falls amongst a PD population [2]. However, less is known about the possible interaction between achieving an increased walking speed in PD sufferers and other gait parameters linked to risk of falls, such as decreased minimum toe clearance and increased stride time variability [3,4]. An important first step in a more comprehensive understanding of the influence of walking speed in PD sufferers is to establish the effects of a short term bout of faster walking on other key gait parameters.

The aim of this study was to investigate the effect of imposing a faster walking speed on both minimum toe clearance and stride length variability in the gait of PD fallers, PD non-faller and otherwise healthy aged matched controls.

METHODS

Thirty participants between the ages of 50 and 70 (10 PD sufferers with a history of falls, 10 PD sufferers with no history of falls and 10 aged matched healthy participants) walked for one minute on a treadmill at their preferred speed as well one minute at 130% of their preferred speed. Retro-reflective markers on both the feet of each participant were tracked with a 10 camera motion analysis system, operating at 120Hz and were used to calculate average toe clearance as well as the standard deviation of stride timing across each minute of walking. Both of these dependent variables were subsequently compared across walking speeds for each group ($\alpha<0.05$).



RESULTS AND DISCUSSION

Figure 1: Mean toe clearance and stride timing variability for the age-matched Older Adults, PD Non-Fallers and PD fallers while walking on the treadmill at 100% and 130% of their preferred walking speed.

An increase in walking speed resulted in a significant increase in minimum toe clearance, and decrease in stride time variability, for both PD non fallers and healthy aged match controls. However, there was no significant effect of walking speed on either toe clearance or stride time variability in the PD faller group (Figure 1).

Both minimum toe clearance and stride time variability have been linked with an increased risk of falls in PD populations previously [3,4]. The current results support that both of these parameters are sensitive to imposing an increased walking pace in PD non fallers and healthy aged match controls. However, PD fallers did not exhibit the same significant changes to minimum toe clearance and stride time variability as the other two groups. This, in conjunction with recent evidence of PD fallers exhibiting reduced postural stability at higher imposed walking speeds [5], suggests that PD fallers may not have the same response to a higher walking pace as those at a lower risk of falls. Furthermore, these results suggest some caution in trying to achieve a more 'normal' gait for PD sufferers by focusing on increasing walking speed alone.

The current investigation is an important first step in better understanding the influence of attempting to increase the walking speed in a PD population. Specifically, while the process of gait retraining therapies was not replicated, the results do highlight the importance of further investigation into the ideal outcomes of such retraining therapies.

CONCLUSIONS

This study indicates that imposing a faster walking speed on PD fallers does not result in the same changes in minimum toe clearance and stride time variability as PD non fallers or aged matched controls. Further research is required to establish a more comprehensive understanding of the effects of altering the walking speed of PD sufferers.

ACKNOWLEDGEMENTS

The support Professor Peter Silburn in the recruitment of participants for this study is warmly acknowledged.

P267 - USE OF A NOVEL HOSPITAL-BASED MOTION ANALYSIS SYSTEM TO QUANTIFY FUNCTIONAL OUTCOME IN TOTAL KNEE ARTHROPLASTY

INTRODUCTION

Functional improvement of the knee joint is one of the most important outcomes following total knee arthroplasty (TKA) [1]. According to recent research, three-dimensional motion analysis is the most effective method of measuring dynamic knee function [2]. Nevertheless, clinical use of this technology is currently practically and economically infeasible. Consequently, orthopaedic clinicians are more likely to use quick qualitative alternatives to assess the functional outcome of treatments such as TKA [3]. Despite their popularity, these methods have been found to poorly correlate with quantitative methods, highlighting the need for accurate and reliable quantitative tools that are appropriate for use in the orthopaedic environment [4].

Thus, this study aimed to investigate the feasibility of using a motion capture system in a clinical environment to assess the functional outcome of TKA patients.

METHODS

A small-scale motion capture system was designed for use in a clinical environment. The system consists of a treadmill and two frames, onto which infra-red cameras and a load cell are mounted (Figure 1). Custom-written software controls the treadmill and records biomechanical data. A bespoke cluster-based biomechanical model was developed for use with this system.

Figure 1: A photograph of the motion-capture system in the hospital.

To test the feasibility of using this system in an orthopaedic clinic, the functional outcome of 30 Medacta Sphere TKA patients were recorded at the Royal Infirmary of Edinburgh. Knee function was assessed approximately two-weeks pre-operatively and six-weeks post-operatively. Patients wore clusters of retro-reflective markers as they carried out tasks to assess maximum knee ranges of motion (ROM), maximum isometric knee strengths, and walking kinematics. All assessments were carried out on the treadmill. The recorded data were analysed statistically ($\alpha = 0.05$).

RESULTS AND DISCUSSION

Patients exhibited lower ROM and strength in the operative knee than the non-operative knee pre-operatively, but differences were not statistically significant ($p > 0.05$). The operative knee was also found to flex to a lesser extent than the non-operative knee when walking. Again, differences were not significant ($p > 0.05$). Knee ROM, strength and walking kinematics improved post-operatively in both knees ($p > 0.05$ for all assessments). ROM differed statistically between knees post-operatively ($p < 0.0001$), but strength did not ($p > 0.05$).

On average, the assessment took 16.9±1.9 minutes ($n = 60$: pre- and post-operative timings for 30 patients); significantly shorter than typical 3D biomechanical analyses. A benefit to a system such as this is that patients can be assessed biomechanically during routine clinics. Patients are therefore not required to travel to a separate location on a different date. Benefits to clinicians include the fact that, unlike traditional motion capture protocols, the data does not need to be processed. Hence, useful biomechanical data can be obtained in real-time with this system.

Most importantly, the results recorded were consistent with those in the current literature, giving us confidence in the data.

CONCLUSIONS

Our study has indicated that this system has the potential to be used in a clinical environment. If successful, motion capture technology could be used in future practices to better report TKA outcome.

P268 - COMPARISON OF IMMEDIATE EFFECT OF MOBILIZATION, SLING EXERCISE ON CHRONIC NECK PAIN

Cheng Shin Tsai Cheng Feng Lin
Department of Physical Therapy, College of Medicine, National Cheng Kung University, Tainan, Taiwan
Corresponding author email: connie@mail.ncku.edu.tw

INTRODUCTION

The mechanical chronic neck pain (MCNP) is a common problem in modern life [1]. The chronic neck pain brought many influence for patients, such as range of motion (ROM), pain intensity [2], muscle stiffness, joint position error (JPE) [3], muscle strength, deep neck muscle endurance, and the electromyography firing [4] . Mobilization and exercise are often used for clinical practice to quickly relieve the syndrome and these two treatments are always combined in clinical practice. But there is no study to make a comparison of these two therapies. The separate clinical effect for chronic neck pain of these two treatments is unknown. It is interesting to know whether the active therapy (exercise) or passive therapy (mobilization) is better for curing the MCNP. Thus, the sling exercise and mobilization are chosen for comparison. Recently, the sling exercise is often used for clinical practice and with positive feedback from patients. However, there is less research to discuss its effect on MCNP. In addition, the influence of the sling exercise for the neck biomechanics is unknown. Mobilization is used in clinical practice to treat chronic neck pain for a long time. But mobilization is criticized that there is no standard process during the treatment. To sum up, the aim of the study is making a comparison of the immediate effect between mobilization and sling exercise.

METHODS

All participants (6 participants) were recruited from the campus and university hospital. The ages of the participants were from 18-50 and they have had neck pain lasting for at least three months. All participants were randomly assigned to three groups for different treatments. The inclusion criteria of this research are the patients with neck pain for at least three months and the neck disability index presenting score 5-15. The exclusion criteria were no neurological signs. Red flag for the neck, no shoulder relation disorder, traumatic accidents, serious pathology, and didn't received any cervical injury before. The outcome measurement of the study would be collect before and after the treatment. The pressure pain threshold (PPT) and tissue hardness (TH) were measured by a hand held digital tissue hardness meter/algometer. The head ROM were measured by the CROM device. The muscle strength of the neck is measured by a hand hold dynamometer. The deep neck flexor (DNF) ability were recorded by the cranioflexion test. Last the EMG and (JPE) were measured by the motion capture system and Delsys EMG system. Then the mobilization group would receive 15 min treatment, and the dose of the mobilization is conducted each set as 30 sec mobilization and rest for 30 sec with totally 15 sets. The force of the mobilization were simultaneously showed on monitor to make sure the accuracy of mobilization. The sling exercise group would receive 15 min **c**ervical set exercise with physical therapist supervision. Then, the placebo group would receive 15 min sham laser on the trigger point of the neck. The paired T test was used to analyze the treatment effect in each group. The independent T test was used to analyze the basic data (age, body height, body weight, BMI).

The marker set

RESULTS AND DISCUSSION

There was no significant difference in baseline data between placebo group and sling exercise group. But the mobilization group showed larger height (p=0.035), weight (p=0.014), and BMI (p=0.010) than placebo, and larger body weight (p=0.044) and BMI (p=0.001) than sling group. From the result of the outcome measurement, the DNF showed no difference in the three groups. The visual analog scale (VAS) only showed significant lower after treatment in mobilization group (p=0.018). The ROM showed improvement in every plane of the head in mobilization group, especially in neck flexion (p=0.01), extension (p=0.02), and right rotation (p=0.01). Then the sling exercise group showed improvement only in extension (p=0.015). The muscle strength didn't change significantly in mobilization group and sling exercise group. But in placebo group, it showed strength decreasing in all planes and especially in left side-bending (p=0.014). The PPT showed significant improvement on right trapezius in mobilization group (p=0.05) and sling exercise (p=0.05). The TH showed significant decreasing on right trapezius (p=0.02) and left sub-occipital (p=0.027) in mobilization group and significant increasing right SCM (p=0.039) and left levetor scapulae (p=0.04). In the JPE, it showed the error decreasing in mobilization in horizontal plane (p=0.03) and the error increasing in all plane, especially in horizontal plane (p=0.01) in placebo group. The EMG showed no difference after three treatments.

CONCLUSIONS

From the result, it revealed that mobilization showed more improvement in pain, tissue situation, and proprioception than other groups. This result may suggest that mobilization is still a good clinical practice for mechanical chronic neck pain with short time demand. But the terminal result should be confirmed with larger sample size

P269 - STATIC ANALYSIS OF SHOULDER, NECK AND SPINE POSTURE WHILE USING SHOULDER SLINGS AND LONG ARM SPLINT WITHIN 15 MINUTES

[1] **Cheng Shin Tsai**, [1]Ching Yao Lin, [1]Yi Kuan Liu, [1]Kai Lan Hsu
[1]National Cheng Kung University
Corresponding author email: jerry12375@gmail.com

INTRODUCTION

The fixation of the fracture arm is the common process for the patient after surgery. Shoulder sling is always recommended for patient for fixation in clinical practice. The advantages of shoulder sling are supporting and immobilizing an injured arm, collarbone, or shoulder. It prevents edema, promotes rest and healing, and hold a fractured arm in alignment. [1] On the other hand, it also accompany with the disadvantage that a sling is often uncomfortable where the strap drapes over the opposite shoulder and neck area.[2] It is because that slings will pitch the shoulder into an unnatural forward position. Muscles, tendons, and ligaments tend to accommodate to the position that they are placed in. With abnormal posture, the patients always argue with the neck pain after the sling usage .Therefore, the aims of the study is wondering how the sling usage influence on the neck posture. The research analyzed the static condition of shoulder ,neck and spine posture while using shoulder slings and long arm splint within 5,10,15 minute separately. Try to find the relationships between the posture of subjects and the wearing time of shoulder sling, and the difference between usage of triangular sling and commercial shoulder sling.

METHODS

There were four participants in the research with no musculoskeletal dysfunction. There are two kinds of the sling for the research. (Triangular bandage and shoulder sling). The participants were asked to conduct the static sit posture task during the initial position, 5, 10, and 15 minute. The initial position were instructed an optimal posture by the physical therapist. Then the sling with the long arm splint were set after capturing the static initial position. The same process above were repeated after completing one kind of sling. There were 11 marker sets for measuring the posture, top of head, bilateral tragus, bilateral eye, bilateral acromion, c7, sternum, t4. The posture angle could be defined by four parameter [3]. The head tilt was defined as the line from the midpoint of eyes to the midpoint of tragus compared to the global vertical line. The neck protraction angle was defined as the line from midpoint of tragus to c7 compared to the global vertical line. The shoulder protraction was defined as the line from the right acromion to c7 compared to the horizontal line of the global. The cervicothoracic angle is defined as the line from midpoint of tragus to c7 compared to the line from the c7 to t4. The group effect would be analyzed by unpaired T test and the time effect would be analyzed by paired T test.

RESULTS & DISCUSSION

From the unpaired t-test, first, we found there's no significant differences between groups in head tilt angles. Also, for head protraction angle (figure1), significant differences ($p<0.05$) were found between statics and other 3 groups for wearing triangular bandage, 5 mins and 15 mins for shoulder slings. Then, for shoulder protraction angle, significant differences ($p<0.05$) were found between statics and other 3 groups for wearing sling, 10 mins and 15 mins for triangular bandage. Last, for cervical-thoracic angle, there's a significant difference only between 5 mins and 15mins using shoulder sling. From our results, we can found that for head, neck and shoulder postures, wearing slings or bondage will be significant different with the standard sitting posture. But we couldn't find the effort on postures in short time factor.

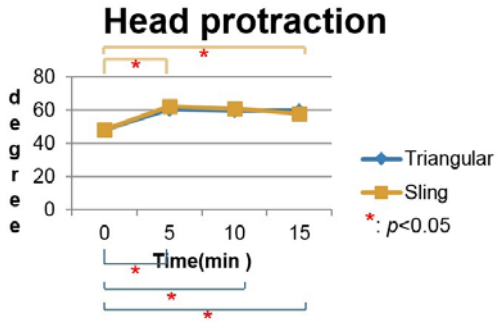

Figure1 head protraction

CONCLUSIONS

Neck pain is one of the major complaints following arm sling and long arm splint application, but the mechanism was not clear. Postural change after arm sling use is thought to be a cause of neck pain, but this hypothesis has not been clear studied. There are three main research results in this project. First, shoulder slings not only compress the soft tissue around the neck, they also change the posture of the head and neck, such as head protraction and shoulder protraction. The postural change of the head and neck is found to be related to chronic neck pain [4]. Second, there is no significant difference in postural change and pain between using traditional triangular bandage and shoulder sling. Third, some kinds of postural change, such as cervical-thoracic spine angle, have linear correlation with time. Thus, prolong use of shoulder sling and long arm splint should be avoided, clinically. There are some limitations in our study. First, the free time between two different testing is 5 minutes. Second, the testing period is only 15 minutes, which may not able to result in significant different. However, the linear correlation was noted in some kinds of postural change. It implied that the changes may worse with time. In conclusion, although arm sling and long arm splint can provide stability and immobilization of the upper limb, prolong use may cause postural change of the head and neck, than result in chronic neck pain.

P270 - GAIT MODIFICATION IN PATIENTS WITH KNEE OSTEOARTHRITIS DECREASES THE KNEE ADDUCTION MOMENT: A 12 WEEKS PHYSIOTHERAPEUTIC INTERVENTION

[1,2] Tim Gerbrands; [2,3]Martijn F Pisters MF; [1]Sabine Verschueren; [1,2]**Benedicte Vanwanseele**

INTRODUCTION

Knee osteoarthritis is a chronic and incurable joint disease leading to pain, loss of function and high socio-economic cost. Its progression seems strongly related to the knee adduction moment (KAM), which represents the medio-lateral distribution of joint loading. Laboratory research indicates that gait modification might effectively reduce the KAM but that individual selection of the strategy is important (1), but the effects of a clinical gait modification training have insufficiently been established. The aim of this study was to examine the effect of a clinical gait modification training on knee adduction moment, pain and physical functioning in patient with knee osteoarthritis

METHODS

Seven patients with radiographically diagnosed medial tibio-femoral knee OA were instructed to walk in three conditions in a 14m long gait laboratory: comfortable walking (CW), medializing the knee at initial contact (Medial Thrust, MT) and leaning the trunk laterally towards the affected leg during the stance phase (Trunk Lean, TL). Self-selected modification amplitudes remained within comfortable limits. A wireless active 3D-system (Charnwood Dynamics Ltd., Codamotion CX 1, sampling rate: 200Hz) was used to determine kinematics of the most affected leg and the torso. A recessed forceplate (Advanced Mechanical Technology, Inc., OR 6-7, sampling frequency: 1000Hz) measured the ground reaction force for one step per trial. Knee pain and function in daily life was assessed using the KOOS questionnaire. Kinematics of the foot, lower and upper leg, pelvis and torso were tracked by 20 infrared markers and modelled as rigid bodies using Visual3D (C-motion, Inc., Germantown, MD).

The modification strategy that reduced the KAM peak the most was selected for the training program. Patients trained their new gait strategy twice per week for six weeks under the supervision of a physical therapist. These six weeks were followed by one training per week for another six weeks to maintain and further improve implementation the gait modification into daily life. Patients were considered well-trained when they could apply the strategy over ground at similar speed as comfortable walking at baseline.

After the training, patients came back to the gait laboratory and were first instructed to walk comfortably (T1_CW) and secondly to walk as was taught during the physiotherapy sessions (T1_Strat). KAM peak and KAM impulse, defined as the area under the addiction moment curve, were compared between t0 and t1.

RESULTS AND DISCUSSION

Seven patients (4 female, 3 male, age: 61.1±7.1, height: 1.64±0.09, weight: 72.2±10.1) received training and fully completed the program. Two patients trained to walk with Medial Thrust, the others with Trunk Lean.

After training, the KAM peak during comfortable walking was reduced by 26% (T0_CW: 0.33±0.08 Nm/(Bw·Ht); T1_CW: 0.25±0.04 Nm/(Bw·Ht)) and the KAM impulse was reduced by 43% (T0_CW: 0.16±0.07 Nms/(Bw·Ht); T1_CW: 0.09±0.04 Nms/(Bw·Ht)). When asked to walk as taught during training, the KAM peak reduced even further up to 34% (0.22±0.04 Nm/(Bw·Ht)), and the KAM impulse by 46% (0.08±0.06 Nms/(Bw·Ht)). KOOS score for pain improved by 37% (T0_CW: 54.4±8.9; T1_CW: 73.4±11.3), and the score for function improved by 28% (T0_CW: 59.8±12.2; T1_CW: 73.3±12.5).

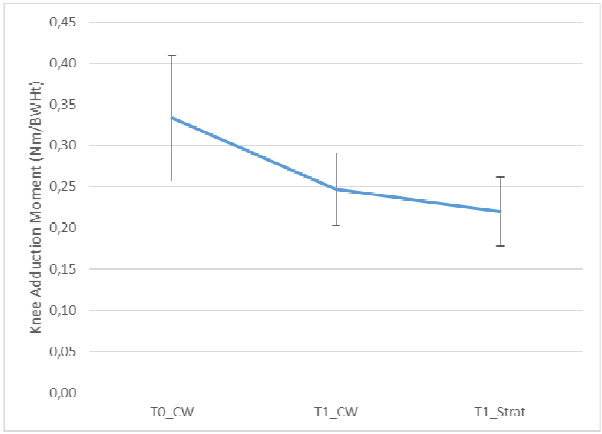

Figure 1: Peak external knee adduction moment (Nm/BWHt) during comfortable walking before (T0_CW) and after (T1_CW) training and when asked to perform the learned strategy (T1_Strat). Data are mean±standard deviation.

CONCLUSIONS

The results indicate that a gait modification training based on an individually selected gait modification strategy reduces the knee adduction moment on the long-term and improve pain and function of patients with knee osteoarthritis.

As the disadvantages of gait aids such as insoles, walking poles and braces often outweigh the advantages, gait modification may provide an alternative strategy to reduce the knee adduction moment. However, research on the short and long-term effects of clinical gait modification training should be investigated in a randomised clinical trial.

P271 - A BIOMECHANICAL ANALYSIS OF AN UNDER-SIZED PEDICLE SCREW AFTER FATIGUE LOADING – AN IN-VITRO HUMAN CADAVERIC STUDY

Jaw-Lin Wang[1], Yu-Tang Shih[1], Yi-Hsing Chen[2], Dar-Ming Lai[2]
[1]Institute of Biomedical Engineering, National Taiwan University, Taipei, Taiwan, [2]Department of Surgery, National Taiwan University Hospital, Taipei, Taiwan
Corresponding author email: jlwang@ntu.edu.tw

INTRODUCTION: Screw-rod type of spinal instrumentation is widely used in the treatment of spinal disorders. Despite the advances in medical technology innovations, screw looseness remains one of the most frequent failures with this type of implantation system. The selection of screw size plays a crucial role in the success of spinal instrumentation as larger sized screws increase the risk of pedicle failure during insertion but small-sized screws are thought to compromise the stability of the instrumentation. By investigating the relationship between screw diameter and the pullout strength of pedicle screw after fatigue loading, this study seeks to find quantitative biomechanical data to assist surgeon in the selection of the appropriate screw. Two hypotheses were proposed for this research: 1) the fixation strength of larger screw will be higher than that of smaller screws immediately after implantation. 2) After fatigue loading, while the fixation strength will decrease for all screw sizes, larger screws will more effectively retain their fixation strength.

METHODS: 27 human cadaveric thoracic spine vertebrae (T3-T8) were harvested from 5 human cadavers (2 males & 3 females, ranged: 52-83 years). The bone mineral density (BMD) measurements were obtained by dual-energy radiographic absorptiometry (DEXA) using a QDR-4500A scanner (Hologic Inc., MA, USA). The mean BMD of the specimens was 0.645 g/cm^2 (ranged: 0.353-0.848 g/cm^2), which is indicative of severe osteoporosis. Two sizes of poly-axial screws (4.35mm x35 and 5.0mm x35, Depuy Synthes Spine Inc., West Chester, PA) were randomly chosen and implanted into each of the two pedicles of each vertebrae by an experienced surgeon and specimens were randomly distributed into control group (n=9), fatigue group of 5,000 cycles (n=9) and fatigue group of 10,000 cycles (n=9). The fatigue test was conducted by material testing instrument (Bose® ElectroForce® 5500, Bose Corporation, MN, USA.) with peak-to-peak loadings of 10-100N at 1 Hz for 5,000 and10,000 cycles. Each specimen was then embedded into the epoxy resin mold with rib before being placed in the custom jig for performing the axial pullout tests using a material testing instrument (Bose® ElectroForce® 3510, Bose Corporation, MN, USA.) at a constant pullout rate of 5 mm/min. The ultimate pullout strength (N) were obtained for analysis.

A paired t-test was conducted to determine the differences of pullout strength between the different screw sizes. One-way ANOVA was conducted to determine difference of pullout strength between the control group and the two fatigue groups. If significant differences were observed, the post-hoc tests were conducted to determine the relationship between each group. A p-value of less than 0.05 was considered to be statistically significant.

RESULTS SECTION: The BMD was of no significant different between each group (p=0.492). In the 5.0 mm group and the 4.35 mm group, the averaged pullout strength were 363.3(138.3)N and 259.0(159.3)N in the control group, 332.5(165.2)N and 316.1(106.0)N in the 5,000 cycles fatigue group, 208.0(90.1)N and 229.3(99.9)N in the 10,000 cycles fatigue group (figure 1).The difference of pullout strength among the three groups were not significant (p=0.089, 0.405). In the control and two fatigue groups, there were no significant differences between the two sizes of screws (p=0.071, 0.716, 0.639). In the control group and two fatigue groups, there were no significant differences between two different sizes of screws (p=0.105, p=0.118, p=0.770). The pullout strength of the larger screws was higher than that of the smaller screws in the control group but in the fatigue groups, pullout strength was closer to each other.

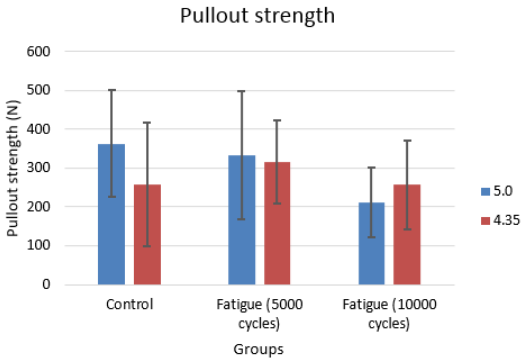

Fig. 1 The pullout strength between two different sizes of pedicle screws (5.0 mm vs. 4.35 mm) in three group.

DISCUSSION: In terms of the pullout strength, even though no significant difference was found in each group, our results indicated two tendencies. First, The pullout strength of the larger screws was higher than that of the smaller screws in the control group but in the fatigue groups, pullout strength were closer to each other. Second, for the larger-sized screw (5 mm) the pullout strength decreased with the number of fatigue cycles. However, the pullout strength of smaller-sized screw (4.35 mm) seems to be invariant with fatigue cycles. Overall, we proved the first hypothesis, but failed the second one. Two main findings were concluded in this research: First, the pullout strength of the larger-sized screw was higher than that of the smaller-sized screw right after the implantation. Second, both sizes of screws exhibited similar pullout strengths after fatigue loading. The pullout strength of larger-sized screws is not higher than that of smaller-sized screws. This indicates that the smaller-sized screws may be chosen for less risk of pedicle breakage without sacrificing fixation strength.

INTRODUCTION

Treatment of Anterior Cruciate Ligament (ACL) injury constitutes one of the most studied topics on the scientific community of orthopeadic sports medicine. The efficiency of the scientific teams in recognizing the risks of an ACL injury is of crucial importance for prevention, as approximately 350,000 injured individuals receive ACL reconstruction in the US annually. Furthermore, more than 90% of ACL injured individuals develop early knee osteoarthritis within 10 years from injury. Despite the remarkable scientific advances muscle strength, biomechanical and functional asymmetries persist in ACL reconstructed patients (Xergia 2013), even more than two years after reconstruction and predispose to increased risk for secondary injury. Thus, it is of crucial importance for the clinicians to have reliable and easily applicable tools in order to evaluate functional asymmetries and recognize increased risk for a secondary injury. Such tools are dynamic functional tests as the hop tests (single, triple, cross over hop) and the International Knee Documentation Committee 2000 subjective knee form (IKDC 2000). The purpose of the present study was to assess the asymmetries of three single-limb hop tests (single, triple and cross over hop test) as predictors for the functional outcome score via the IKDC 2000 (Logerstedt D 2012). We hypothesized that the three single-limb hop tests are significant predictors for the functional outcome of the IKDC 2000, in ACL reconstructed patients 6-9 months after reconstruction.

METHODS

Twenty-four men with ACLR age, (26.4 ± SD) at 6 to 9 months (7.0± SD) post-operatively completed functional evaluation of the single triple and cross over hop tests and IKDC 2000. A backwards multiple regression test was performed with IKDC as the outcome variable and the three hop tests as the predictors. The cut-offs for entering the regression model were set at 0.05 and for removal at 0.15. Multicollinearity statistics were produced as the hop tests may be highly correlated to each other.

RESULTS AND DISCUSSION

All three hop tests were retained in the final model (adjusted R^2=0.33, p=0.012). The collinearity statistics found that the variance inflation factor was <2.5 for each hop test, thus it was determined that multicollinearity did not pose a serious threat to the validity of the final model. Using a more conservative model where variables were removed at the 0.10 level resulted in a model that included only the single leg hop test that was the most predictive of IKDC (adjusted R^2=0.25, p=0.008).

CONCLUSIONS

Single triple and cross over hop tests can predict knee function 6-9 months after ACL reconstruction. The single hop test is a strong predictor of the self- reported knee function but the strongest predictor for self-reported knee function is the combination of all three hop test (single, triple and cross over hop tests). Performing all three tests is relatively quick and simple suggesting that the additional explanation of the variance by the triple and crossover hop tests may be valuable. It is of importance to mention that ¼ of variability of ACLR function can be explained from the single hop test, which can be very helpful for clinicians, as with only one functional test can identify functional deficits. However, stronger prediction for functional outcomes after ACL reconstructed can be shown by using the three dynamic tests of single, triple and cross over hop in order for the clinicians to assess the progression of the rehabilitation protocol towards a safe return to sports.

INTRODUCTION

Collagen is a main protein of connective tissue, composed of highly-regular distributed glycine, proline and hydroxyproline amino acids. The sequence of those three acids create a single chain, which folding with the same two others, takes the form of tropocollagen (TC) helix structure. At higher level of spatial scale, TC helices are able to merge, forming a fibrils and fascicles units present in both – animal and human tissues. Although (depending on tissue function and location) there might be distinguished over a dozen types of collagen, the most common for human tissues is collagen type I. This one may be found in skin, ligaments, tendons or even within the organic part of bones.

The studies on collagen type I properties, performed at atomic, coarse-grained as well as at macroscale level, have already been reported i.e. by Buehler [1][2], Mlyniec [3], Gautieri [4] or Morin [5]. As a result, the broad range of biomechanical and chemomechanical properties of collagen (elastic and shear modulus, persistence length, fracture and self-assembly mechanisms, influence of loading rate on collagen viscoelasticity and failure behavior) are already well-known. However, there is still lack of thorough studies on kinetics of high-temperature degradation of collagen I type. Therefore, the objective of this work was to investigate this phenomena at the lowest possible spatial scale – at atomic level. Using the reactive molecular dynamics (MD) method it was possible to obtain all necessary data to employ Arrhenius methodology for determining the value of reaction energy barrier. Calculated activation energy may be used for future optimization of collagen tissues storage conditions.

METHODS

The 1QSU collagen-like peptide from the PDB database [6], representing TC structure with 1.75 Å resolution, was multiplied to obtained a symmetrical matrix arrangement of collagen chains. A mutual distribution of chains was based on equilibrium simulation results reported by Mlyniec et al. [3]. A developed structure was placed into a simulation box filled with water solvent. A final model was pre-optimized and then subjected to set of high-temperature NVT-MD simulations A reactive nature of simulated phenomenon was included by application of ReaxFF force field, developed by van Duin [7].

RESULTS AND DISCUSSION

For each simulated temperature, a degradation process was confirmed by registering a rapidly increasing number of decomposition by-products, among which the most numerous were carbon monoxide (CO), carbon dioxide (CO_2), ethene (C_2H_4) and propene (C_3H_6). Due to the stable monotonicity for carbon monoxide production, the CO concentration was selected for further analysis of the temperature influence on the rate of collagen type I decomposition.

After determined the reaction order it was possible to calculate a speed of reaction rate k for each case of simulated temperature. An obtained Arrhenius plot, together with logarithmic form of Arrhenius equation, allowed to calculated the value of activation energy as well as the pre-exponential factor. Moreover, an order of magnitude of the results is consistent with reactive MD studies of other natural polymers decomposition [8].

CONCLUSIONS

In the presented work a high-temperature degradation of collagen I type was investigated at the atomic scale using molecular dynamics approach with ReaxFF force field. Based on Arrhenius methodology, for the most numerous products od collagen decay (carbon monoxide), the potential barrier, which has to be overcome to initiate the reaction, was calculated. An obtained results was used for further investigation on scalability of developed model and validation of periodic boundary conditions. Moreover, the results might be used in future to optimize the temperature and environmental conditions for collagen tissues storage.

INTRODUCTION

Limb malalignment has been associated with onset and progression of knee Osteoarthritis (OA), the leading cause of physical disability. A 5 degree varus alignment increases compressive medial compartment force from 70 % to 90% of the total load in the tibio femoral joint. Excessive stress is believed to damage joint tissues. The Atlas™ Knee implant is a second-generation device, which uses a compressive polycarbonate urethane (PCU) material to function like a spring. This technology is designed to offload a portion of the medial compartment force (up to 32lbs) exhibited in patients with early to moderate medial compartment knee OA, while preserving all the natural tissues in the knee joint, thereby maintaining joint stability. The aim of this study is to investigate the Atlas™ implant's capability of reducing compartment contact pressure and sensitivity to surgical placement about the medial tibial-femoral joint.

METHODS

A three-dimensional (3D) subject-specific finite element model (FE) of a left cadaveric knee joint (male, 50 years old, 1.65m, 68-kg) was previously developed and compared with *in-vitro* testing to provide an experimental validation (Mootanah, R. *et al.* 2014). The specimen was imaged using a 3T MRI-scanner. CUBE sequencing was used to create 3D representations of the menisci and ligaments and SPGR sequencing for the bones and cartilage. Tissues were segmented in Mimics (Materialise, Leuven, Belgium), assembled in CATIA (Dassault Systèmes, France) and meshed in Abaqus (Dassault Systèmes, France). Osseous and soft-tissues were meshed with linear tetrahedral and eight-noded hexagonal elements, respectively. To evaluate a range of orientations that may load the Atlas™ implant the FE knee model simulated force and moments experienced during the gait cycle for a healthy 68-kg subject. The tibia was free to move in five degrees of freedom and rotated from 0°-60° in the sagittal plane in a physiological manner. An array of candidate surgical locations ascribing approximately a 1cm circle around the medial femoral and tibial condyles were used to simulate different orientations of the Atlas. Specifically, the ball and socket joints of the femoral and tibial base, were posteriorly, vertically, or anteriorly oriented. The coordinates of each candidate location were tabulated and analyzed as a function of Atlas length change across stance phase during knee flexions spanning 0°- 60°. Upon determining the optimal surgical placement of the Atlas™ implant a stress analysis was performed with the knee at 20 degrees of flexion simulating the instant of maximum varus thrust at weight acceptance during stance phase. Medial compartment stress was predicted pre and post virtual surgical installation of the Atlas™ implant. Using axial forces from a healthy 68kg male during stance phase and a titration of bending moments (0, 5, 10, and 15 Nm) the ability of the Atlas™ implant to reduce contact pressure was simulated.

RESULTS AND DISCUSSION

The Atlas™ implant location for the femoral and tibial components when positioned with an approximately vertical orientation on the medial femoral epicondyle and tibial condyle provided the maximum target compression (4mm) and produced an acceptable length change during 0°- 60° of flexion for a size 46 implant.

Color plots of the tibial contact pressure distributions are presented in Figure 1. The top row illustrates pre Atlas contact pressures. Contact pressures increased with increasing bending moments as expected. The Atlas reduced peak contact pressure at the cartilage-cartilage and cartilage meniscus interfaces.

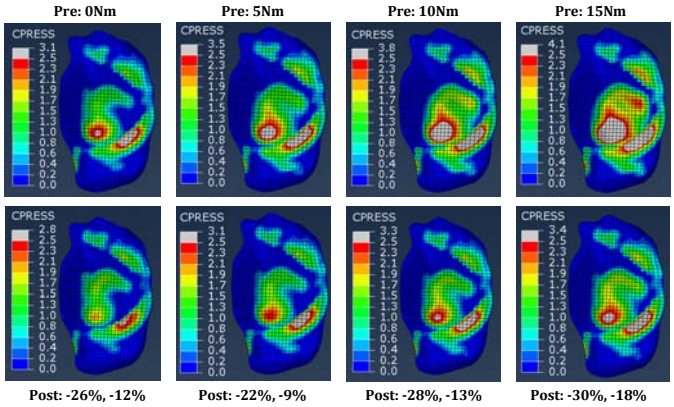

Figure 1: Contact pressure pre Atlas™ (top) and post Atlas™ bottom with 0, 5, 10, and 15Nm of bending moment for knee simulations at 20 degrees of flexion.

CONCLUSIONS

The Atlas implant reduced contact pressure from 9% to 30% across a range of bending moments spanning 0 to 15Nm under axial load simulating the weight acceptance period of stance phase. This implant has the advantage of preserving all the natural tissues in the knee joint, thereby maintaining joint stability.

P275 - STRESS IN THE MEDIAL KNEE COMPARTMENT IN RESPONSE TO ATLAS™ KNEE SYSTEM

INTRODUCTION

Osteoarthritis (OA), a degenerative joint disease, was reported to account for 1% of total deaths in 2002 worldwide [1]. Joint malalignment is a strong predictor of the development and progression of OA [2]. As little as 5° of varus malalignment increases the compressive forces in the medial compartment from 70% to 90% of the total knee joint load [3], leading to excessive joint stress and tissue damage within the diarthrodial joint. The Atlas™ knee implant, placed subcutaneously alongside the medial aspect of the knee joint, is designed to offload the medial-compartment of the knee. This may halt the debilitating symptoms associated with OA progression. A polycarbonate urethane (PCU) absorber of the implant provides an opposing force to reduce a portion of the total compressive load experienced at the medial-compartment during the weight-bearing phases of gait and posture. The goal of this study is to investigate the effect of the Atlas™ knee implant on knee joint contact stress.

METHODS

A three-dimensional subject-specific validated finite element model (FE) of a left cadaveric knee joint [4] was used in this study. Computer aided design models of the Atlas™ components were meshed, assigned material properties and boundary conditions in Abaqus FE software, and virtually fixed to the medial aspect of the knee model to simulate treatment of medial knee OA. To evaluate the compressive and shear stress distribution within the medial compartment of the knee in response to the Atlas™ implant, the FE knee model was driven by the simulated compressive force experienced during the gait cycle of a healthy 68-kg subject. The femur was fixed and the tibia was rotated in the sagittal plane and free to move in six degrees of freedom in response to the loading conditions. Peak shear stress was computed in the medial compartment of the knee with and without the Atlas™ implant at 10 and 20 degrees of knee flexion with the corresponding axial loads of 408N and 811N, respectively. Varus (adduction) moment at each knee flexion ranged from 0Nm to 15Nm to simulate different varus angles. Note that the 20 degrees of knee flexion corresponds to the end of weight acceptance, when varus thrust is maximum.

RESULTS AND DISCUSSION

Shear stress in the medial tibial cartilage with and without the Atlas™ implant at different knee angles are shown in Figure 1, with a representative shear stress distribution with and without the Atlas™ implant at 10 and 20 degrees of knee flexion angle and varus bending moment ranging from 0 to 15 Nm. Medial compartment shear stress was 0.88MPa without the implant and 0.67MPa with the implant at 20 degrees without bending moment, demonstrating a 23.9% reduction. At 10 degrees without bending moment shear stress was reduced by 43.2% from 1.41MPa to 0.8MPa. The results show the capability of the Atlas™ implant to counteract the increased medial compartmental loading as a result of varus malalignment resulting from medial knee OA

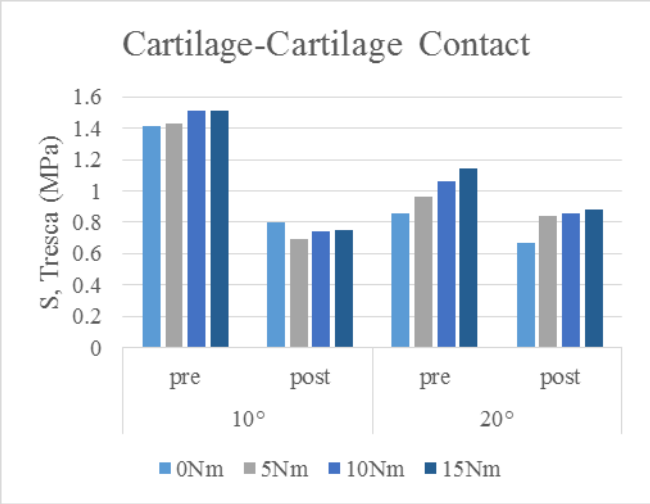

Figure 1: Shear stress reductions in the medial knee compartment for 0Nm, 5Nm, 10Nm and 15 Nm at 10 and 20 degrees in response to Atlas™ knee system.

CONCLUSIONS

Stress was reduced in the medial knee compartment with various varus moments ranging, 0Nm to 15Nm as a result of the Atlas™ knee system. The findings of this study suggest that this approach for managing varus knee OA may be a viable treatment option.

P276 - ESTIMATION OF SHOULDER MUSCLE FORCES DURING ACTIVITIES OF DAILY LIVING USING AN EMG-INFORMED NEUROMUSCULOSKELETAL MODEL

[1]**Azadeh Kian**, [2]Claudio Pizzolato, [3]Mark Halaki, [3]Karen Ginn, [2]David G Lloyd and [1]David Ackland

INTRODUCTION

Estimation of individual muscle forces and their contribution to motion is essential for understanding clinical conditions affecting the shoulder, including stroke, frozen shoulder syndrome and rotator cuff tears; however, it is currently impossible to measure muscle and joint loading non-invasively.

A solution to the mechanical indeterminacy problem at the shoulder is in the use of electromyogram (EMG)-informed neuromusculoskeletal (NMS) models [1-3]. EMG-informed models capture muscle co-contractions that purely optimization-based methods (i.e. static and dynamic optimization) are often not able to reliably predict. However, while EMG-informed models have been successfully applied to the lower limb, only a limited number of studies have employed this approach in the upper limb [4]. One major reason for this is the difficulty in recording EMG from the deep musculature such as the rotator cuff, which require intramuscular fine-wire electrode placement [5]. The aim of the present study was to develop an EMG-informed NMS model to estimate the individual forces produced by 26 major superficial and deep muscles surrounding the glenohumeral joint and scapula during shoulder movement.

METHODS

A healthy 31-year-old female (1.65 m, 58 kg) was recruited for testing. The subject was asked to perform a set of active shoulder motions at a constant speed (shoulder flexion, shoulder abduction, reaching and touching the top of the head) and passive dynamic tasks (shoulder flexion and abduction), as well as a set of isometric contractions at 50% of maximum effort at the midrange of the shoulder motion in flexion, extension, abduction, adduction, internal and external rotation. Trajectories of 14 reflective markers attached to upper-limb bony landmarks were simultaneously collected using a motion capture system and EMG recorded using 5 surface electrode pairs (pectoralis major, biceps brachii, triceps brachii, upper and lower trapezius) and 12 intramuscular (fine wire) bipolar electrodes (rhomboid major, supraspinatus, infraspinatus, serratus anterior, teres major, latissimus dorsi, pectoralis minor, subscapularis, infraspinatus, anterior, middle and posterior deltoid). External forces during sub-maximal contractions were measured using an instrumented cable and pulley system.

A generic upper-limb model developed in OpenSim [6] was scaled to the subject's dimensions using a static pose. Three dimensional joint angles and moments were calculated for all motion trials using inverse kinematics and inverse dynamics, respectively. Musculotendon kinematics were calculated using the muscle analysis tool in OpenSim, and EMG data were filtered and rectified [7]. Joint angles and moments, as well as processed EMG data were used as the inputs to a Calibrated EMG-informed NMS framework (i.e. CEINMS) [8]. Musculotendon parameters were first calibrated to the subject using data from isometric tasks and both active and passive dynamic trials. A trial of abduction in the scapular plane was then analysed in open-loop and used for estimation of joint moments and muscle forces.

RESULTS AND DISCUSSION

The clavicular head of pectoralis major during the first half of shoulder abduction and the middle deltoid during the second half of abduction showed the highest levels of forces (Figure 1). The muscle force magnitudes and timing were in reasonable agreement with previous modelling data [5, 9]. Estimated deltoid forces reflect its role as a major producer of shoulder abduction torque. Estimated forces for the sternocostal components of pectoralis major reflect their role as antagonists of shoulder abduction. The high estimated forces in the clavicular head of pectoralis major cannot be explained in terms of a role for this muscle in producing abduction torque.

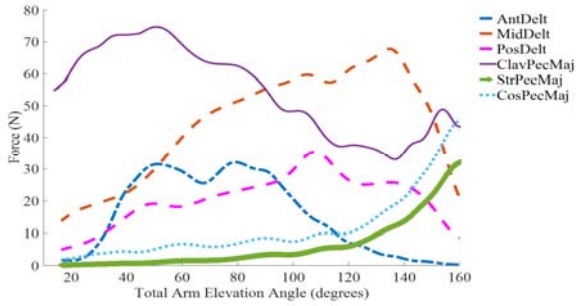

Figure 1: Forces estimated by the NMS model for the shoulder muscles: anterior deltoid (AntDelt), middle deltoid (MidDelt), posterior deltoid (PosDelt), clavicular head of the pectoralis major (ClavPecMaj), sternal head of pectoralis major, and the costal head of the pectoralis major (CosPecMaj) over a full range of abduction in the scapular plane.

CONCLUSIONS

This study presents preliminary data for the first EMG-informed NMS model of the shoulder using a superset of all major shoulder region muscles on one subject for a given set of upper limb tasks. At this stage of its development, the NMS model has estimated forces for the majority of muscles demonstrating trends that would be expected during shoulder abduction.

P277 - USING COMPUTER SIMULATED EMG SIGNALS TO IMPROVE VISUAL ONSET DETECTION

[1]Erik Kowalski, [1]Brian Vu, [1]Clara Phillips, [1]Danilo S. Catelli and [1]**Mario Lamontagne**
[1]University of Ottawa, Ottawa, Canada
Corresponding author email: mlamon@uottawa.ca

INTRODUCTION

Visual detection (VD) for the onset of electromyography (EMG) data is often the first method taught to students in an introductory biomechanics course. However, a selection bias does exist with VD [1], which may become even more variable when the signal to noise ratio (SNR) is low.

By using a computer simulated signal, the true onset and SNR can be controlled, allowing the user to get feedback to see if they are over- or under-estimating the true onset. It is expected that individuals with no EMG experience would improve, so we wanted to determine if the simulated signals could be used to improve experienced EMG users. Therefore, the purpose of this study was to determine if experienced EMG users would improve their VD ability after training with simulated EMG signals.

METHODS

Nine individuals with at least 1 year of EMG VD experience (7.1±8.8 years) participated in the study and completed two sessions separated by 48 hours. In each session, the participants completed the three sets of 10 signals each, for a total of 150 onset selections per session.

The simulated signals were designed using the previously reported methods [2], which created not only a visually similar signal, but with comparable distributions in the frequency domain. Noise is calculated by the square root of E (power) divided by 2*SNR, this is then scaled by a normal random value (from -1 to 1) to create the noise vector. The true onset was defined by the muscle relax period and signals the beginning of the transient relax-contraction period. Using Matlab (R2015b, The Mathworks Inc., Natick, USA), 10 signals with five bursts of muscle activity in each signal were simulated. Random samples of noise were added to create conditions with SNRs of 5, 10, 20, 40 & 80 dB. Two signals of each SNR were generated. A graphical user interface (GUI) was created which displayed the signals in a random order and allowed the user to select the onset of the signal.

At the end of each session, participants were allowed to view their selected onsets along with the true onset, for each signal. The absolute difference for each selected onset was calculated and a paired t-test was done to determine if any significant differences existed between the two sessions.

RESULTS AND DISCUSSION

There was a significant improvement ($p < 0.001$) in VD between the first session and the second session for all SNRs.

As the signals became cleaner (i.e. the SNR became greater), absolute onset detection improved. This indicates the importance of determining the SNR of all signals when processing EMG. When SNR is low (<20 dB), caution should be taken when interpreting onset results, as our participants had an absolute error of more than 50ms in session 1, and an absolute error of approximately 40ms even after session 2.

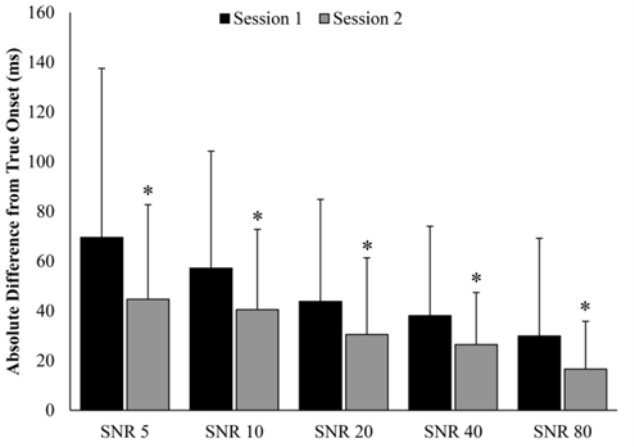

Figure 1: Absolute difference from true onset (ms) between Sessions 1 & 2 for different signal to noise ratio. * Significantly different ($p < 0.001$) from Session 1.

A third follow-up session, a week or two weeks after the second session, would be wanted in order to determine if the training benefits remained. Therefore, it is unknown if the benefits will remain long term.

CONCLUSION

The use of simulated signals can be a valuable training tool to improve the visual onset detection in individuals who had more than one year of EMG experience. Large errors of more than 40ms still remain in SNR of less than 20, so caution should be used when interpreting EMG onset data on poor quality signals, or on signals with no mention of SNR.

P278 - STRESS DISTRIBUTION OF THE FOOT DURING QUASI-STATIC STAND: A 3-D FINITE ELEMENT ANALYSIS

[1] **Barbora Pankova**, [2]Tomas Koudelka and [1]Karel Jelen
[1] Charles University in Prague, Faculty of Physical Education and Sport, Dept. of Anatomy and Biomechanics
[2] Czech Technical University in Prague, Faculty of Civil Engineering, Dept. of Mechanics
Corresponding author email: bapanka@seznam.cz

INTRODUCTION

Although the research of the biomechanics of the foot is widely developed, it still offers further improvements and refinements of this structure capturing, particularly in the field of mathematical models. The use of anatomically accurate finite element (FEM) models of the human foot in research studies has increased rapidly in recent years. In recent literatures, many other theoretical models, such as kinematic models [1], mathematical models [2], and finite element models [3] of the foot had been developed. In our work, the plaster cast from the foot imprint was created, which was possible to scan using stereophotogrammetry. The foot 3D mathematical model was then created with help of the FEM computer simulation to capture the partial pressures on the interface of the foot and imprinting material and its surroundings, respectively.

METHODS

The objective of this study is to quantify stress distribution of the foot during quasi-static stand in 3D using a footprint in imprinting material, when knowing its mechanical properties. One foot of the subject was chosen for the construction of the FEM foot model. The footprint was taken by means of sinking both feet in a dental mass, while being in the resting stance. From this imprint, the positive plaster cast was created, whose surface was possible to scan using stereophotogrammetry. The digital model of the imprint surface was prepared with the help of triangulation laser scanner. After this, the triangular irregular network (TIN) was prepared, which represents the surface of the scanned object on the basis of measured 3D points of the object.

Extraction of prescribed values of vertical displacements from the measured values was another task in the FEM input data preparation process. The foot imprint simulation in the dental imprint mass was solved as 3D time dependent nonlinear mechanical problem in the ADINA software. The simulation started from the undeformed state of prismatic specimen. The nodes on the specimen bottom surface and its sides were fixed during the whole simulation while the nodes on the top surface, out of the contact area, were free. The nodes in the contact area were subjected to the foot load generated as the vertical prescribed displacements that were increased gradually in the course of time. These nodal prescribed displacements were proportional to the *z*-coordinate obtained from the stereophotogrammetric measurement. Resulting distribution of vertical stress component is depicted in Figure 1.

RESULTS AND DISCUSSION

The deformed shape from the ADINA simulation matches the measured values almost exactly because these values were prescribed directly from the measurement. A minor error can be caused because of the linear approximation of the *z*-coordinate due to the transfer of the values from the measured mesh to the FEM mesh. Thus the validation of the foot imprint model had to be performed with the help of knowledge of the total mass of the female subject, which was 65 kg. In this case, the sum of vertical reactions calculated at the nodes in the contact area was 320.5 N, which corresponds to 32.67 kg. This value is in a good agreement with the female subject half weight – the load of one foot during the quasi-static stand.

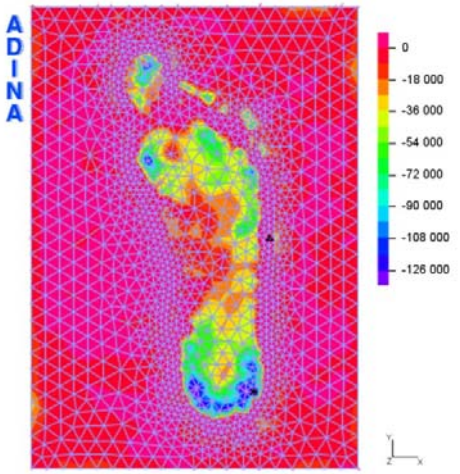

Figure 1: Distribution of the vertical stress component on the top surface [Pa]

CONCLUSIONS

We can state that the partial pressures resulting from this mathematical model match the real pressures on the interface of the foot and imprinting material and its surroundings, respectively, quite closely. Principally, these simulations can be used to determine the contact pressures in practical cases, e.g., between the foot and its footwear. There are expected further methodological steps with the possibility to be used, e.g., in the design of footwear construction.

INTRODUCTION

Cell adhesion to the vascular wall is of fundamental importance in leukocyte immune function and cancer metastasis. Leukocyte adhesion is a multiple-step phenomenon, which is initiated by tethering and rolling via PSGL1-P-selectin binding followed by firm adhesion via CD11/CD18-ICMA1 binding. Previous works have provided considerable insight into leukocyte and circulating tumor cell (CTC) rolling. However, the size of capillaries is often smaller than that of those cells, and the space is not large enough for cell rolling. Despite a lot of works about leukocyte and CTC rolling, cell motion in capillaries has remained unclear. In this study, we thus numerically investigated the behavior of an adherent cell in capillaries whose diameter is comparable to or smaller than that of the cell itself. We present a numerical analysis of the behavior of a cell in capillaries under ligand-receptor interactions. We showed that cell exhibits "bullet" motion in capillaries and this motion effectively decreases the velocity of the cell.

METHODS

The cell was modeled as a spherical capsule with radius a = 4 μm, whose membrane follows the Skalak's constitutive law [1]. An adhesion molecule, P-selectin, was considered as a receptor on the capillary wall, with corresponding ligand, PSGL1, on the cell membrane. Assuming that the ligand-receptor interaction between these molecules is a slip bond, Bell's model [2] was employed. Load on the membrane was determined by a finite element method and fluid flow was solved by a lattice-Boltzmann method, where these methods were coupled by an immersed boundary method. Our coupling method was successfully applied to simulate the flow of leukocyte [3] and circulating tumor cell [4]. In this study, the mesh size of LBM was set to be 125 nm, and that of FEM was approximately 125 nm (an unstructured mesh with 20,480 elements). Bond parameters used in this study are described in [5].

RESULTS AND DISCUSSION

First, we investigated the behavior of an adherent cell subjected to 312 s^{-1} shear rate in a capillary whose radius is slightly larger than the cell (R/a = 1.125; R is capillary radius). When the cell was initially placed near the wall, the cell showed rolling motion (Fig. 1A). However the cell was placed at the center of the capillary, the cell exhibited bullet motion, where the cell deformed into a bullet-like shape (Fig. 1B). When capillary size became smaller, the cell always exhibited bullet motion, where the adhered surface area of the cell membrane increased (Fig. 1C). A state diagram of adhesion modes as functions of capillary size and receptor density (D_R) is presented in Fig. 1D, where firm adhesion was defined as the condition in which the velocity was < 0.1 μm/s. For R/a = 1.125, the cell exhibited both bullet and rolling motions (a transient state), except for D_R = 1/μm^2 in which case only rolling motion was observed. For $R/a \leq 1$, the cell always exhibited bullet motion, but its velocity was low. In this study, we assumed P-selectin as receptor on the wall and PSGL-1 as corresponding ligands on the cell. Because these molecules are mainly responsible for leukocyte rolling, the interaction between PSGL1 and P-selectin has been considered as a weak ligand-receptor binding. However, our results suggest that even under the interaction between PSGL1 and P-selectin, a cell undergoing bullet motion is able to firmly adhere to the wall in capillaries.

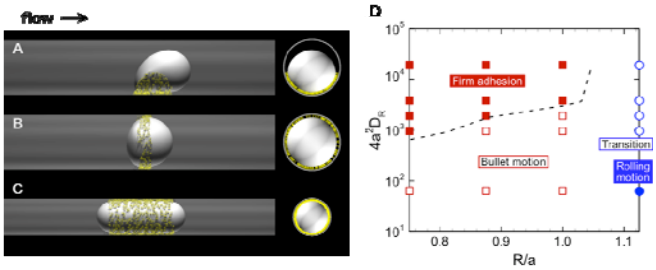

Figure 1: Snapshots of a cell exhibiting (A) rolling motion for R/a = 1.125, (B) bullet motion for R/a = 1.125, and (C) for R/a = 0.75. Ligand-receptor bindings are visualized by yellow rods. Flow direction is from left to right. (D) State diagram of adhesion modes in capillaries as functions of normalized receptor density (y-axis) and normalized capillary radius (x-axis). The closed squares represent firm adhesion, and the open squares are bullet motion. The open circles are transient states, and the closed circle is rolling motion. The dashed line shows the velocity is 0.1 μm/s.

CONCLUSIONS

We found that an adherent cell transitions from rolling to bullet motion when the capillary diameter is reduced. Bullet motion effectively reduced the velocity of the cell and allowed the cell to firmly adhere to the wall even under the weak ligand-receptor interaction between PSGL-1 and P-selectin. These findings may help in understanding such phenomena as leukocyte plugging and cancer metastasis.

INTRODUCTION

Measurement of human posture and movement is an important area of research in the physical therapy and rehabilitation fields. Various attempts have been initiated for different clinical application goals, such as diagnosis of pathological posture and movements, assessment of pre- and post-treatment efficacy and comparison of different treatment protocols. Image-based methods for measurements of human posture and movements have been developed, such as the radiography, photogrammetry and video analysis. In addition, motion analysis for measurements of human posture and movements have been developed, such as the motion analysis system and floor reaction force. However, it is found that these methods are complicated to set up, time-consuming to operate and could only be applied in laboratory environments. The accelerometer and gyroscope are widely used in research and clinical applications as easy-to-use, mobile robust and cost-effective device. The aim of the present study was to assess the validity and reliability of the 3-axis gyroscope device for measuring trunk motion.

METHODS

Three equipments were used in this study, including (a) VICON motion analysis system (Oxford Metrics, Oxford, UK), (b) the sensor consists of a 3-axis accelerometer and a 3-axis gyroscope. The motion analysis system and the sensor (a, b) were used to collect the data in dynamic calibration.

(a)VICON motions analysis system with six cameras with infra-red light source was used to monitor the three-dimensional coordinates of the retro-reflective markers with 120 Hz sampling rate. The sign of VICON motion analysis system was adopted as flexion, lateral bending to left, left rotation were considered to be positive, and movement in opposite directions were represented by negative value for all data.

(b) Sensor with 120 Hz sampling rate was used to monitor. With the sensor located on the upper (the seventh cervical vertebra: C7) and lower (the third lumbar vertebra: L3) trunk. The sign of angular velocity was adopted as flexion, lateral bending to right, left rotation were considered to be positive, and movement in opposite directions were represented by negative value for all data.

The postural change of half flexion, flexion, right and left rotation flexion, right and left lateral bending from neutral standing position (upright standing) on the sagittal and coronal and transvers planes in thorax, pelvis were assessed simultaneously, using the sensor and motion analysis system in eleven healthy subjects {six men and five women, the mean and standard deviation (SD) of age, weight, and height were 22.1 ± 1.2 years, 62.1 ± 11.5 kg, 1.68 ± 0.07 m respectively.} who were without back injury and spinal deformity. Written informed consents were obtained from all subjects prior to the experiments. Each trunk movement was performed for three trials. The angular taken by integrating angular velocity were compared with that taken by the VICON motion analysis system (Oxford Metrics, Oxford, UK).

RESULTS AND DISCUSSION

The reliability in each trials was determined by the intra-class correlation coefficient (ICC) of three times and, in each trials, their values were >0.69 and >0.34 for the C7 angle and L3 angle, respectively. The correlation coefficients of the upper trunk measurements are >0.52 for the angle measurement of the flex, lateral bending, rotation flexion in domain planes of half flexion, flexion, right lateral bending, left lateral bending, right rotation flexion and left rotation flexion. The correlation coefficients of the lower trunk measurements are >0.41 for the angle measurement of the flex, lateral bending, rotation flex in domain planes of half flexion, flexion, right lateral bending, left lateral bending, right rotation flexion and left rotation flexion.

	flexion angle	lateral bending angle	rotation angle
half flexion	r=0.87	r=0.62	r=0.13, p>0.05
flexion	r=0.76	r=0.25, p>0.05	r=-0.33, p>0.05
left rotation flexion	r=0.86	r=0.66	r=0.59
right rotation flexion	r=0.52	r=0.88	r=0.63
right lateral bending	r=0.67	r=0.68	r=-0.03, p>0.05
left lateral bending	r=0.74	r=0.77	r=-0.19, p>0.05

Figure 1: The correlation coefficients of the upper trunk measurements (angle integrating C7 angular velocity and thorax angle)

	flexion angle	lateral bending angle	rotation angle
half flexion	r=0.92	r=0.25, p>0.05	r=0.41
flexion	r=0.73	r=-0.46	r=0.16, p>0.05
left rotation flexion	r=0.94	r=0.68	r=0.89
right rotation flexion	r=0.84	r=0.69	r=0.86
right lateral bending	r=0.58	r=0.73	r=0.89
left lateral bending	r=0.95	r=0.58	r=0.87

Figure 2: The correlation coefficients of the lower trunk measurements (angle integrating L3 angular velocity and pelvis angle)

CONCLUSIONS

In this study, the angle measurement of using the sensor was highly correlated in dominant trunk movements of flexion, right and left lateral bending, right and left rotation, and reasonably close in magnitude to those of the motion analysis system. The results of this study demonstrated that use of 3-axis gyroscope could estimate the change of the thorax angle and pelvis angle.

P281 - MULTIJOINT IMPEDANCE CONTROL OF IMPULSE DURING IMPACT PHASE OF FOOT-FIRST LANDINGS

Edward V. Wagner, Henryk Flashner, Jill McNitt-Gray
University of Southern California
Corresponding author email: evwagner@usc.edu

INTRODUCTION

Advancement of the ongoing interaction between the control and dynamics of a system is made possible through study of its behavior under different stimuli, conditions, or inputs. The purpose of this study is to develop and experimentally validate a dynamic model of sufficient complexity to predict system behavior during the initial contact and preceding flight phase of a foot-first landing. This validated model was then used to determine how flight phase and impact phase control regulates ground reaction forces (GRFs) during normal, soft, and hard two-foot landings.

METHODS

A 2D model of the human body with 4-rigid links connected by ideal hinge joints, comparable to the jumping model of Bobbert & vanSoest [1], was developed using simulation software (Simulink/Simscape Multibody, MATLAB). Muscle actuators were replaced with uniaxial joint torque actuators. Body segment parameters were scaled to the subject (female: 1.575m, 64.5kg) [2]. Link lengths were determined from segment endpoints digitized from video records. The vertical interaction of the foot and the landing surface was modeled as a nonlinear spring-damper in parallel, with the same mathematical form as Gruber [3]. Horizontal interaction between the foot and the landing surface was modeled using Coulomb friction with a coefficient of friction of 1. Currently, the GRFs acting on the foot are applied at two points of contact (toe, heel). Future versions will incorporate a moving center of pressure.

Torque actuators at each hinge used closed-loop feedback control to provide phase specific ankle, knee, and hip torque-time curves as inputs during simulation. These control architectures include: joint angle PD-following control during flight phase and impedance control during the initial phase of contact, impact. The impact phase was defined as twice the time duration from contact to peak VGRF. While the flight phase following-control uses experimental kinematics as reference input trajectories, the impedance control uses whole body coordinated joint torques to accomplish the kinetic equivalence of simplified spring-damper systems with piecewise-linear reference trajectories.

Differences between model-simulated and experimentally-measured VGRF and Vertical Impulse were used to determine the ability of the model to simulate experimental results during the flight and impact phase of landings. Experimentally measured GRFs (1200 Hz, Kistler, 1200Hz) and segment kinematics (ultra-high-speed 11,000 fps, Phantom v711) were acquired during land-and-stop tasks performed by former gymnast from a 0.445m platform onto two force plates using self-selected normal, soft, and hard landing techniques [4].

RESULTS AND DISCUSSION

The 4-rigid link model driven with nonlinear multijoint PD control produced impact phase VGRF impulses accurate to within 3% of their corresponding experimental impulses for each condition. The simulated peak VGRFs scaled in magnitude across the soft, normal, and hard landing cases comparably to those of the experimental peak VGRF, matching each condition's peak within 2%. Experimental peak VGRFs varied across the soft, normal, and hard landing cases ranging from 4.41-7.61 times body weight (BW), with a normal landing peak VGRF of 4.87BW.

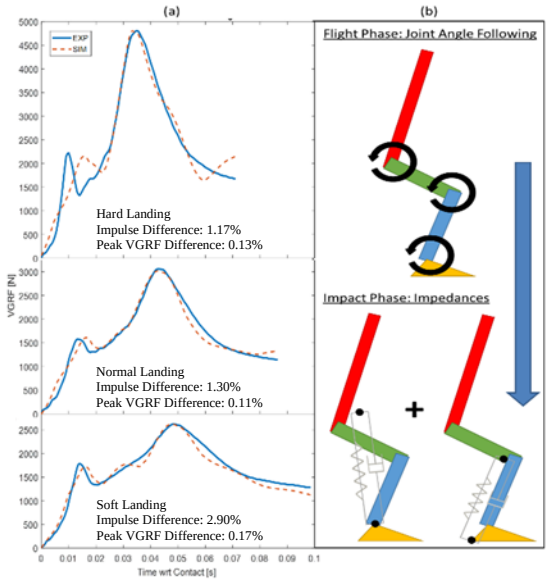

Figure 1: (a) Comparison of experimental (blue) and simulated vertical GRFs (red dashed) under hard, normal, and soft landings (top to bottom). Minimal differences between curves indicate simulated results closely matched experimental results throughout the impact phase. (b) Control methods used during the flight and landing phases of simulation. Note, the effective spring-dampers from using multijoint impedance control during impact.

CONCLUSIONS

A simple model with multijoint control was developed for flight (Joint-following) and impact (Impedance) phases of a landing. It was validated by effectively simulating landing under normal conditions (< 1.5% differences). Using the same validated model with flight and impact phase control, the simulations predicted the new experimental GRFs under soft and hard landing conditions (< 3% differences) by modifying only the control coefficients. Thus, the model effectively predicted experimental GRFs in each condition.

P282 - SIMULATION OF A PASSIVE ASSISTIVE DEVICE TO REDUCE RUNNING EFFORT

[1] **Cara G. Welker**, [1]Cole S. Simpson, and [1-2]Elliot W. Hawkes
[1]Stanford University [2]University of California, Santa Barbara
Corresponding author email: ewhawkes@stanford.edu

INTRODUCTION

Locomotion is a central part of our everyday lives and plays a huge role in physical and mental health. Because humans are very adept at locomotion as a result of evolution and learning, increasing gait efficiency has proven difficult. Although several groups have increased human walking efficiency using powered exoskeletons, only one unpowered device (an ankle exoskeleton) has increased walking efficiency [1]. However, no one has yet determined a way to increase running efficiency with an ungrounded, unpowered device.

Most of the energy required for running is used to support the body against gravity and propel the body forward. However, one study suggests that the cost associated with leg swing is approximately 20% of the total metabolic cost [2]. This finding suggests that a device used to assist leg swing could reduce the energetic cost of running, and we wondered if we could parametrize a passive device to do so.

METHODS

Using OpenSim 3.3 [3], a musculoskeletal model with 23 degrees-of-freedom and 92 musculotendon actuators was scaled to match subject data from Hamner *et al.* (1.83 m tall, 65.9 kg) [4]. A linear spring with a dead-zone (our passive assistance device) was added to the model as an object in the Pathspring class connecting the left and right legs and attached to various locations on the ankles, shanks, and knees. The optimal muscle activations were then computed using the computed muscle control (CMC) tool [5] and experimental running data from Hamner *et al.* (3.96 m/s) [4]. Running effort was computed as the sum of the squared muscle activations over the gait cycle [6].

In order to determine the device parameters, experimental joint torques were divided by the moment arm between each joint and the device's line of action. These normalized torques were plotted against the length of the linear spring to determine an ideal resting length and linear stiffness such that the device provided assistive torques with a magnitude equal to or smaller than experimental joint torques.

RESULTS AND DISCUSSION

Most of the various device attachment points reduced running effort, but because the most significant decreases were seen when the device was attached to the ankles, subsequent calculations were performed with this geometry path. Using the plots of normalized torque versus length of the linear spring, a resting length of 0.5 m was selected because it was the minimum length such that the band never resisted experimental joint torques. Additionally, a linear stiffness of 60 N/m ensured that the torque provided was less than the magnitude necessary for running.

Simulations performed with the chosen inputs for the parametrized spring attached at the ankle showed a total decrease in effort of 7.37%, with a 9.65% decrease for the right leg and a 4.96% decrease for the left leg over one gait cycle (see Figure 1). This difference between the two legs is likely due to asymmetric step lengths, which resulted in more assistive forces applied to the right leg in swing phase.

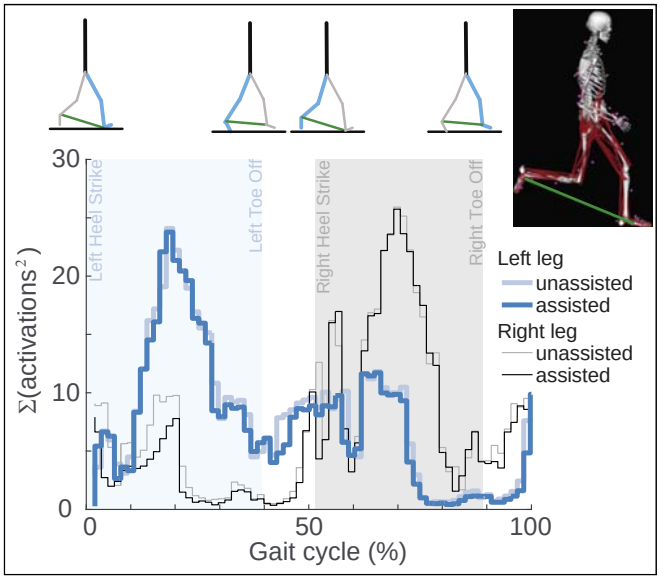

Figure 1: Sum of the muscle activations squared with and without the assistive device over one gait cycle.

This analysis assumes that our device does not change running kinematics and ground reaction forces. Because the selected parameters resulted in applied forces under 30 N, kinematic changes would likely be small and may even improve efficiency as the user learns how to best use the device.

CONCLUSIONS

Our simulations suggest that it is possible to create an assistive device to reduce running effort in the form of an elastic band attached between the two ankles, a simple and lightweight solution compared to other exoskeletons. Assuming a simple model of a linear spring with a dead-zone, an ideal resting length and linear stiffness of 0.5 m and 60 N/m, respectively, were calculated so the device would only assist the experimental knee and hip joint torques. Simulations with this implemented device reduced running effort by more than 7%.

P283 - PREDICTIVE SIIMULATION OF THREE-DIMENSIONAL WHOLE-BODY HUMAN WALKING ON LEVEL GROUND

INTRODUCTION

Walking is a challenging motor task requiring sophisticated coordination of a large number of body segments and joints. Over the past decades, a huge amount of gait measurement studies have been conducted using three-dimensional (3D) motion analysis technique. However, the results have been descriptive in nature, which tells us what happens but not why it happens. Predictive gait simulation, which is capable of predicting human walking kinematics and kinetics, has great potential to improve our understanding of the fundamental mechanism underlying human walking. In this paper, a 3D whole-body predictive human model has been constructed to simulate normal human walking on level ground. Combined inverse dynamics and optimisation method was used. The performance of different optimisation criteria were investigated.

METHODS

A 3D whole-body human model was constructed with 13 body segments (head, torso, pelvis, upper arms, forearms, thighs, shanks and feet) and 30 degree of freedoms (DoFs) (see Figure 1). The interaction between the foot and the ground surface was modelled as a rigid frictionless rollover, where the three translational DoFs of the ankle joint centre were determined by the foot rollover angle [1]. Quaternion "Q" was used to represent the 3D rotation of each joint, of which the time trace was defined using a fifth-order Fourier series. Then the 3D kinetics of the whole-body system was evaluated using a 3D inverse dynamics approach. In this study, the human walking behaviour was formulated as an optimal control problem by minimising certain criteria "F" whilst subjected to multiple constraints "C" as follows:

Find: Q
To: minimise $F(Q)$
Subjected to: $C_i \leq 0$, $(i = 1, \ldots, m)$

Two major criteria were investigated, where the first one is to minimise the dynamic effort, which is defined as the time integral of the absolute value of all joint torques and the second one is to maximise the stability, which is defined as the time integral of the angular momentum about the body's centre of mass [2]. The weighted sum of the two objective functions F_1 and F_2 (weighted by ω_1 and ω_2 respectively) was used as the objective function. The kinematic and kinetic constraints include joint motion range, segment motion range, swing leg condition, stance leg condition, double support condition, ground reaction force and moment condition and also task constraints etc.

RESULTS AND DISCUSSION

3D whole-body gait measurement for a healthy male subject (age: 25; weight: 68.8kg; height: 177cm) was conducted to support and validate the modelling. The summation of the time interval of the difference between the predicted and measured quaternion trajectory of the whole body joint was calculated for different weighting sets ω_1 and ω_2. The minimal error was found at the weighting combination (0.65, 0.35), while the largest error was obtained at the weighting combination (0, 1). However, the error of other weighting sets from (0.2, 0.8) to (1, 0) have no significant difference as long as the dynamic effort is included in the objective function, which means the dynamic effort plays an important role in regulating dynamic walking motion. On the other hand, it indicates that keeping the net moment about the body's centre of mass (CoM) around zero may not be critical. Additionally, at the best weighting set, the predicted ground reaction forces were in good agreement with the measured force plate data.

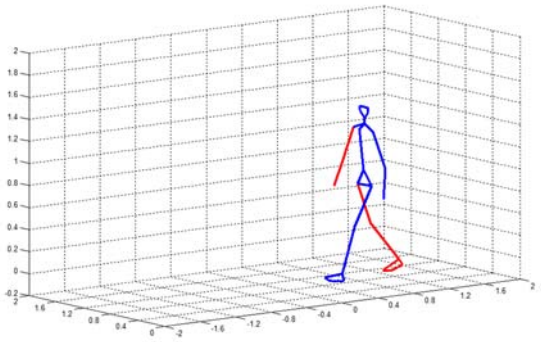

Figure 1. A representative normal walking motion generated by the 3D whole-body predictive gait model

CONCLUSION

In this study, we have used a combined inverse dynamics and optimisation method to predict 3D whole-body human walking based only on three simple gait descriptors. The errors between the simulation results and measurement data at different weighting sets ω_1 and ω_2 for the two performance criteria (dynamic effort and stability) were assessed. The minimal error was found at weighting combination (0.65, 0.35) implying that minimising dynamic effort may be a critical control principle during human walking motion.

P284 - IDENTIFY AND QUANTIFY ERROR IN FORCE RECORDING WHEN USING A TREADMILL

[1]Alessandro Garofolini, [1]Simon Taylor and [1]Julien Lepine
[1]Victoria University, Melbourne, Australia
Corresponding author email: alessandro.garofolini@vu.edu.au

INTRODUCTION

A critical tool for gait analysis research is the ground installed force platform; however, there has been a demand for force platforms to be installed within treadmills because this allows ground reaction forces collected across multiple strides [1]. The main problem with the instrumented treadmill is the dynamic behavior (natural frequencies) inherent to its structure which induces mechanical vibrations that may affect the reading accuracy of the strain gauge (force sensors). Depend on its mass and stiffness, the treadmill structure may generate vibrations and create small oscillations of the centre of mass of the treadmill, that in-turn can induce noise on the force measurements [2]. The natural frequencies of the treadmill may also amplify the force reading at these frequencies.

Although the noise may disappear when averaging or integrating forces over several steps, it can affect gait analyses based on step-by-step measurement of force. Clinical gait analyses are often interested in derived features of the force signals during initial period of foot-to-ground impacts (e.g. loading rate and impact peak), which rely on accurate representation of a high frequency waveform [3].

The impact peak is a specific gait parameter that happens at an event within the first 50 ms of the stance phase while running. Forces are commonly recorded at a sample frequency of 1000 Hz; maximum frequency measurable is 500 Hz (Nyquist frequency). This allows investigation of events happening with an as small as 2 ms period without potential aliasing error. However, if the force signal is over amplified at the same frequencies at which the impact peak occurs, a magnifying error is introduced, corrupting the results. Aim of this study was to perform an easy test to identify the source of error and quantify its magnitude.

METHODS

A calibrated impact (modal) hammer (THOREX 708, 218A) has been used to produce multiple impacts on the force platforms (FPx2) embedded into the treadmill (DBCEEWI, AMTI, USA). A set of 20 impacts were generated at five locations of each platform.

The experiment was also performed on over-ground embedded force platforms for comparison. The force signal from the hammer, and from the force platforms, were collected using Nexus (Oxford Metrics Ltd, Oxford, UK) at a sample frequency of 2000 Hz. The impact hammer has been calibrated using a known mass and accelerometer [4].

The FRF (Frequency Response Function) between the hammer and force platform signals, was examined. This function describes the relationship between both force signals in the frequency domain [5]. The FRF was also used to normalize and average the impulse response over the 20 impacts.

RESULTS AND DISCUSSION

The treadmill/hammer FRF presents three peaks between 20 Hz and 120 Hz, whereas the over-ground/hammer FRF shows a relatively flat response (Figure 1).

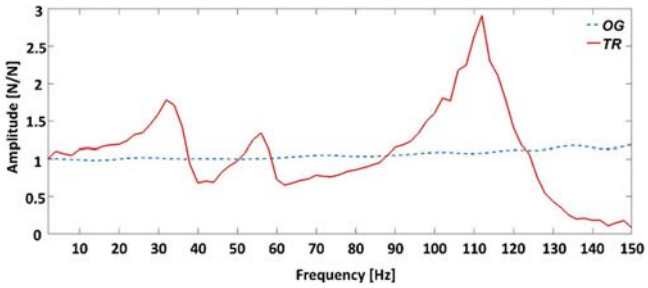

Figure 1: Frequency Response Function of the treadmill/hammer (TR, solid red) and of the over-ground/hammer (OG, dotted blue).

Figure 1 suggests that the force reading from the over-ground is consistent throughout the analyzed frequencies, whilst the signal from the treadmill is biased. Any real force applied on the treadmill above 10 Hz, will result in a recorded force that significantly over- or under-estimates the true force signal. For instance, at 30 Hz the ratio is 1.60, therefore the force at 30 Hz is 37% greater than what it is in reality (i.e. the force induced by the hammer). At 32 Hz there is a 10% increase with respect to 30 Hz. Thus, between 32 ms and 33 ms of the loading phase, the measured signal will show a 10% increase in the first peak force that does not exist in reality. At 40 Hz (0.68) the recording on the treadmill will underestimate the force by 47%.

Moreover, the natural frequency of the treadmill is around 32 Hz, which is a significant drop compared to the 59 Hz natural frequency reported by the manufacturer [6]. This further emphasizes the need to test the FPs in the specific environment and condition in which the treadmill is used.

CONCLUSIONS

To conclude, test of the treadmill force recording performed in the time domain, may hide systematic measurement errors. Analysis of the frequency domain may reveal unexpected, unwanted, yet crucial, characteristics of the force signal. Such an investigation should always be performed as a quality data assurance.

P285 - ACCURACY OF SEMI-AUTOMATED MUSCLE SEGMENTATION

[1]**Jeremy P Higgs**, [1]Laura E Diamond, [1]Bryce A Killen, [1]Giorgio Davico, [1]Jason M Konrath, [1]Martina Barzan, [2]Sjoerd Kolk, [1]Rod S Barrett, [1]David G Lloyd and [1]David J Saxby

INTRODUCTION

Subject-specific neuromusculoskeletal (NMS) models can accurately estimate measured *in vivo* articular contact forces [1, 2]. These subject-specific NMS models use medical imaging (e.g. magnetic resonance imaging (MRI) or computed tomography) to capture anatomical characteristics (e.g. bone geometry) and muscle features (e.g. origins/insertions, lengths, volumes, and lines of action). Standard methods to acquire muscle features from MRI involve manual segmentation of individual muscles, which is a laborious and time consuming process.

A novel semi-automated muscle segmentation tool, being developed for the Mimics image processing software (Materialise NV, Leuven, Belgium), may overcome the time demands of manual segmentation. The aim of this study is to assess the accuracy of this novel segmentation tool by comparing the semi-automated volumes to manually segmented volumes for 12 lower limb muscles.

METHODS

Twenty participants from a larger dataset of anterior cruciate ligament reconstruction patients [3] underwent full lower-limb MRI. While participants were in a supine position, a 3T scanner (Philips Medical Systems, Australia) acquired axial T_1-weighted three-dimensional fast field echo sequences (slice thickness = 2.4 mm; voxel size = 1.2×1.3×1.2 mm^3). The images provided excellent visibility of the outer margin of the muscles.

The biceps femoris long head (BFLH), biceps femoris short head (BFSH), gracilis (GRAC), rectus femoris (RF), sartorius (SART), semimembranosus (SM), semitendinosus (ST), vastus intermedius (VI), vastus lateralis (VL), vastus medialis (VM), lateral gastrocnemius (LG) and medial gastrocnemius (MG) of the unaffected healthy leg were manually segmented by a single experimenter (JMK) using Mimics. Each manual muscle segmentation was added to seed an Atlas database. This database is used by semi-automated tool when generating muscle volumes. In the semi-automated workflow, the first step is to create image masks of all relevant muscles with a well-defined outer boundary for each participant. This was done by thresholding the MRIs to isolate the entire muscle bulk. Subsequently, based on the inertia properties of the image mask, the most similar Atlases (n=x) within a pre-defined overlap threshold (80%) are selected. Based on techniques from Redert et al. [4], the semi-automated segmentation tool then performs a non-rigid transformation and scaling of atlases to the input mask, transforming the individual muscles along. Voxels in the input mask are then assigned to a transformed muscle or not, based on a voting mechanism between the best matching atlases. Finally, the tool uses a smart expand, as the muscle overlap areas are small.

We first compared, using mean percentage difference, the within-subject manual segmented muscle volumes to semi-automated segmented volumes generated from the participant's own Atlas. Second, we used the Atlases from the other participants to generate muscle volumes for each participant, and compared these to manual segmentation volumes and expressed the result as mean percentage difference.

RESULTS AND DISCUSSION

Currently, four participants had been completed. Semi-automated muscle volumes generated by each individual's own Atlas resulted in a mean difference of 6.28% from manual segmentation volumes (Table 1). When the Atlases for the other participants were used to segment the remaining participant, mean differences nearly doubled (11.55%). This increase in mean differences may be due to the limited Atlas database size.

Table 1: Mean percentage differences in muscle volumes between semi-automated and manual segmentation.

Muscles	% Δ using own Atlas (SD)	% Δ using alternate Atlases*
BFLH	6.13 (4.34)	13.24 (14.64)
BFSH	9.99 (6.59)	11.94 (6.67)

CONCLUSIONS

Semi-automated muscle segmentation has the potential to rapidly accelerate the creation of subject-specific NMS models. However, the preliminary muscle volumes generated through semi-automated segmentation were substantially different from manual segmented volumes. Accuracy will likely improve as the Atlas database grows. The aim of the current work is to perform the comparison on a larger dataset (i.e. n=20), apply the tool to new tissues (i.e. bone), and extend our study to a pediatric population.

P286 - COMPARING PERFORMANCE OF TWO METHODS TO PROCESS INERTIAL DATA IN GAIT ANALYSIS

[1] **Sara SP Marreiros**, [1]H Martin Schepers, [1]Giovanni Bellusci, [2]Mark de Zee [2]Michael S Andersen & [1]Angelos Karatsidis

INTRODUCTION

Optical motion capture (OMC) systems are extensively used and validated to acquire and analyze both healthy and pathological gait patterns, however they are limited to laboratory environments and do not allow for analysis in the subjects' daily living environment. Inertial motion capture (IMC) systems are an alternative to OMC systems without the restriction of a laboratory environment. However, the accuracy of the estimated subject kinematics using IMC is typically degraded by magnetic distortions present in the environment. Recently, new methods for IMC systems have been developed that do not suffer from this drawback and reliably estimate subject kinematics irrespective of the magnetic environment. The purpose of this study was to compare the performance of two IMC based methods for gait analysis against the OMC system.

METHODS

Five trials of ground level walking at self-selected speed were collected from 8 healthy young participants (2 females and 6 males; age=31.0±8.8 years; BMI=23.8±1.9kg/m^2) with no history of lower limb injuries. Kinematic data were collected using an 8-camera optical motion capture (OMC) system (Qualisys) and an inertial motion capture (IMC) system (17 sensors, MVN Link, Xsens) with both systems sampling at 240Hz. Force data from 3 force plates (AMTI) were also collected at 2400Hz and used to identify complete gait cycles of each leg.

Hip, knee and ankle angles (flexion-extension [FE], adduction-abduction [AA] and internal-external [IE] rotation) from IMC were calculated using two methods; (A) the commercially available MVN Studio (Xsens) v. 4.3.1, that estimates the relative orientation between segments based on the assumption that a homogeneous magnetic-field is measured by all 17 sensors [1] and (B) estimation of the relative orientation between segments that does not rely on this assumption [2]. As a reference, joint angles were calculated from the OMC data though inverse kinematics performed in AnyBody Modeling software using a lower limb stick model [3] with the hip, knee and ankle joints modeled as spherical joints and segments' axis system matching the MVN body model.

Angles calculated using the two IMC methods were compared with the angles obtained from the OMC data in terms of Pearson's correlations coefficient (*r*) and root-mean-square-errors (RMSE). Differences in *r* and RMSE medians between methods A and B were assessed with Wilcoxon signed-rank test. Alpha was set to $p<0.05$.

RESULTS AND DISCUSSION

Both methods A and B showed good performance in reproducing the FE angles of hip, knee and ankle with high correlations obtained between IMC and OMC and RMSE lower than 7.38° in both methods (Table 1). Significantly higher correlations between OMC and IMC using method B were obtained in the hip and ankle joints for both FE and IE rotation angles compared with method A (Table 1). Method B presented significant lower RMSE relative to OMC compared with method A in adduction-abduction angle in all joints (hip, knee and ankle) and in the IE rotation for knee and ankle joints. An overall improvement in estimation of AA and IE rotations was found with method B.

Differences between systems, in particular the low correlations in IE and AA knee angles might be explained by the small values of these angles that are highly affected by soft tissue artifacts and likely not accurately measured by any of the systems. Also, the assumption of defined joint angles during the static calibration in the IMC system and differences in AnyBody and MVN model definitions are known limitations that need to be further investigated.

CONCLUSIONS

In this study we compared two different IMC based methods to extract joint angles against an optical reference. Both methods show that the joint angles can be estimated with good correlation and RMSE, especially for the flexion/extension angles. Method B outperformed method A on most variables analyzed and showed more consistent performance.

P287 - WEARABLE TECHNOLOGY FOR SPINE ASSESSMENT: A SYSTEMATIC REVIEW

[1] **Enrica Papi**, [1]Woon S Koh and [1]Alison H McGregor
[1]Imperial College London
Corresponding author email: e.papi@imperial.ac.uk

INTRODUCTION

Quantitative and objective assessment of low back pain (LBP) functional motion is key to guide targeted treatment options. Dynamic assessment of the spine will provide information overlooked by static radiographs and contribute to our understanding of the mechanical factors that may be related to the development and persistence of LBP of which the aetiology is still not fully understood [1].

Spine movement analysis techniques have evolved mainly around the use of 3D motion tracking systems and electromagnetic tracking devices. These systems provide complex description of body segments but are not suitable for every day clinical and home settings. The use of wearable technologies has gained popularity in movement analysis studies due to their versatility, portability and the possibility for long-term monitoring [2]. In the context of LBP and in the interest of being able to capture spine movement in real life settings, this review aims to understand the state of the art of current use of wearable technologies for the assessment of spine movement.

METHODS

An electronic search was performed up until August 2016 in PubMed, Embase, ACM, Scopus and IEEEXplore. The search strategy combined terms under the following general categories: sensors, wearable, outcome, spine (Table 1). Reference lists of relevant studies were cross-referenced and hand searches were also performed. The articles retrieved were included in the review if they assessed the spine using wearable, portable technology in an adult population performing dynamic movements. For the articles to be reviewed the technology described should have been suitable for long-term monitoring and used to monitor spine kinematics, kinetics and posture parameters. Two reviewers independently identified relevant papers. Customised data extraction and quality appraisal form were developed based on forms previously used in similar studies, to extrapolate key details and identify risk of biases of each study.

Table 1: Specific search terms used in the review.

General	Specific search terms
Sensors	sensor OR sensors OR sensing OR inertia OR inertial OR accelerometer OR gyroscope OR goniometer OR goniometry OR electrogoniometer OR “smart textile” OR “body sensor network”
	AND
Wearable	wearable OR portable OR movable OR worn OR ambulatory OR “non-invasive” OR “body-mounted”
	AND
Outcome	kinetic OR kinetics OR kinematic* OR motion OR motions OR movement OR assessment OR “joint angle”
	AND
Spine	spine OR spinal OR back OR cervical OR thoracic OR lumbar OR vertebra*

RESULTS AND DISCUSSION

The search identified 1837 potentially relevant articles with 15 articles identified from references of related articles and hand searches.1610 articles remained for consideration after removing duplicates. Twenty-two articles satisfied the inclusion criteria and were included in the review. Twelve papers were deemed of medium quality (score 33.4-66.7%), and 10 of high quality (score> 66.8%). Comparison with a gold standard system was described in 17 articles. Nineteen papers aimed to validate portable tools for spinal movement assessment. The sample size of the papers reviewed was small with only 4 articles having a population greater than 25. The majority focused on healthy young adults. Range of motion was the commonest tasks assessed (13/22); 6 articles reported data collection outside of a laboratory environment.

Some of the papers described newly developed systems whereas others validated the application of off-the shelf technologies (16/22). The type of sensors used varied from electrogoniometers, strain gauges based sensors, textile piezoresistive sensor and uniaxial to triaxial accelerometers, the latter often used in conjunction with gyroscopes and magnetometers. The number of sensor units used differed across the papers, with on average two sensor units positioned on the back of the participants. T12, L1 and L5 spinous processes were the preferred spinal landmarks. Data were collected at a sampling frequency ranging 3Hz to 100Hz and stored for subsequent processing in the majority of studies, only one study used real time feedback. The systems described results in quite cumbersome devices with cables often connecting the sensors. Moreover sensors were positioned on the spine with the use of external fixations method and rarely embedded into clothing (2/22) affecting their wearability and simple everyday use. Outcomes were more commonly reported in the sagittal plane of movement and relatively to the spine lumbar segment. Outcomes included: 3D angles, range of motion, spine curvature sagittal angles, angular velocity, joint moments, and joint forces. Comparisons among studies in terms of reliability and accuracy of systems used are difficult as different measures were used to report them, they were calculated on different outcomes and during different test circumstances. However, all studies showed good agreement between the outcomes from wearable tools and the gold standard when used.

CONCLUSIONS

This review demonstrates the applicability of wearable technology for spine movement analysis. However, improvements should be made to enhance ease of use of the systems described to facilitate in field measurement. Moreover studies are needed to further demonstrate applications to clinical populations, such LBP patients.

P288 - VALIDITY AND RELIABILITY OF AN IPOD TOUCH IN MEASURING KNEE JOINT POSITION SENSE

[1]Sam Lyons, [1]Joseph Cordell, [1]Julianne Gossage, [1]David N Suprak, and [1]**Jun G San Juan**
[1]Western Washington University
Corresponding author email: jun.sanjuan@wwu.edu

INTRODUCTION

The ability of an individual to sense limb position and movement accurately is essential to the development of motor learning as well as the continuous internal programing of complex movements [1]. Therefore, the ability to assess joint position sense (JPS) with a quantitative measurement gives clinicians valuable information as to the status of their patients. Currently, most clinical assessments of proprioception are either qualitative or require the use of equipment that is not readily available [2].

Therefore, the specific aim of this research study is to test the validity and reliability of the iPod touch in measuring absolute error in knee joint position sense compared to a gold standard (i.e. camera based kinematics). We hypothesize that the iPod touch will produce an excellent reproducibility in measuring absolute joint position sense error with regards to both reliability and validity.

METHODS

Forty-one subjects (21 males, 20 females) participated in the study; aged 22±3.42yrs, with an average height of 172.22±8.61cm, and an average mass of 70.53±13.02kg. All subjects were recruited from the campus of Western Washington University.

An Apple iPod Touch with a preloaded customized software was utilized to measure joint position sense. For the gold standard measurement, Qualisys ProReflex high speed cameras motion capture system was used to measure joint angles.

All data collection took place at Western Washington University over the course of a two-day protocol. Day one testing consisted of a standardized warm-up followed by the application of the iPod Touch, via a neoprene sleeve, and retroreflective markers. Specifically, the retroreflective markers were placed on the subject's right lower extremity bony landmark (i.e. greater trochanter, lateral epicondyle of the femur, and lateral malleolus). After being outfitted, the subject then sat on the edge of a table with shank hanging 90 degrees from horizontal and including 2cm of space between the table and the popliteal fossa. Once testing began, the iPod provided all audio feedback to take the subject through their position-reposition task. The task consisted of three trials to both 30 degrees and 60 degrees of knee extension (six trials total) which were randomized by the application. Accuracy of the iPod was measured by analyzing the difference in absolute error between the iPod touch and the Qualisys motion capture system. Day two of the testing consisted of the same protocol however, only the iPod was utilized to measure JPS. Day two was used to assess the inter-day reliability of the iPod to measure JPS. Throughout all testing, subjects were asked to wear tight clothes as well as keep their eyes closed in order to eliminate external cues.

RESULTS AND DISCUSSION

After examining the root mean square of the absolute error between the iPod and the Qualisys motion capture system, it was determined that at 30 degrees of knee extension, the iPod is accurate to 0.49 degrees (Figure 1). At 60 degrees of knee extension, the iPod is accurate to 0.50 degrees. When analyzing the Bland-Altman plots it was apparent that the iPod data slightly overshoots that of the Qualisys data. Specifically, within the 30-degree condition, the mean difference/bias was +0.24 degrees. With regards to the 60 degree condition the mean difference/bias was +0.21 degrees.

The inter-day reliability was measured using an inter-class correlation (ICC). The ICC was 0.62 for the 30-degree position, indicating a good relationship for reliability. The 60-degree position exhibited an ICC of 0.77 indicating an excellent relationship for reliability.

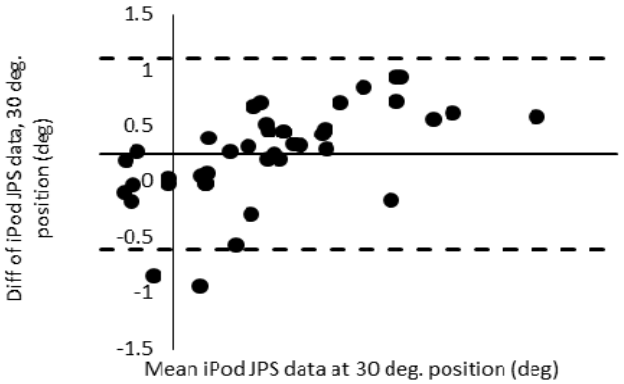

Figure 1. Knee JPS Bland-Altman plot at 30° of knee extension. The solid line represents the mean difference or bias (0.244°) between the Qualisys and iPod and the dashed lines represent the 95% limits of agreement (Upper Limit = -1.09º, Lower Limit -0.61º)

CONCLUSIONS

Based on the results, when comparing the Apple iPod to a gold standard in measuring knee JPS, the iPod is accurate by up to 0.49 degrees at 30 degrees of knee extension and 0.50 degrees at 60 degrees of knee extension. At smaller joint angles the iPod touch will have a slightly higher accuracy in measuring joint position sense error. With regards to reliability, both elevation angles presented good reliability, however at greater degrees of knee extension, the iPod software may be more reliable.

ACKNOWLEDGEMENTS

We want to acknowledge Dr. Andy Karduna for the use of the JPS app.

P289 - APPLYING DATA CORRECTION TO STRAP MOUNTED ACCELEROMETERS

[1] **Tina Smith**, [2]Michael Baker and [2]Richard Foster
[1]University of Wolverhampton
[2]Corata Limited
Corresponding author email: tina.smith@wlv.ac.uk

INTRODUCTION

The tissue underlying skin mounted accelerometers introduces errors to the data they collect [1]. As a consequence various data correction attempts have been made to minimise the effect of local tissue-accelerometer vibration [1,2]. However, accelerometers are not always mounted directly onto the skin. It is often impractical to do so for studies that measure activities during day-to-day living where strap mounting may be a more common attachment method. Therefore an understanding of the response of strap mounted accelerometers is also necessary.

As the straps surround irregular shaped body segments strap mounted accelerometers may suffer from poor coupling when compared to skin mounted accelerometers, as well as additional vibration of the strap and pre-loading effects of tissue due to strap tension. This can be especially prevalent for straps around the waist, mounting accelerometers to measure motion at the spine. The aim of this study was to investigate whether the damped frequency (fd) and the logarithmic decrement (γ) of the local system (accelerometer, strap and local tissue) can be estimated so that the Smeathers' method of data correction [2] can be applied to strap mounted accelerometers at the lumbar spine.

METHODS

Six participants were fitted with tri-axial strap mounted accelerometers (GENEActiv, Action; 100 Hz) at the 4th lumbar vertebrae (L4). A variation on the nudge test [2] was performed whereby the strap was pulled down by approximately 2 cm and then released to provide an initial high acceleration disturbance whilst the participant was in a standing position. Three trials were completed and vertical acceleration data was imported into Excel to examine the accelerometer response.

From the decaying sinusoidal wave the fd and γ were calculated. The period between the first two successive negative peaks (A1 and A2) and their amplitudes from the steady state position (-1g) was determined. The fd was obtained from the reciprocal of the period and the γ calculated from the following equation [2]:

$$\gamma = \log_e (A1/A2)$$

From the fd and γ the natural frequency and damping ratio of the local system was obtained using the equations previously reported by Smeathers [2].

RESULTS AND DISCUSSION

Following strap release the initial high acceleration response from the accelerometer showed a complex waveform which may represent multiple modes of vibration. Thereafter the response at lower acceleration levels showed the classic decaying oscillation of a simple mass, spring, damper system. The fd and γ were therefore obtained from the latter section of the accelerometer data (Figure 1).

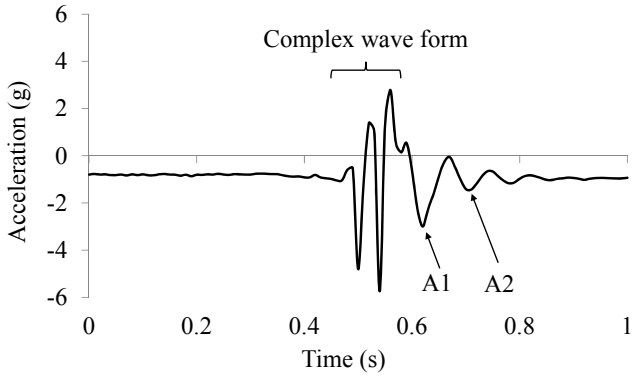

Figure 1: Typical accelerometer output showing the initial response to a high acceleration disturbance, the decaying oscillations and points of measurement.

The natural frequency ranged from 10.7 to 22.8 Hz, which was within previously reported ranges [2]. The damping ratio (0.18 to 0.30) at L4 was lower than reported previously (0.45) [2]. This is potentially due to the greater mass of the accelerometer (20g v 2.5g) and greater tissue mass due to strap mounting in the current study, as similar ranges (0.20 to 0.38) were reported for an accelerometer and mounting system of mass 25.4g attached to the skin at the 3rd lumbar vertebrae [1]. From the obtained natural frequency and the damping ratio an amplitude correction as function of frequency for the path from the spine to the accelerometer can be estimated from Smeathers' transmissibility equation derived from a linear spring, mass, damper model [2].

CONCLUSIONS

At lower levels of acceleration it is possible to measure the fd and γ for a strap mounted accelerometer system. These parameters can be used to estimate an amplitude correction as a function of frequency for each individual. Further work is needed to validate this transmissibility correction when appropriately applied to strap mounted accelerometer data of varying magnitudes and frequencies.

P290 - COMPARISON OF THE LOAD CONTRIBUTION OF THE KNEE JOINT LIGAMENT BUNDLES: COMPUTATIONAL MODELLING VS DESMOTOMY

[1] **Ryo Takeda**, [1]Lu Yu, [1] Makoto Genma and [1]Katsuhiko Sasaki
[1] Hokkaido University
Corresponding author email: r.takeda@eng.hokudai.ac.jp

INTRODUCTION

About 40% of knee joint injuries cases are related to ligament damage single and double bundle reconstruction techniques are the most common methods of treatment[1]. However, there are controversies on which is more effective in restoring the load capabilities of cruciate ligaments. The difference of the two treatment methods depends on consideration of load capabilities of bundles within the cruciate ligaments[2]. The focus of this study will to compare the load contribution of the anteromedial (AM) and posterolateral (PL) bundles of the ACL and posteromedial (PM) and anterolateral (AL) bundles of the PCL. Two different approaches will be used to measure the loads of the ligament bundles, load estimation through computational modelling and a selective desmotomy study using knee joint specimens. In both cases, loads induced during anterior-posterior (AP) translation motion on the femur and tibia.

METHODS

・Computational Model: A knee joint numerical analysis model OpenSim (v3.2, The National Center for Simulation in Rehabilitation Research) was used to create a musculoskeletal knee simulator. First, an analytical model composed of femur, tibia, ligament bundle (ACL (double bundle: AMB, PLB), PCL (double bundle: ALB, PMB), MCL, LCL) was prepared (Figure 1). In addition, the relation between the strain ε and the force f of the ligament bundle were calculated as follows:

$$f = \begin{cases} k\varepsilon^2/4\varepsilon_l & (0 \le \varepsilon \le 2\varepsilon_l) \\ k(\varepsilon - \varepsilon_l) & (\varepsilon > 2\varepsilon_l) \\ 0 & (\varepsilon < 0) \end{cases} \quad (1)$$

$$?? = (l - l_0)/l_0 \quad (2)$$

Here, k is the ligament stiffness, ε_l is the spring constant at 0.03, and l_0 is the ligament length under no load.

・Desmotomy Model: A knee joint biomechanical testing platform was designed and developed (Figure. 1) for this study. The platform consisted of a 6 axis force/torque sensor(DynPick, Wacoh-Tech) attached to a single axis material testing machine (EZ graph, Shimadzu) and a bespoke DoF passive fixture. 12 porcine stifle joints were used as desmotomy knee joint models. The femur bone was placed on the force sensor side, and the tibia was placed on the side of the testing machine base side.

The ligament bundles were cut in the order of the MCL, LCL, AMB, PLB, PMB, ALB. Before and after each cut, a 6 mm displacement in the anterior and posterior (AP) direction was applied to model and loads measured. In this work, the decrease in load was after the cut was assumed as the load of the cut bundle. The model placed in the platform at 30, 60, 90 and 120 deg of knee joint flexion and measurements were taken three times at each angle.

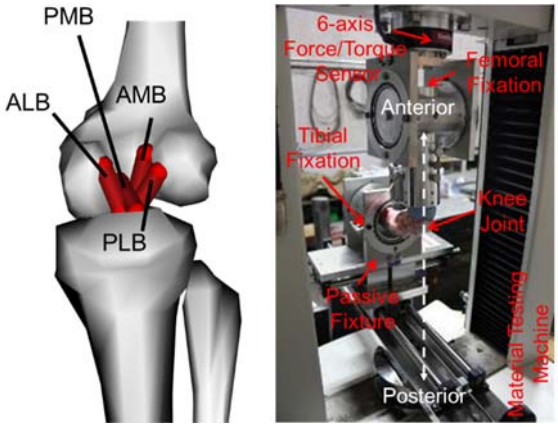

Figure 1: Computational knee joint model and knee joint biomechanical testing platform.

RESULTS AND DISCUSSION

Table 1 shows the load contribution of each ligament bundle obtained from the computational model and desmotomy. The load contribution rate (%) of each ligament bundle in the AP direction at each knee flexion degree is shown. The upper row is obtained from the desmotomy and the lower row is the result estimated by computational model. Desmotomy results shown here are the mean and standard deviation of 3 trials.

Flexion angle (deg)	MCL		LCL		ACL				PCL	
					AMB		PLB			
	Ant.	Post.	Ant.	Post.	Ant.	Post.	Ant.	Post.	PMB	ALB
Cutting Study

90	0±0	6±4	0±0	6±6	48±13		51±12		15±12	91±20
120	1±1	7±1	0±0	6±6	39±26		59±26		19±16	73±15
Simulation										
30	23	98	0	0	77	0	0	0	0	2
60	46	19	1	0	53	1	0	0	24	56
90	44	13	0	0	56	8	0	0	3	76
120	-	0	-	0	-	1	-	0	0	0

CONCLUSION

It was found that each ligament bundle has different supporting force contribution ratio in the AP direction. AMB, PMB and ALB, the tendency of was consistent between the two approaches. However PLB, showed large differences. Thus it maybe necessary to consider the attachment position and length of the ligament bundles.

P291 - DIFFERENCES IN LOADING RATE AND IMPACT MEASURES IN GRF OF THREE SPORTS SHOES

[1] **Rodrigo R Bini**, [2] Adriane M S Muniz and [3] Felipe A Moura
[1] La Trobe University - Australia
[2] School of Physical Education of the Army - Brazil
[3] State University of Londrina - Brazil
Corresponding author email: r.bini@latrobe.edu.au

INTRODUCTION

Frequency analysis of ground reaction forces (GRF) during walking gait has been employed to assess aging [1] and injury [2] mostly involving the use of Fast Fourier Transformation (FFT). Given that impact during gait involves a relatively short time (~50 ms) [3], FFT methods are limited because, for a sampling rate of 1kHz, the available sampling to transform in frequency units would be 50 data points. This leads to a poor resolution in the frequency domain, with a need for employing time-frequency methods.

In this issue, a previous study observed that high frequency content during impact phase of walking has been associated with a reduced cushioning property of materials used for insole mounting [4]. However, no study to date compared shoes with different components in terms of frequency content of GRF. This information is important because it will reflect cushioning properties of the shoe [4]. Therefore, the aim of this study was to compare the proportion of high frequency content and impact related measures in shoes with different midsole structure during walking.

METHODS

Ten healthy male subjects participated in the study. They performed ten barefoot walking trials over a wooden walkway 11 meters long for familiarization. After familiarization, participants performed ten trials of barefoot walking at the target speed (5 ±0.25 km/h) followed by, in random order, ten walking trials using an Adidas Gel Mavericks 3 shoe, a Mizuno Prorunner 17 shoe and a custom made shoe with styrene-butadiene rubber (SBR) midsole. At the center of the walkway, a pair of force plates (FP4060-10, Bertec Corporation, USA) were embedded to enable measurements of the ground reaction forces at 1kHz. Only trials at which each foot contacted each force plate in full and that were within the target walking speed were kept for further analysis.

After determining heel strike (using a 20 N threshold), time to the first peak force was defined in order to select a range between 10-90% of the first peak for assessing loading rate and the percentage of impulse at the vGRF above 30 Hz. For this latter variable (%>30Hz), a high pass digital filter (Butterworth, zero lag) was employed and resulting impulse over time (> 30 Hz) were normalized by the total impulse between 10-90% of the first peak force. After logarithm transformation of data, loading rate and %>30Hz were compared among shoes using Student's t-tests and Cohen effect size, assuming significance when $p \leq 0.05$ and $d > 0.8$.

RESULTS AND DISCUSSION

Lower loading rates were observed for the Mizuno shoe compared to the SBR shoe ($p = 0.05$ and $d = 0.94$). In addition, %>30Hz was also larger for the SBR shoe compared to the Mizuno shoe ($p<0.01$ and $d = 1.12$). No differences were observed comparing the Adidas shoe to the Mizuno shoe or to the SBR shoe (see Figure 1).

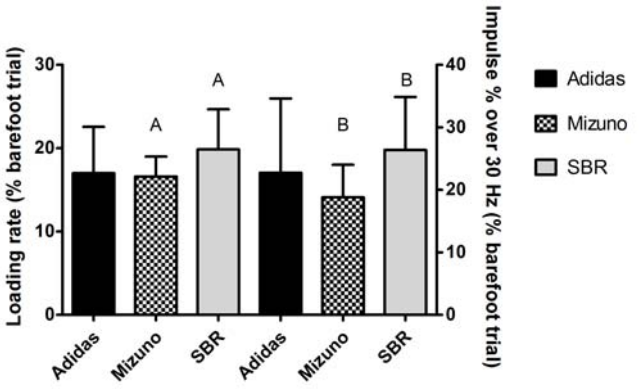

Figure 1: Mean + standard deviation for Loading rate and Impulse over 30 Hz for the Adidas, Mizuno and SBR shoes. Equal "A" letters indicate significant difference for loading rate whilst equal "B" letters indicate significant differences for Impulse % over 30 Hz ($p \leq 0.05$ and $d > 0.8$).

These results indicate that the use of EVA for the construction of the Mizuno midsole resulted in lower impact compared to the Adidas and to the SBR shoe. Higher Shore A measures for the SBR shoe midsole hardness (60-70) give support to these results. However, it is yet to be determined if these results would be sustained during running.

CONCLUSIONS

Shoes with a component of EVA in their midsole structure have the potential to minimize impact during walking compared to Gel and SBR.

INTRODUCTION

Upper body motion during gait may be a marker of incipient pathology, intervention response and disease progression in Parkinson's disease (PD) [1]. It is unknown whether variables obtained from the upper body provide novel information of PD gait or merely a reflect of lower body mechanics. The aim of this study was to determine if upper body variables: 1) can provide unique information from lower body measurements; and 2) are beneficial to classify early stage PD gait independently and in combination with traditional lower body measurements.

METHODS

Seventy participants with early stage PD (69.2 ± 9.9 yr, Female: 23, UPDRS III: 36.9 ± 12.3) and 64 age-matched controls (71.6 ± 6.8 yr, Female: 29) walked for two minutes around a 25m circuit. Sixteen spatiotemporal variables were measured using a 7m meter Gaitrite mat located along the circuit, and were selected *a priori* according a five-domain (pace, rhythm, variability, asymmetry and postural control) validated model of gait [2]. Upper body variables proposed in the literature to measure different aspects of gait (magnitude, smoothness, harmonicity, attenuation, regularity and symmetry) were calculated for anterio-posterio, mediolateral and vertical directions, using three inertial sensors (128 Hz, APDM) located at the head, neck and pelvis. This process resulted in 78 upper body variables [3]. We addressed aim 1 with Pearson's product-moment correlations calculated between upper and lower body variables. To address aim 2, we used a univariate (receiver operator characteristic (ROC) curve) analysis to quantify how well upper body variables alone could discriminate the PD group from the controls. Finally, binary logistic regression analysis was performed to determine whether the upper body variables provide additional discriminative information when combined with lower body variables.

RESULTS AND DISCUSSION

Apart from the lower body domains of pace being strongly correlated with regularity and mildly correlated with symmetry, and rhythm being mildly correlated with magnitude and smoothness, upper and lower body gait domains did not significantly correlate. Therefore, upper body variables provided unique information relative to traditional lower body spatiotemporal measurements of gait and are not merely a reflection of the lower body mechanics.

The univariate analysis showed that 44 of the 78 upper body variables significantly discriminated PD from control participants ($p<.05$). Variables representative of step regularity, as taken from pelvis signals in the ML direction, discriminated best (greatest area under the curve = 0.81). Therefore, on a univariate basis, although regularity and pace were highly correlated, the measurements of the upper body outperformed those of the lower body.

When the 16 spatiotemporal characteristics were entered (forward stepwise) into a binary logistic regression, the model classified group membership with 74% accuracy. Upper body variables resulted in a model with 83% accuracy, therefore again showing the upper body variables, as collected from three locations of the upper body, better classified PD gait relative to the lower body variables. From single upper body segments alone, the neck best classified group membership (78.4%) relative to the pelvis and the head (72.4% and 70.9, respectively). This indicates that 3 sensors are optimal but if multiple sensors on the upper body are not available, a single sensor at the neck may provide the most discriminative results. Finally, when spatiotemporal characteristics entered the model first and upper body variables were added as a second step, the latter variables significantly contributed ($p<.001$) to an increase of 16% in the accuracy of the prediction model (from 74% to 90%).

CONCLUSIONS

Most upper body variables provided additional and unique information about PD gait with respect to traditional spatiotemporal variables obtained from the lower body. Univariate and multivariate analyses showed that this additional information was increasingly beneficial in discriminating/ classifying movements symptomatic to early PD. Due to the upper body measurements providing additional classification accuracy to the lower body gait model, we recommend that if to be used as a biomarker, assessing upper body variables in conjunction to traditional variables will create a more holistic characterisation of PD gait.

P293 - FEASIBILITY OF REAL-TIME DETECTING AND PREVENTING RELATED INJURIES OF UNEXPECTED FALLS USING SMART MOBILE DEVICES

[1] Cheng-Wei Lin, [1]**Yu-Cheng Chen** and [1, 2*]Bing-Shiang Yang

INTRODUCTION

Injuries and deaths often occur in the elderly when falls happened. Every year, 2.8 million older people are treated in emergency rooms for fall injuries [1]. To prevent injuries from fall impact, fall should be detected early enough to provide sufficient lead time to trigger fall-protecting device before impact. The application of inertial measurement units (IMU) for fall detector can detect simulated fall during activities of daily living (ADLs). However, there are only few studies working on fall detection which are accurate enough and provide sufficient lead time in unexpected fall to prevent injuries [2].
Therefore, the aim of this study was to develop a real-time fall detection system with sufficient lead time for triggering fall-protection device before impact.

METHODS

We used a smart phone with IMU (combined with a tri-axial accelerometer and a tri-axial gyroscope) and operating system as a real-time fall-recognizing detector which can also generate a signal for protection device. We recruited 12 healthy adults (height: 1.69 ± 0.03 m; weight: 67.33 ± 7.52 kg; age ranged from 21 to 25 years) to perform ADLs and unexpected falls during the experiments. Subjects were asked to perform an ADL experiment, including 10 ADLs (sit, sit to stand, squat, squat to stand, lying onto bed, rising up from bed, walk, jog, going upstairs and going downstairs) for 10 trials. Besides, subjects also performed a walking test on a walkway with multiple trials. During the trials, one unexpected trip and one unexpected slip was induced by our custom-made equipment and environment. The aim of those experiments was to recognize the unexpected fall during ADLs.
We analyzed the previous ADL and unexpected fall experiment data and set up the fall detection algorithm in the Android system. The thresholds of the algorithm were set to 4.6 m/s^2 which calculated by the mean value plus with 3 times standard deviation from minimum acceleration in 3 axis superposition accelerations in all fall trials and 3.6 rad/s angular velocities in pitch and roll directions which was from the previous study [3]. The time delay between two thresholds was set to 225 ms to ensure trip or slip occur. We recruited 30 young healthy subjects (height: 1.69 ± 0.04m; weight: 63.17 ± 7.37kg; age ranged from 20 to 28 years) to perform unexpected falls and real-time fall recognition tests. Subjects were asked to perform the same walking test and smart phone alarmed when detecting a fall. The aim of this experiment was to improve the real-time fall detection system through a smart phone.

RESULTS AND DISCUSSION

Figure 1 showed that sensitivity and specificity of unexpected fall recognition from ADL were 90.24% and 94.75%. Lead time of the trip and slip (lying down) was 156.50 ± 18.34 ms. The minimum was 135 ms. 95% confidence interval (CI) was (119.82, 193.18) ms. Lead time of slip (sitting) was 94.71 ± 27.96 ms. The minimum was 51ms. 95% CI was (38.79, 150.63) ms.

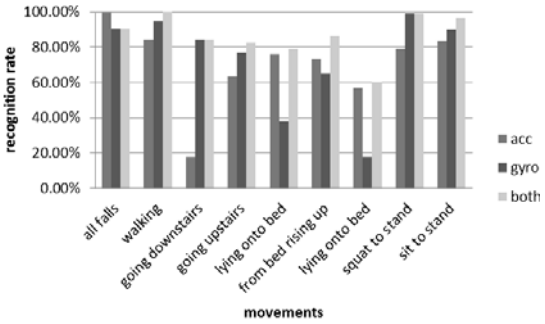

Figure 1: Recognition rate of fall. First category shows the sensitivity in both slips and trips, and others show the specificity in each ADL. Three bars in each category represent the recognition rate of accelerometer (acc), gyroscope (gyro) and combination of accelerometer and gyroscope (both).

Real-time fall recognition test results show 100% sensitivity in trips and 91.67% sensitivity in slips. Lead time of trips and slips (lying down) was 175.96 ± 53.07 ms. The minimum was 100 ms. 95% CI was (69.81, 282.10) ms. Lead times of slip (sitting) was 107.71 ± 45.51 ms. The minimum was 67ms. 95% CI was (13.68, 195.74) ms. The real-time recognition was corresponded to the experiment of the previous stage on unexpected fall and ADL recognition tests.

CONCLUSIONS

We developed a fall detection system with enough lead time to trigger protector in unexpected fall through a smart phone. All of above lead time are smaller than 35 ms that sufficient protector triggering on the market.

P294 - INTERSEGMENTAL FOOT MOTION WHILST NEGOTIATING AN INCLINE SLOPE

Nachiappan Chockalingam, Robert A. Needham, Aoife Healy and Roozbeh Naemi
Staffordshire University
Corresponding author email: n.chockalingam@staffs.ac.uk

INTRODUCTION

Previous studies have indicated that at similar inclination angles, slope walking has a greater fall risk than stair walking [1]. Within the current built environment research, although there have been some studies on human locomotion in inclined surfaces, there is still a paucity of structured research to understand the intersegmental foot motion whilst walking on an incline. This understanding is very important in terms of not only ergonomics and designing structures, but also to contribute to the clinical management in musculo-skeletal and neurological rehabilitation. The purpose of this paper is to explore the relationship between medial-forefoot and rear-foot movement during walking on an incline slope.

METHODS

Eight male participants with no history of musculoskeletal impairments participated in the study. Ethical Approval was sought and received from the University Research Ethics Committee.

An eight-camera motion capture system (VICON, Oxford, UK) was used to collect rear-foot and medial fore-foot kinematic data over five trials for each walking condition; level over-ground and 13° incline. We employed a previously described multi-segment foot model [2] and the marker coordinate data was processed in Visual3D (C-motion-Inc, MD) using a low-pass Butterworth filter with a cut-off frequency of 6Hz. Data was normalized for time to 100% of the stance phase.

RESULTS AND DISCUSSION

Figure 1 – 3 provides an outline of the results. The solid black line indicates the movement in three planes during level-ground walking and the red line indicates the movement during incline walking. In terms of the sagittal plane data, dorsiflexion is represented by a negative value. In terms of the frontal plane, positive values indicate inversion. On transverse plane movement, a positive value specifies adduction. The shaded area indicates the standard deviation band. Statistical parametric mapping (SPM) analyses were applied to kinematic waveform data to compare medial-forefoot angles between walking conditions [3].

There is a significant difference in the intersegmental movement between the medial fore-foot to rear-foot in the frontal plane (Figure 1D). The figures clearly indicate that the SD band is wider for the incline walking condition when compared to over-ground walking which could be an indication of higher variance between individuals. One could argue that individuals use differing movement strategies for adapting to various foot – floor interaction.

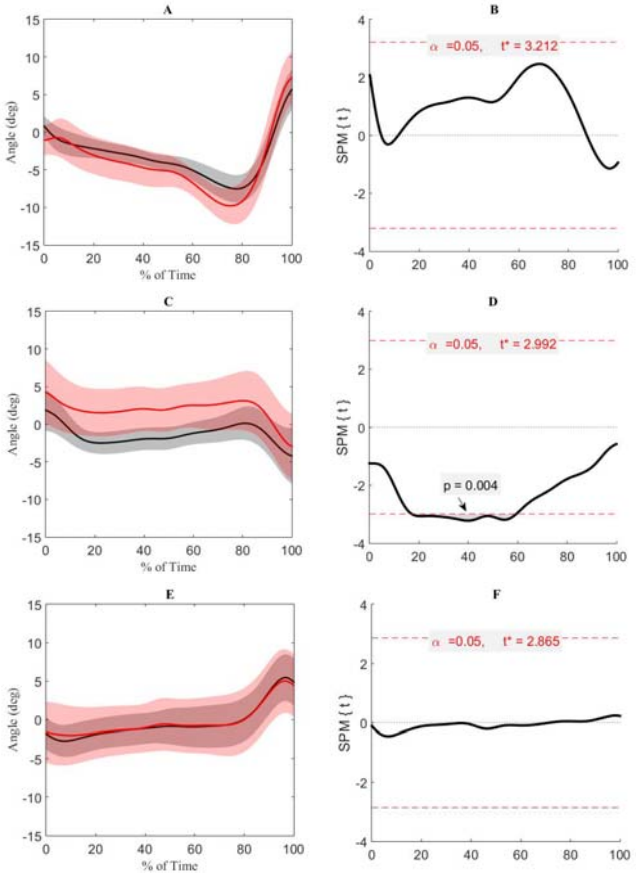

Figure 1: Mean forefoot relative kinematic waveforms in the sagittal (A), frontal (C), and transverse plane (E) (black - level / red – 13° incline / shaded area denotes standard deviation across time) representing walking data from 8 participants. SPM *t*-test outputs for the sagittal (B), frontal (D) and transverse plane (F) are presented.

Although we have shown a significant difference in frontal plane angles which could be used as a surrogate measure to indicate balance or the lack of it, we are yet to establish which segment contributes more to the change in this relative movement. This needs further structured examination. Such knowledge of the intersegmental foot movement can also have implications in designing prosthetic foot as well as ankle foot orthotics that are best suited for walking on an inclined surface. Furthermore, the reported information has significant relevance to both sport and clinical interventions.

CONCLUSIONS

There is a significant difference in the intersegmental range of motion in the frontal plane during walking on an inclined surface.

P295 - A DATA-DRIVEN MODEL TO CLASSIFY GAIT PATTERN IN CHILDREN WITH CEREBRAL PALSY

[1]**Julie Choisne**, [1]Geoffrey Handsfield, [2]Nada Signal, [2]Denise Taylor, [3]Nichola Wilson, [3]Susan Stott and [1]Thor Besier

INTRODUCTION

Ankle-foot orthoses (AFOs) are prescribed to help children with cerebral palsy (CP) improving gait mechanics. However, the clinical outcomes from AFO use are not always predictable due to variations in design, fitting, and patient pathology. Currently, prescription of AFOs relies on clinical assessments and 3D gait analysis (3DGA). However interpretation of 3DGA data is subjective and it is not clear how 3DGA features quantitatively inform the prescription of AFOs. Consequently, AFO prescription is inconsistent, depending heavily on the expertise and knowledge of the orthotist or prescribing clinician and requires a process of trial and error. Classifying children's gait pattern based on their 3DGA could help in prescribing alike AFOs to children that display similar gait pattern. Data-driven modelling approaches to complex data-sets have the potential to reveal non-intuitive relationships between 3DGA parameters in children with CP [1,2].

The aim of this study was to investigate whether a data driven modelling approach could be used to classify patients and predict outcomes of AFOs using 3DGA.

METHODS

Computational model: A Self Organizing Map (SOM) was used to cluster patient's gait pattern [3] based on their barefoot 3DGA (Figure 1). SOM visualizes high dimensional data in 2D representation preserving the topological features of the original input. Once we identified clusters on the SOM, a k-mean classifying algorithm was used to classify patient's gait pattern based on the SOM. Input for the SOM were the gait variable scores (GVS) described by Baker et al. [4] from the 9 kinematics variable (3 pelvic rotation, 3 hip rotation, knee and ankle flexion extension and foot progression). GVS are described as the RMS difference across time between a patient gait cycle and the average gait cycle from people with no gait pathology. The output are the coordinate of each patient on the SOM and assigned class determined by the k-mean.

Modelling sample: 200 limbs from patients with CP were included in the study. They had a diagnosis of spastic diplegia or hemiplegia, a GMFCS ranging from I to III and had been prescribed either unilateral, bilateral or no AFOs.

RESULTS AND DISCUSSION

Heatmaps derived from the SOM (figure 1A) allow to explore the relationship between input variables. Hip and pelvis flex/ext display similar heatmaps pattern which means that they are correlated and therefore can be considered redundant for the model. The same happens at the foot, ankle flex/ext and foot progression appears to be correlated. The k mean model implements the results from all input variables to classify each patient into 5 groups (Figure 1B). Each new patient seen in the clinic will be positioned on the SOM in the group that display the most similarity based on its 9 GVS. The next step will be to determine the best AFO that will produce the highest improvement for patients in each group.

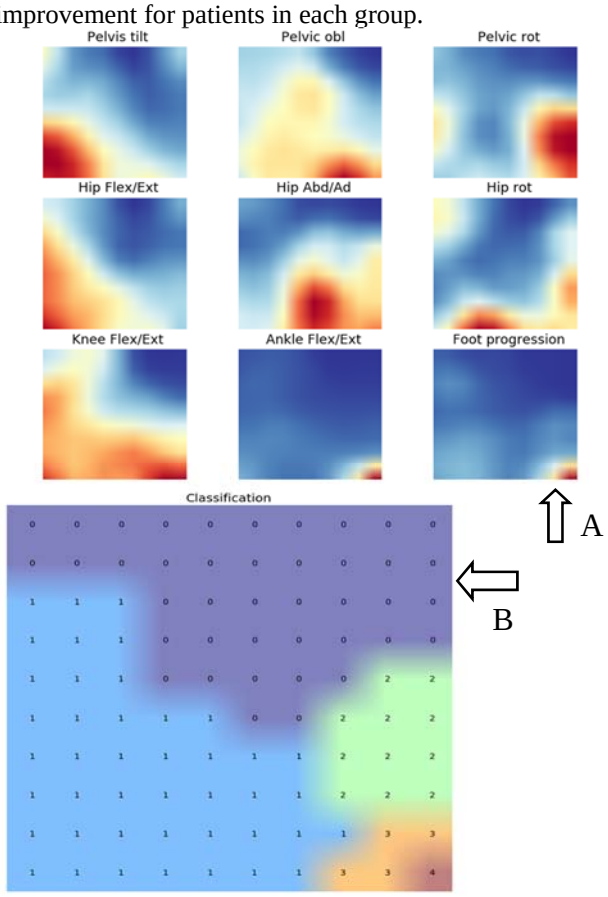

Figure 1: A) Heatmaps showing the distribution of each variable across the SOM. Warmer colors represent higher RMSE and colder colors represent lower RMSE. B) Classification map, which isolated 5 groups of patients.

CONCLUSIONS

Previous classification algorithms are mainly based on postural and gait observations which remain highly subjective. This data-driven model is an unsupervised data visualization technique which has potential to group patients that display gait similarities using high-dimensional data set. Future work should concentrate on finding overlapped between 3DGA input and easy-to-obtain clinical parameters to remove the need for 3DGA in the prescription of AFOs.

P296 - AGE EFFECTS ON MUSCLE ACTIVATION DURING THE LATERAL REACH

[1]Rodrigo Guzmán-Venegas, [1]Claudia Danes-Daetz, [1]Manuela Díaz and [2]L. Eduardo Cofré Lizama

INTRODUCTION

Deterioration of mediolateral (ML) balance has been associated to an increased risk of falling in older adults' population [1]. Clinically, one of the most used tests for ML balance assessment is the lateral reach (LR), a modified version of the reach test, which is performed in the sagittal plane [2]. During the LR a subject raises the arm (left or right) at shoulder level and leans sideward to reach the maximum distance possible. Low scores in the LR have been associated with reduced mobility and increased risk of falling in the elderly. Musculature acting in the frontal plane is most likely to be involved during the LR performance. However, it is not known which specific muscles may explain low LR performance with ageing. The latter is of relevance as it may allow better targeting interventions aimed at improving ML balance in this population. Therefore, the aim of this study is to determine the effects of ageing in frontal plane muscle activation during the LR.

METHODS

Eight healthy older adults (OA) and eight young adults (YG) participated in this study. Each participant performed 3 LR trials in each direction (left and right) with at least 30 sec rest in between. The best LR performance was selected for further analysis. Surface electromyography (EMG) from 4 bilateral lower limb muscles were collected at 1000Hz during the LR using a Delsys Trigno system (Natick, MA, USA): erector spinae (ES), gluteus medius (GM), lateral gastrocnemius (LG) and soleus (SO). Maximum voluntary contractions (MVC) were assessed for each muscle. Maximum activation during the LR task was calculated and normalized to the MVC for each of the muscles. The LR distance was calculated using a reflective marker placed at the distal end of the middle finger using a 3D Vicon system (Oxford, UK) and normalized (LRn) to subject's height. Multiple ANOVAS were performed to determine differences in LRn and muscle activation patterns between older and young adults Since 8 muscles were analyzed, significance level was set at $p<.006$ (.05/8).

RESULTS AND DISCUSSION

The OA exhibited a significantly lower LRn performance than the YG ($p<.01$). Significantly greater ipsilateral GM ($p<.01$) during the LR was found in the OA compared to the YG. Although not significant after Bonferroni correction, OA also exhibited greater PL activation than the YG.

The results of the present study are in line with previous literature showing lower LR performance in older adults [2, 3]. OA greater GM activation is a novel finding that may indicate greater reliance on more proximal ipsilateral musculature to perform the test. Previous studies in ageing gait have proposed a distal-proximal deterioration of motor function with ageing, which may also explain the present findings [4]. However, no significant differences were found in distal musculature and, interestingly, OA showed greater PL activation. All muscles analyzed showed greater activation in OA than YG, except contralateral LG, and greater activation in the ipsilateral than the contralateral musculature. A possible explanation is that OA compensate deterioration of other systems involved in balance control by enhancing proprioceptive inputs when muscles are activated [. This compensation, however, may not be sufficient to achieve same LRn than YG. Since differences in reaching strategy may have affected our results further studies will explore joint kinetics and kinematics as well as sagittal plane musculature that may also affect LR performance.

		Older Adults		**Young Adults**		
		mean	sd	mean	sd	*p*
	LRn	12.3	0.8	15.8	0.8	**<.01**
Ipsilateral	**ES**	4.9	0.8	3.3	0.8	.20
	GM	7.8	0.8	3.2	0.8	**<.01**
	LG	8.3	1.7	7.6	1.7	.79
	PL	5.5	0.9	2.6	0.9	.04
Contralateral	**ES**	5.5	1.3	5.0	1.3	.81
	GM	9.3	2.0	8.1	2.0	.68
	LG	3.5	1.2	4.1	1.2	.72
	PL	3.4	0.7	2.5	0.7	.39

Figure 1: Descriptive statistics for older and young adult's lateral reach normalized (LRn) performance and maximum muscle activation (MVC normalized) for each ipsilateral and contralateral muscle analyzed. Significant between-groups differences are highlighted in bold.

CONCLUSIONS

Compared to the young, older adults exhibit an increased activation of the ipsilateral gluteus medius during the LR yet a lower LRn distance.

P297 - PREGNANCY AND PELVIC GIRDLE PAIN: ANALYSIS OF TEMPORAL AND SPATIAL PARAMETERS AND VARIABILITY OF GAIT

Jeanne Bertuit, Marcel Rooze and Véronique Feipel
Université Libre de Bruxelles
Corresponding author email: jbertuit@ulb.ac.be

INTRODUCTION

During pregnancy, there are physical and hormonal modifications, including weight gain [1], increased ligament laxity [2], alterations in skeletal alignment [3,4], disturbed neuromuscular control and muscle strength [5]. These mechanical and hormonal changes can lead to pelvic girdle pain (PGP) [6]. The prevalence of PGP is by 20% on average during pregnancy [7]. PGP are the results of an increase in pelvic instability due to the decrease of the force closure system during pregnancy [8,9]. Daily activities and gait could be affected by this type of pain [10]. Clinically, it is important to objectify the biomechanical changes during pregnancy in order to justify reeducation and follow-up clinic. Thus, it is essential to know if healthy pregnant women have a specific gait pattern and if PGP induces changes on this pattern.

Previously, we evaluated temporal and spatial parameter, plantar pressure and the evolution of the center of pressure during gait in healthy pregnant women. The pattern of gait displayed significant modifications during pregnancy as compared to nulliparous women. This suggests that pregnant women establish specific and individual strategies, with the aim of maintaining stability during gait with a lower variability [11-12].

The present study analyzed the same gait parameters on pregnant women with PGP. The purpose of this study was to analyze the effects of pregnancy and PGP on temporal and spatial parameters and gait variability at different speeds.

METHODS

Fifty-eight healthy pregnant women (H-PW), forty-six pregnant women with PGP (PGP-PW) between 22 and 32 weeks of pregnancy and twenty-three healthy non pregnant women (control group – CG) walked at 3 different velocities (slow, preferred and fast) on a Gaitrite® walkway with built-in pressure sensors. An analysis of variance (ANOVA) was performed to determine the effect of gait speed and group on parameters.

RESULTS AND DISCUSSION

For PGP-PW compared to H-PW (Fig. 1), cycle time was decreased by 5% ($p=0.040$) and stance time by 2% ($p<0.001$). Single support time was increased by 3% ($p=0.004$). A lower variability of gait parameters was observed in PGP-PW, indicating a high reproducibility of gait.

For PGP-PW compared to CG, gait velocity and step length were reduced ($p<0.001$). Consequently, cycle time was longer. The gait cycle was modified by an increase of stance time by 2% ($p=0.001$) and of double support by 18% ($p<0.001$).

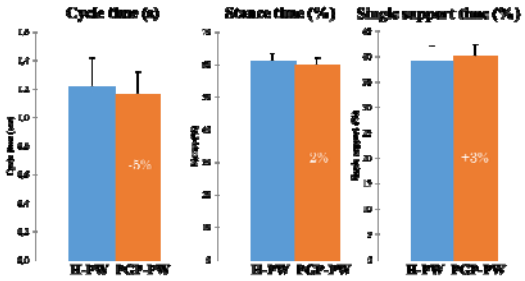

Figure 1: Comparison of gait cycle timing between PGP-PW and H-PW.

CONCLUSIONS

In conclusion, pregnant women with and without pelvic girdle pain had the same gait adaptations during pregnancy. No increase of gait instability was found in women with PGP. Parameters related to an improvement of stability were not changed. However, results suggest a specific strategy for PGP related parameter variability. The low variability of gait parameters may be a form of strategy by which pregnant women take care to reproduce the steady pattern in order to avoid pain and increase the stability of gait.

P298 - IMPACT OF FOOTWEAR AND AGEING ON GAIT AND MUSCLE ACTIVATION

[1] **Simon Franklin**, [1]Francois-Xavier Li and [1,2]Michael J. Grey
[1]University of Birmingham, Birmingham, UK
[2]University of East Anglia, Norwich, UK
Corresponding author email: SXF995@bham.ac.uk

INTRODUCTION

Ageing is associated with a decline in muscle strength and impaired sensory mechanisms which contribute to an increased risk of falls. Common footwear types have been suggested to limit sensory feedback, contribute to foot muscle weakness and an increased likelihood of foot problems. Conversely, walking barefooted has been suggested to promote muscle strengthening and improved proprioceptive sensibility through better activation of foot and ankle musculature [1, 2]. Barefoot-like footwear has been marketed as a method of reaping the benefits of barefoot walking whilst still providing a protective surface.

The aims of this study were to investigate if wearing barefoot-like footwear is equivalent to walking barefoot, if increased muscle activation is provoked and if there are any differences with respect to age and years spent wearing conventional footwear.

METHODS

Seventy healthy adults (age range 20-87) volunteered for this study. All participants walked along a 7m walking lane at their self selected speed five times in four different footwear conditions (barefoot, barefoot-like shoes, their own shoes and control shoes). Kinematics (Vicon MX), kinetics (Kistler force platform) and muscle activity (Wave Wireless surface EMG) of their tibialis anterior (TA), gastrocnemius medialis (GM) and peroneus longus (PL) were recorded simultaneously.

EMG data was rectified and filtered before being time normalized to the duration of the gait cycle (right heel-strike to right heel-strike) and amplitude normalized to the average activity across the gait cycle. The gait cycle was divided into swing and stance phases with the stance phase divided into initial and mid-stance. For age comparisons, participants were grouped into Young (20 - 40 yr), Middle (40-70 yr) and Old (> 70 yr) age categories. Multiple mixed design repeated measures ANOVA were completed for each variable to determine differences between footwear and age.

RESULTS AND DISCUSSION

Walking barefoot lead to reduced step and stride length, increased ankle plantar flexion at foot-ground contact and reduced peak loading ground reaction force (GRF) compared to walking in footwear. These observed differences in kinematics were reduced when wearing barefoot-like footwear.

There were no differences in muscle activation patterns between barefoot and barefoot-like footwear but walking in these footwear conditions resulted in an increase in GM activation during stance (Figure 1). An increase in PL activity was observed in the initial stance phase in the older age group compared to the young age group (Figure 1). Walking barefooted or in barefoot-like footwear resulted in a reduction in PL activation during the mid-stance phase in the older age group (Figure 1).

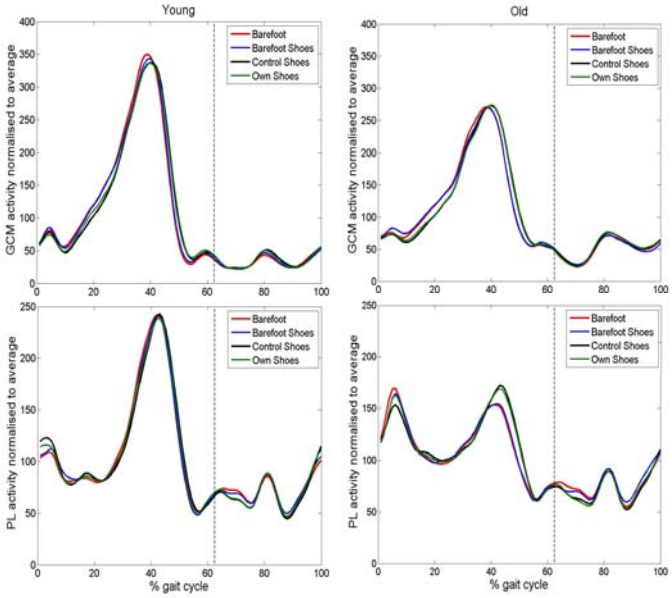

Figure 1: The average activity across the gait cycle of the GM (top) and PL (bottom) normalised to the average activity across the gait cycle in each footwear condition for the young and old age groups.

Aside from the PL activation during mid-stance, the kinematic and muscle activity differences witnessed when walking barefooted or in barefoot-like footwear are consistent across age.

CONCLUSIONS

Walking in barefoot-like footwear is intermediate between barefoot and conventional footwear. Removing supportive structures from footwear appears to increase the balance modulation role of the triceps surae potentially leading to strength increases and improved proprioceptive sensibility. Walking barefooted or in barefoot-like footwear appears to improve lateral ankle stability in older age during the single support phase of gait. This could be due to the increased activation of intrinsic foot muscles.

INTRODUCTION

Plantar pressure measurements are commonly used to determine abnormal patterns of foot loading. Interpreting the pressure profile can be difficult as plantar pressure is a 2D representation of a complex 3D structure. Analysis software available with many commercial pressure platforms can aid in interpretation by subdividing the foot into multiple regions of interest, however these methods become inaccurate once the foot and/or footprint deviates from typical [1, 2].

Footprint anatomical masking based on the multi-segment Oxford Foot Model (OFM) was developed to allow accurate regionalization in the presence of footprint alterations. This masking method has been effectively applied for the investigation of paediatric clubfoot [1, 2] but to date, has only been applied to isolated steps.

The aim of this preliminary study was to implement pressure-kinematics integrated methodology to assess its feasibility and usefulness for the analysis of the entire gait cycle.

METHODS

Pilot pressure and multi-segment foot kinematic data were collected from two participants, i.e., a typical adult male and a child with cerebral palsy (CP). Pressure data were collected using a 2.0m pressure platform (Tekscan Walkway System, 150Hz) and synchronized with 3D marker trajectories captured using a 10-camera motion capture system (Vicon Motion Systems, 100Hz). Reflective markers were attached to the lower limbs and feet according to the OFM. Participants were barefoot and performed six walking trials at a self-selected speed along a 10- metre walkway. The pressure platform was positioned in the centre of the walkway. A dedicated Matlab code was prepared and tested to automatically re-align the reference systems as in [1, 2], superimpose the markers onto the acquired footprints, identify the five regions of interest (ROIs) as in [1], and properly process all the extracted parameters associated with both the single steps and the whole gait cycle.

The procedure to optimize the matching between marker configuration at midstance and maximum pressure footprint was slightly improved with respect to [1, 2] by also minimizing marker displacement in the horizontal plane.

RESULTS AND DISCUSSION

The method was found reliable and repeatable for both participants. Furthermore, parameters from the child with CP were in agreement with those reported in [1]. Work is still in progress to select the most appropriate parameters for the characterization of the whole gait cycle, both in terms of pressure-related parameters and segmental kinematics. Preliminary observations, however, seem encouraging.

As an example, figure 1 compares total and regional loading during a double step phase for the child with CP (top) and the healthy adult (bottom). Interestingly, the findings reveal different loading strategies between the healthy and the impaired participant, both during single support and while transferring load from one side to the other. Specifically, the child shows a higher medial-lateral asymmetry in the forefoot, a greater midfoot loading during both single support phases, and a longer double stance.

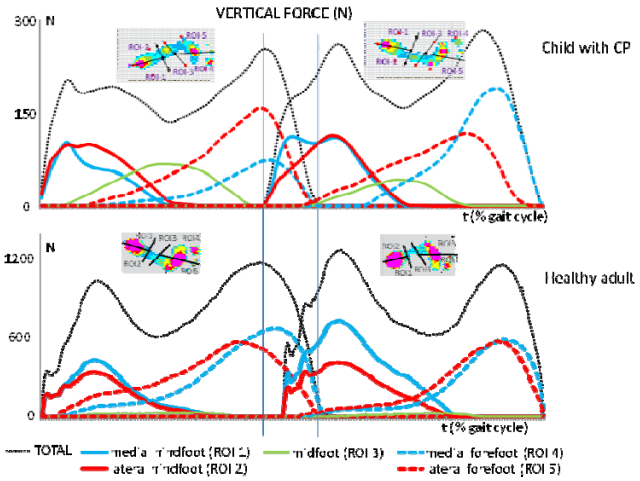

Figure 1: vertical force profiles of the total foot and the five ROIs during a double step phase for the child with CP (top) and the healthy adult (bottom).

CONCLUSIONS

Preliminary findings indicate that the pressure-kinematic integrated methodology can be applied not only to isolated steps but also across multiple steps revealing potentially clinically meaningful information. The greater accuracy of anatomy-based ROIs with respect to geometry-based ROIs seems to help improving knowledge in regional load transfer during double stance especially in the presence of foot deformity. The eventual added value of the new matching procedure will thus be further verified in children with varying levels of foot deformity.

P300 - THE INFLUENCE OF DIABETES AND NEUROPATHY IN LOWER LIMBS MUSCLE FORCE DISTRIBUTION: A MUSCULOSKELETAL MODELING STUDY

[1,4] **Aline A Gomes**, [2] Marko Ackermann, [3] Maria Isabel V Orselli and [4] Isabel C N Sacco

INTRODUCTION

Diabetic individuals present retraction of axons in the motor plate, triggering a process of denervation and reinnervation of muscle fibers, which affects the neuromuscular activity [1] and, consequently, the motor patterns of walking [2]. Muscle force estimation could advance the comprehension of the mechanical and muscular strategies that diabetic patients adopt to preserve walking ability and to guarantee their independence as they deal with their neural and muscular impairments due to diabetes and neuropathy. Our aim was to estimate and compare the lower limb's muscle force distribution during gait in diabetic patients with and without polyneuropathy.

METHODS

Data from ground reaction force (AMTI OR61000 force plate at 100Hz) and three-dimensional kinematics of ankle, knee and hip (eight-camera Optitrack® at 100 Hz) of 10 neuropathic (DNG), 10 diabetic non-neuropathic (DG) and 10 healthy individuals (CG) were used as input variables for the musculoskeletal model gait 2392 (23 degrees of freedom and 92 musculoskeletal actuators) in the OpenSim software. The standard generic model was scaled to fit the anthropometry of each individual collected, prior to the execution of the simulations. The musculoskeletal model of neuropathic individuals presented maximum isometric force reduced in 30% for ankle extensors and 20% for ankle dorsiflexors to mimic the atrophy of ankle muscles due to diabetic neuropathy. The force time series of lower limb muscles were calculated using the static optimization procedure. The peak muscle forces were calculated during selected time bands of the gait cycle. The peak force was compared between groups using MANOVA for the flexor and extensor muscle groups of hip, knee and ankle joints followed by ANOVA and post-hoc of Newman-Keuls ($p<0.05$).

RESULTS

DNG showed higher peak muscle forces at the hip (psoas / $p=0,05$) and knee flexors (biceps femoris short head / $p<0,001$, semitendinous / $p<0,001$ and semimenbranous / $p<0,001$) compared to DG and CG. DNG also presented lower peak force for gastrocnemius medialis and soleus, as well as higher peak force for gastrocnemius lateralis compared to DG and CG (figure 1).

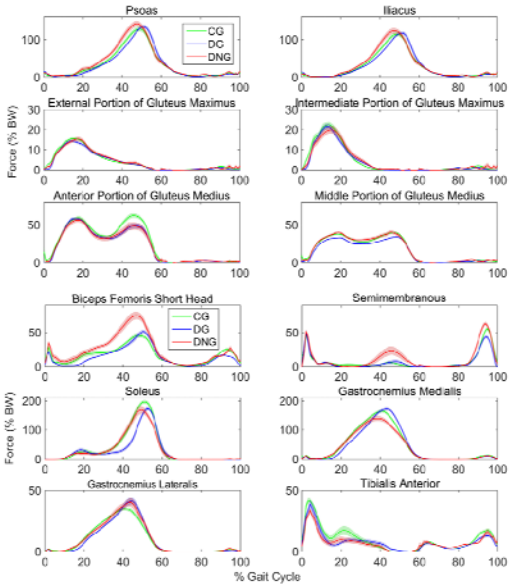

Figure 1: Mean (± 1 SD) of the muscle force time series of the control group (CG - green), diabetic group (DG – blue) and diabetic neuropathic group (DNG – red) during gait.

DG exhibited lower peak force for the hip extensor muscles (semitendinous and semimembranous) and hip abductor muscles, as well as higher peak force for the knee extensor muscles (vastus medialis and lateralis / $p=0,004$) compared to DNG and CG.

DISCUSSION AND CONCLUSIONS

Diabetic patients with and without neuropathy appear to adopt different muscle force distribution strategies in spite of the progressive worsening in their health condition. While reducing ankle extensor forces, DG increased knee extensor muscle forces at early stance and reduced the hamstrings force at the end of swing phase, whereas DNG increased the hamstrings and psoas muscle forces at push-off. The individual contributions of distal and proximal muscles in the push-off phase of DNG suggest the existence of the hip strategy. Maintaining or improving the function of the hip flexors and of the hamstrings could help diabetic neuropathic patients to keep their independency in performing daily living activities by compensating distal losses in muscle forces.

P301 - DEVELOPMEMT OF GERONTOLOGIC WALKING FOR ELDERY GAIT AND POSTURE IMPROVEMENT

[1] **Kiyomi Izumi**, and [1] Takemasa Kawahara
[1] Institute Kenkojumyo Sekaiichi
Corresponding author email: izumi@kenkojumyo.net

INTRODUCTION

Ministry of Health, Labour and Welfare in Japan reported that the population 65 years of age and older became 27% of the whole population in 2016, and estimated to become approximately 40% in 2055. The ratio of elderly people in Japan is the highest in industrialized countries, followed by Italy, Germany, and France.

Elderly people who have problems with walking, use a stick or a walker for the elderly, but their gait and twisted posture have not improved. Therefore, we have developed the Kawahara Walking (Kenkojumyo Walking, meaning gerontologic walking technique) with two poles to improve the elderly's gait and posture. We have been encouraging the elderly to walk with their own feet and to live a cheerful life by solving the problems concerning their posture and feet. In this presentation, the method of Kawahara Walking and the normal pole walking were compared, and we report the effects of Kawahara Walking in a verification test.

METHODS

I. The mechanism of pole walking and the influence on the body were compared between normal pole walking and Kawahara Walking.

1. Normal pole walking [1]

Sports type: Strike a pole around the tiptoe of the opposite side. Push the ground with a pole and move forward. Rehabilitation type: Strike a pole vertically around the step of forefoot of the opposite side. Pull the pole centering on the elbow.

2. Kawahara Walking

Firstly, set the length of poles approximately 10 cm longer than those used in normal pole walking. Then, strike a pole vertically at 3-20 cm over the step of forefoot of the opposite side. Not widen the step length and follow slowly from the heel.

II. Effect of Kawahara Walking

Elderly subjects (n=21, males and females, 59-87 years old) who exercised routinely were divided into KWG group and CTL group. Subjects exercised for 20 minutes a day for three weeks using the Kawahara Walking method in the KWG group and by free walking in the CTL group. Gait, muscular strength, and flexibility of subjects before and after exercise period were measured. The measured values before and after intervention were evaluated by paired t-test with 5% significance level.

RESULTS AND DISCUSSION

Figure 1 shows function of force in pole walking. By normal pole walking, we receive floor reaction force by pushing poles backward. The components of the floor reaction force of a vertical direction and the line make walking easy, and momentum is increased. However, it is considered that the posture is not improved because the body is bent forward.

By using the Kawahara Walking method, the force is applied in horizontal and vertical directions. In the horizontal direction, when a pole is struck in front of the body, the uniform linear motion in a walk is inhibited. The kinetic energy is converted into backward force and places load on a walk. In the vertical direction, floor reaction force rises directly above by the pole being placed vertically.

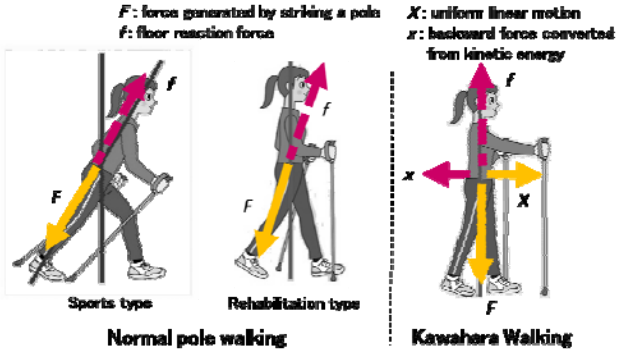

Figure 1: A comparison in function of force between normal pole walking and Kawahara Walking

As a result of the verification test, the angles forward-bent posture from the vertical axes in the both legs support period statistically decreased after intervention in the KWG group ($p<0.001$). The cadence decreased after intervention ($p<0.001$). The leg extension static maximum muscular strength significantly increased after intervention ($p<0.01$). There was no significant difference in walking speed, steps, grips or ante-flexion. There is no difference in any measurement in CTL group. [2]

Furthermore, single stance phase in the free gait before and after the intervention was determined in this study. Single stance phase was significantly extended from 0.363 ± 0.037 sec to 0.393 ± 0.031 sec after intervention in the KWG group ($p<0.05$). Single stance phase after intervention showed good correlation with leg muscular strength and forward-bent angles. Cadence also showed good correlation with forward-bent angles.

CONCLUSIONS

The improvement of posture, extended single stance phase resulted from decrease in cadence, increase in leg muscular strength were shown in the 20 minutes of the Kawahara Walking for three weeks group, suggesting the exercise effects.

The results of this verification test suggested that the gait and posture of the elderly are improved with function of the pole force in horizontal and vertical directions by the Kawahara Walking method.

P302 - AGE-GENDER DIFFERENCE IN PERCEPTION OF SUPPORT SURFACE ROTATION UNDER NORMAL STANDING

[1] **Hee-jun Jeon**, [1]Jae-Hoon Heo, [1]Hyeong-Min Jeon, [1,2#]Gwang-Moon Eom.

INTRODUCTION

Decline of the postural control is one of the major cause of elderly falls. The ability to maintain balance in normal standing is important as itself and as a pre-requisite for locomotion. Combination of various sensory functions, e.g., vestibular, visual, somatosensory functions are used in postural control [1]. Among these sensory functions, somatosense especially the proprioception is of special attention, since proprioceptive exercise can enhance balance control [2].

Age-related decline in the proprioception was reported [3], but the investigations were limited to single joint under non-standing postures, e.g., sitting or lying with the other body parts constrained. It is unclear these findings are valid under normal standing conditions, where the proprioception is integrated from multiple joints. Therefore, this study aims to investigate the age-gender difference in proprioception under normal standing.

Specifically, we investigated the perception of support surface rotation during normal standing. Eyes were closed to exclude visual function. The role of vestibular function was assumed to be negligible, because its sensitivity in normal standing is much lower compared to the proprioception [4]. Hence, the major perception of surface in this study could be attributed to the proprioception.

METHODS

Fifty-two subjects participated in the study. Subjects were divided into 4 groups (12 young men, 21.6±1.6 yrs; 14 young women, 20.5±1.3 yrs; 12 elderly men, 79.0±5.5 yrs; 14 elderly women, 76.5±5.6 yrs). Subjects stood on rotatable platform with their eyes closed. The plate rotated at 0.2°/s at an unexpected timing. Subjects were instructed to press a button if surface rotation is perceived, and the corresponding rotation angle (perception threshold) was recorded. Three trials were repeated for each of pitch and roll direction rotation in random order. Repeated-measures 2-way ANOVA (factors: age and gender) and post-hoc pairwise comparisons (Bonferroni correction) was performed. The significance level was set to 0.05.

RESULTS AND DISCUSSION

Fig. 1 shows the threshold angle of perception. ANOVA showed interaction of age and gender, so that a post-hoc analysis was added. Perception threshold of the young was lower than that of the elderly, irrespective of gender. In addition, perception threshold in elderly men was lower than elderly women. The results indicate that the perception of support surface rotation is degraded with aging and the age-related decline is more severe in women.

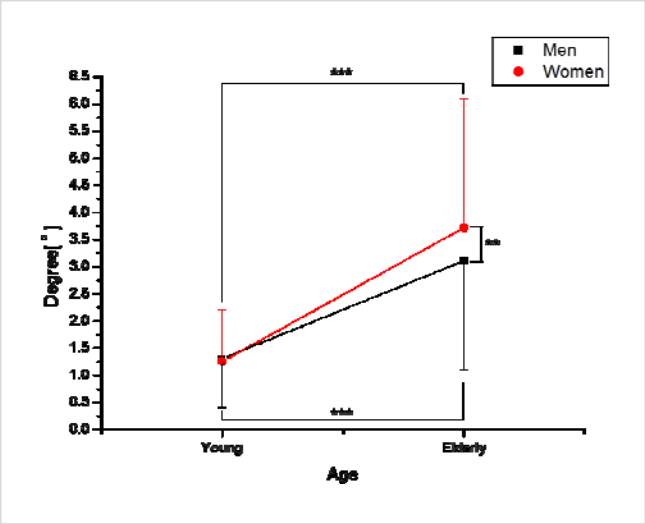

Fig. 1 Threshold angle of perception with eyes closed

Since the somatosensory information is mainly used for the perception of body orientation in quasi-static conditions [4] and the vision was excluded in this study, the surface rotation would be perceived mainly by somesthetic cues (proprioception) integrated from multiple joints of lower limbs. Therefore, the results suggest that the integrated proprioception from lower limb declines with aging and more in women. This may explain the age-related decline in postural control and worse balance in elderly women, which is supported by the increased postural imbalance with the decline in single joint proprioception [5].

CONCLUSIONS

The perception of support surface rotation (mainly affected by the integrative proprioception of lower limbs) is degraded with aging and the age-related decline is more severe in women.

P303 - CONTRIBUTIONS OF FOOT PROPRIOCEPTORS TO THE DETECTION OF POSTURAL PERTURBATIONS IN FREE-STANDING HUMANS ASSESSED BY DIRECT RECORDINGS FROM THE POSTERIOR TIBIAL NERVE

INTRODUCTION

As an inverted pendulum, the human body needs to constantly work against the forces introduced by gravity and locomotion to maintain a stable posture. Muscle spindle and cutaneous afferents provide the neural substrates required for detecting the position of the body in space (proprioception). It has been shown that absence of these inputs in the feet leads to increased postural instability [1]. The distribution and behaviour of skin afferents in the foot has been reported [2], but not during standing. Moreover, no studies have yet characterized the behaviour of muscle spindles in the intrinsic muscles of the foot, either at rest or during standing. In the present study, we aimed to investigate the behavior of muscle and cutaneous afferents in the foot and identify temporal correlations between adjustments in posture and neural activity in unsupported freestanding and in response to postural perturbations. We achieved this by recording, for the first time, from the posterior tibial nerve,

METHODS

Sensory nerve activity was recorded via a fine tungsten electrode inserted into the posterior tibial nerve, located posterior to the medial malleolus of the ankle. This was performed while the subject was seated above a motorized platform with their knee and ankle joints at ~90 degrees. Once a satisfactory nerve signal had been obtained, afferents were characterized by muscle supplied (muscle spindles) and type and receptive field (cutaneous afferents). Nerve activity was recorded (NeuroAmpEX, ADInstruments) under the following conditions: 1. transition from seated to standing, 2. natural freestanding for 5 minutes, 3. sinusoidal linear motion at 0.2 Hz and 5 mG in the X (antero-posterior) direction and 4. in the Y (mediolateral) direction.

Throughout the protocol, the subjects' feet were placed on a force plate that determined centre of pressure and z-axis forces. A goniometer on the contralateral foot detected changes in ankle angle. Surface electrodes on the ipsilateral tibialis anterior and soleus muscles recorded electromyographic information. Video capture was used to interpret natural foot movements.

RESULTS AND DISCUSSION

Successful recordings were obtained from 16 muscle spindle afferents supplying the intrinsic muscles of the foot, and 15 cutaneous afferents supplying the plantar surface of the foot, from 16 healthy subjects across 25 experiments. Preliminary assessment of the recordings revealed that muscle spindle afferents encoded postural perturbations (Figure 1). Conversely, many cutaneous afferents were silent at rest but were excited by compensatory movements of the toes during platform motion. Detailed analyses will need to be performed on a larger sample to allow us to identify specific patterns of behavior during postural sway and imposed perturbations, but nevertheless, these findings demonstrate the importance of sensory information from the foot in the detection in variations in posture from a stable state.

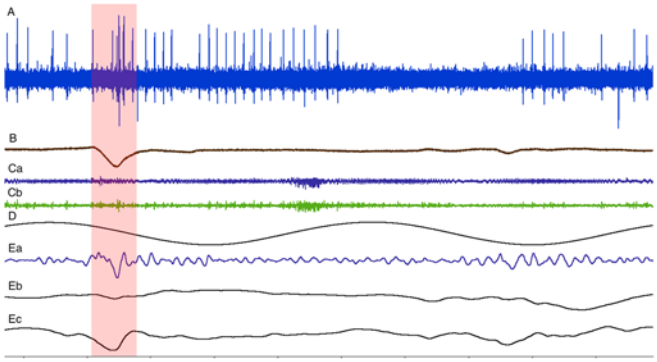

Fig. 1: Nerve recording from a single muscle spindle afferent supplying abductor hallucis in freestanding with postural perturbations (A). Also shown is ankle angle (B), EMG activity of tibialis anterior (Ca) and soleus (Cb), acceleration of the platform (D), force in the Z-axis (Ea) and centre of pressure in the X (Eb) and Y (Ec) directions. Highlighted in red is a compensatory response to platform acceleration.

CONCLUSIONS

For the first time, we have recorded from muscle spindle afferents supplying the intrinsic muscles of the foot, identifying patterns of behaviour during freestanding and postural perturbations. We have also recorded from cutaneous afferents from the sole and toes for the first time and, in these conditions, shown neural correlation with changes in posture during natural freestanding and postural perturbations. This novel data is the foundation for further exploratory studies examining the role of proprioceptors in the posture maintenance.

P304 - VALIDITY AND RELIABILITY OF AN ELECTRONIC PRESSURE-SENSOR WALKWAY, THE ZENO®, FOR THE QUANTIFICATION OF CENTER OF PRESSURE IN HEALTHY AND LOW BACK PAIN SUBJECTS

[1,2]**Clara Leyh**, [1]Cyrielle Emon, [1]Cyrine Siala, [1]Laurent Devalet and [1,2]Véronique Feipel
[1]Laboratory of Functional Anatomy, Université Libre de Bruxelles (ULB)
[2]Laboratory of Anatomy, Biomechanics and Organogenesis, Université Libre de Bruxelles (ULB)

INTRODUCTION

Information about center of pressure (COP) displacement during gait is of interest to evaluate postural control and physical function [1-3].

The Zeno Walkway® is a pressure-sensor carpet similar to GAITRite® that identifies static and dynamic pressure data and computes spatio-temporal and COP gait parameters. Contrasting with pedobarography or force plates that evaluate single steps, several gait cycles can be completed on the Zeno which allows the assessment of numerous footprints representing a more natural gait [4]. But while the reliability and the validity of spatio-temporal parameters were broadly investigated [5-7], there is little information available concerning those of the COP parameters processed by the Zeno [8].

The aim of this study was to evaluate the reliability and the validity of the Zeno Walkway® for the measurement of center of pressure progression during barefoot walking in healthy subjects and subjects with low back pain.

METHODS

25 healthy subjects (HC) (females: n=16; age: 24±5 years; males: n=9; age: 25±4 years) and 8 patients with low back pain (LBP) (females: n=5; age: 28±9 years; males: n=3; age: 43±9 years) walked 3 times at 3 different self-selected speeds (slow, preferred, fast) over a 11 m long path containing a 6 m long electronic walkway (Zeno Walkway®, ProtoKinetics:) and 2 pressure plates (0.5 m long Footscan®, RSscan International). The order of gait speeds was randomized and the process was repeated 2 weeks later.

The posterior-anterior, medial–lateral and resultant displacements (COP*x*, COP*y*, COP*xy*) and velocities (V*x*COP, V*y*COP, V*xy*COP) were computed from contact data during stance phase of gait. For each group, ICC of type (3,1) and (2,k) were used to evaluate respectively the test–retest reliability between the 2 sessions and the level of absolute agreement between the 2 instruments. 95% of limits of agreement (95% LoA) and mixed-model ANOVA were completed.

RESULTS AND DISCUSSION

Concurrent validity. For each speed condition, COP*x*, COP*xy*, V*x*COP, V*y*COP and V*xy*COP differed between instruments (p=0.00) and ICC (2,k) demonstrated poor to fair-to-good reliability (ICC=0.30-0.73). The Footscan computed greater COP values, especially those related to posterior-anterior axis (COP*x* and V*x*COP).

Test-retest reliability. At slow speed, stance time was significantly longer at the first session (p=0.00). For each speed condition, ICC values were excellent for COP*x*, COP*y*, COP*xy* and V*y*COP (ICC=0.81-0.95) and fair-to-poor for V*x*COP and V*xy*COP (ICC=0.41-0.73). V*x*COP and V*xy*COP presented at preferred speed the lowest ICC values (ICC=0.41-0.44). 95% LoA and mean differences between tools and sessions are reported in Table 1. Bias and LoA showed better agreement than reported for the comparison between Zeno and force plates [8].

CONCLUSIONS

Zeno appears to be a reliable tool for measuring COP displacement at 2 weeks interval in HC and patients with LBP. A previous study established good concurrent validity for Zeno [8]. Our results suggest the need of further investigations to evaluate Zeno, force plates and Footscan concurrent validity.

P305 - EFFECT OF MOTION CONTROL SHOES ON GAIT AND SHOULDER SYMMETRY IN PATIENTS WITH LEG LENGTH DISCREPANCY

Cheng-Feng Lin, Cheng Shin Tsai
Department of Physical Therapy, College of Medicine, National Cheng Kung University, Tainan, Taiwan
Corresponding author email: connie@mail.ncku.edu.tw

INTRODUCTION

Leg discrepancy is an important factor to cause the gait asymmetry [1]. This change may affect not only the appearance but also the biomechanics of the whole body [2], then leading to the musculoskeletal dysfunction. For example, low back pain is often seen in the long leg in the patient with leg discrepancy [3]. In clinical practice, many ways are used to correct the leg discrepancy that including full-length padding or insole, shoes with additional height, arch support, and surgery. The insole and shoes are common solutions to solve the problem [4]. However, some insoles are too expensive and they need a larger pair of shoes for fitting the insole and foot simultaneously. Hence, the aim of this study was to use an adjustable motion control shoes to correct the leg discrepancy and gait pattern. The adjustable motion control shoes can offer the arch support by inserting some card-shape support in the bottom of the shoes, and increase the shoe height by locking some screws under the bottom of the shoes without sacrificing the foot space. It was expected that the ground reaction force (GRF), the lower extremity kinematic and the shoulder height difference might be corrected with this adjustable motion control shoes.

METHODS

Ten participants were recruited for this study (Female: N=4; body height: 162±4.24 cm, body weight 54.75±10.24 kg; Age: 23.5±4.36 years; L't leg length: 87.25±3.59 cm; R't leg length 87.25±2.36 cm; Male: N=6; body height: 170±4.67 cm, body weight 69.33±6.59 kg; Age: 21.67±1.21 years; L't leg length: 87.75±4.08 cm; R't leg length 88.92±3.44 cm). All of the participants received the basic data measurement that including body height, leg length, body height, age, history taking). They are also evaluated with medial longitudinal arch. After history taking, physical therapist would evaluate walking pattern. Then the participants were attached for 46 markers to the bony landmark of the whole body. The participants were asked to perform the level walking in three different conditions: walking with adjustable motion control shoes (Adjusted), walking with unadjusted motion control shoes (Unadjusted), and their own running shoes (Own) under random order. The ground reaction force during walking was collected with two fixed forced plate (Type 9281B, Kistler Inc., Switzerland) and the kinematic data was measured by the motion capture camera (Motion Analysis Eagle System). The shoulder height difference angle was the angle between the line connecting left acromion to right acromion and the line parallel to the global horizontal. The lower extremity kinematic data were sagittal plane hip angle, knee angle, and ankle angle and frontal plane ankle angle at the maximum GRF time. All the kinematic data was calculated with the 3D Euler angle method. The one way ANOVA was used to compare the condition effect in these parameters. The statistical difference was set at $p<0.05$.

RESULTS AND DISCUSSION

No significance was found in the range of shoulder height difference among three groups (Adjusted: 5.53±2.37 degrees; Unadjusted: 6.30±4.16 degrees; Own: 5.93±2.37 degrees). No significance was found on the vertical ground reaction force among three groups (Adjusted: 1.44±0.35 Kg/BW; Unadjusted: 1.41±0.25 Kg/BW; Own: 1.40±0.47 Kg/BW). A significant difference was found in the ankle pronation (+) / supination (-) angle among three groups (Adjusted: -1.96±1.4 degrees; Unadjusted: 2.37±0.18 degrees; Own: 5.79±1.1 degrees).

Although no significance was found among some parameters, a trend of these data may suggest that the adjusted motion control shoes have certain effect on modifying the shoulder height and ankle pronation /supination angle. The decreasing shoulder height difference (or increased shoulder symmetry) may further affect their body image as well as the loading over the lumbar spine. In addition, participants also gave feedback that wearing adjusted motion control shoes decreased their "medial-lateral body sway" during level walking, though this feedback cannot be quantified.

Figure 1. Definition of shoulder height angle difference.

CONCLUSIONS

The adjustable motion control shoes decreased the ankle pronation angle and may have effect on decreasing shoulder asymmetry.

ACKNOWLEDGEMENTS

We would like to thank Homax Ltd, Taiwan for providing shoes for this research.

P306 - QUANTIFYING GAIT VARIABILITY OF SUBJECT WITH PHASE PORTRAIT ANALYSIS

[1] Arif Sugiharto, [1]**Sandro Mihradi**, [1]Tatacipta Dirgantara and [1]Andi Isra Mahyuddin
[1]Institut Teknologi Bandung

INTRODUCTION

The variability of human movement could be explained as the normal variations that occur in motor performance in some repetitions of a task [1]. If a person tries to repeat the same movement more than once, the second and subsequent movement is not necessarily identical. Gait variability becomes one of important parameters in understanding the human movement. It may serve as a sensitive and clinically relevant parameter in the evaluation of mobility, fall risk and the response to therapeutic interventions [2]. In one study, the increase of complexity and variability of limb segment motion during gait due to injury has been observed with phase portrait analysis [3].

Phase portrait on gait analysis is defined as the curve between the joint angle and angular velocity. Quantifying gait variability of normal subjects can be done by using phase portrait parameter. The average value of phase portrait in the gait cycle is represented by the value of its centroid. Gait variability is indexed by measurements of the motion of centroid points from cycle to cycle.

METHODS

In this study, gait analyses were conducted on 10 normal subjects. Subjects were instructed to walk on a treadmill with a speed comfortable to each of them. Data were taken up to six gait cycles. Gait variabilities were then analyzed on hip, knee, and ankle segment.

RESULTS AND DISCUSSION

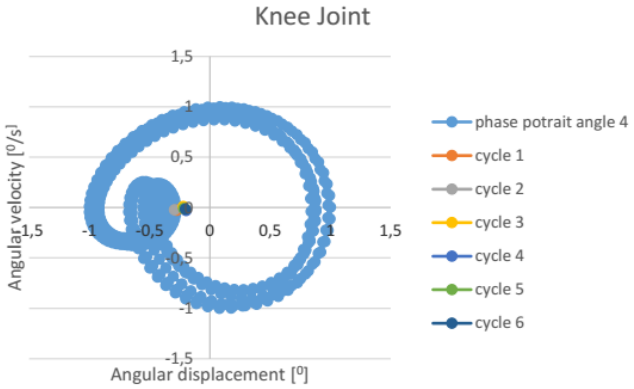

Figure 1: Phase portrait of knee joint.

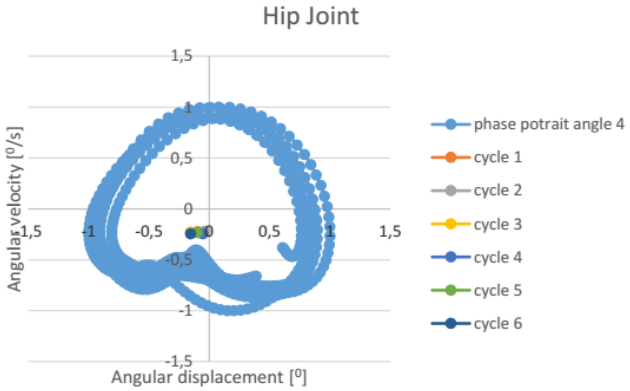

Figure 2: Phase portrait of hip joint.

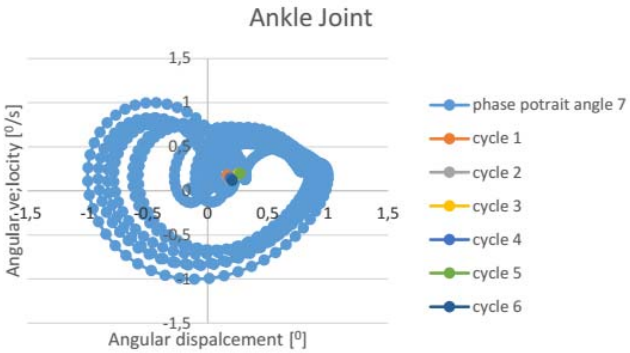

Figure 3: Phase portrait of ankle joint.

Based on the results of 10 subjects, it is seen that for the majority of them the variability of the hip segment is higher than variability of ankle segments, and variability of ankle is higher than the variability of knee.

Variabilities in each segment were also compared against the anthropometry value of lower limbs and body mass index (BMI). However the results did not reveal any correlation between the variability of each segment against the lower body anthropometry and BMI.

P307 - STAIR DESCENT TRANSITIONS IN THE ELDERLY: COORELATIONS BETWEEN LOWER LIMB JOINT IMPULSES, CADENCE, BALANCE LEVEL AND AGE

[1] **Vera Moniz-Pereira**, [2]Silvia Cabral and [3]António P. Veloso

INTRODUCTION

Stair negotiation has been associated with a higher fall and injury risk, especially for older adults [1]. Although several risk factors have been reported for falling, gait/balance disorders or weakness seem to be particularly important [2].

During stair negotiation, older adults appear to have a lower sagittal plane range of motion and to produce lower joint moments in the knee and ankle, as well as higher sagittal plane range of motion and joint moment at the hip, than younger adults [1]. These differences have been associated with the decrease in strength and changes in coordination, which occur with ageing [1]. However, in most of these studies, older adults aren't characterized/distinguished in terms of physical function or balance. The purpose of this study was to verify the correlations between lower limb joint impulses, produced during stair descent transitions, age, balance and cadence, in a sample of community dwelling older adults.

METHODS

This study followed a cross-sectional design. The sample included 33 healthy, community-dwelling older adults, with 60 or more years and able to climb and descend a flight of stairs without using the handrail. Subjects' balance level was defined by summing the scores obtained on items 4 – step up and over, 5 – tandem walk, 6 – stand on one leg and 7 – stand on foam eyes closed, from Fullerton Advanced Balance (FAB) Scale [3].

Kinematic and kinetic data were collected using 8 infrared cameras (Qualisys Oqus 300) working at a frequency of 200Hz and synchronized with 2 Kistler force plates (9281B, 9283U014), one in front of the stairs and the other embedded below the first step. The passive markers were placed following the CAST marker set [4]. Participants walked at their comfortable pace. Three trials from each subject were processed in Visual 3D software (Professional Version v5.02.27, C-Motion, Inc). A 10 Hz 4th order Butterworth filter was applied to both kinematic and kinetic data. An 8 segments model (feet, shanks, thighs, pelvis and trunk) was built and optimized using global optimization [5]. Rotational impulses were obtained from lower limb joint moments, which were computed using standard inverse dynamics.

After checking for normality assumptions, Spearman correlation coefficient was determined using the software IBM SPSS Statistics (version 23). The significance level was set at $p \leq 0.05$.

RESULTS AND DISCUSSION

The tested older adults had, on average, 71.6 ± 4.5 years (63-81) a balance score of 14.7 ± 1.4 points (11 – 16) and 9 (57.6%) were female. Cadence was shown to be negatively correlated to the ankle and knee joint impulses produced on the trailing limb, which controls the lowering of the center of mass (Table 1), and positively correlated with the leading leg knee and hip joint impulses, which accept the weight on the ground. Further, moderate negative correlations were also found between joint impulse produced in the hips on both legs and balance level. No correlations were found between joint moments and age.

CONCLUSIONS

This study shows that, within a subsample of older adults living in the community, lower limb joint rotational impulses, produced during stair descent, seem to be more related with cadence and balance level than with age. Thus, subgroup analysis rather than the typical young vs older adults' comparisons, may be important in order to have a better comprehension about functional decline in the elderly.

P308 - CARRYING A BACKPACK OR PULLING A TROLLEY INDUCED GAIT ASYMMETRY IN CHILDREN?

Eva Orantes-Gonzalez, Jose Heredia-Jimenez
University of Granada, Spain.
Corresponding author email: maevor@ugr.es

INTRODUCTION

Carrying a backpack or pulling a school trolley with different loads has been previously related with changes in spatiotemporal gait parameters. With respect to gait asymmetry (GA) analysis, previous authors computed the use of ground reaction forces to analyze the GA while carrying a backpack [1] or carrying a bag on the shoulder [2]. No previous studies analyzed GA in children using the spatiotemporal gait parameters, and are neither there any previous studies about school trolleys and GA analysis.
Therefore, this study analyzed the GA while carrying a backpack or pulling a trolley with different loads in children.

METHODS

Fifteen students from an elementary school (aged 10.06 ± 1.70 years) participated in this study. The average body mass was 42.37 ± 14.11 kg, and the average height was 1.47 ± 0.14 m. The participants were healthy and did not report any history of orthopedic trauma or neurological problems. Each child was measured with a scale and measuring rod (SECA769, Hamburg, Germany). Participants walked under seven experimental conditions: no bag condition (control), carrying a backpack and pulling a trolley, both with 10%, 15% and 20% of the participant´s body weight (BW).

A 3D motion capture system (Qualisys AB, Göteborg, Sweden) was used to analyze the gait variables with a modified CAST model marker set without head or upper extremity markers. The reflective marker locations were collected through nine infrared high-speed cameras recording at 250 Hz. Each participant walked at their usual speed along a 15 m walkway. First, children walked with no bag to familiarize themselves with the protocol. Then, children completed the experimental condition in a random order. Children walked for one minute under each condition. Three minutes of rest was given between each of the experimental conditions to avoid fatigue.
This study analyzed the ratios, indexes, and GA of the following parameters: step length, swing time, and stance time, according to the equations proposed by Plotnik et al. [3] and Patterson et al. [4]
The Shapiro–Wilk test was used to determine the normal distribution of the different variables. The comparisons of GA parameters were analysed using a repeated measures ANOVA. The level of statistical significance was set at $p < 0.05$.

RESULTS AND DISCUSSION

Any of the GA values analyzed in this study showed significant differences between the experimental conditions (Table 1).

Table 1. Symmetry values of gait for the different experimental conditions expressed as mean (standard deviation)

	CONTROL	CARRYING A BACKPACK			PULLING A TROLLEY			p value

Step length GA	2.76 (2.59)	4.64 (2.76)	2.41 (2.19)	2.79 (2.88)	3.78 (2.60)	3.57 (2.50)	3.41 (2.56)	0.112

GA: Gait asymmetry

In spite of the fact that previous studies reported an increase in the asymmetry index (analyzing ground reaction force) while carrying an asymmetrical bag [2], in the present study, a non significant increase or decrease in GA parameters were obtained. Those results could indicate that carrying a backpack or pulling a trolley did not make children walk asymmetrically even when they used a school trolley.

CONCLUSIONS

Carrying a backpack or pulling a trolley with different loads (range from 10% to 20% BW) did not produce an increase in GA in children.

ACKNOWLEDGEMENTS

The authors thank all of the participants: children and parents who took part in this study. The work of Orantes-González, E was supported by the Ministry of Education, Culture and Sports of Spain (ref. FPU13/00162)

P309 - THE EFFECT OF DISCRETE VERSUS CONTINUOUS WALKING TRIALS ON SELF-SELECTED WALKING SPEED

INTRODUCTION

A typical gait collection involves a subject walking from one end of a capture volume to the other. This process begins with the initiation of gait, followed by steady walking, where data is captured. Following capture, gait is terminated and the process is repeated until the desired number of gait cycles is collected. Outside the laboratory people generally engage in steady state walking. In the laboratory, gait parameters measured during discrete walking are considered representative of steady state walking.

Walking speed and walking speed variability are global descriptors of gait quality, and affect gait kinematics and kinetics [1]. Walking speed variability has been reported to be higher during discrete trials than during continuous walking [2]. Accordingly, outcome variables may be affected simply by the choice of protocol. Therefore, the purpose of this study was to investigate the effect of discrete walking versus continuous walking on walking speed and walking speed variability. We hypothesized that walking speed would be faster and inter-trial speed variability lower during continuous walking than during discrete walking trials.

METHODS

Skin-mounted marker trajectories were captured with a 12-camera Qualisys system, while 12 males and 13 female adults performed two walking tasks. The first task represented a typical gait collection procedure, where beginning from a stand-still, the participants walked 12 m from one end of the capture volume to the other and then stopped. Each completed six trials. Data were recorded in the center 4 m of the capture volume. The second task involved continuous walking, where the subjects walked the lab in a "figure of eight" shape that included the discrete trial walkway. Data were collected through the same portion of the capture volume as for the discrete trials for the second through the seventh lap. The trial order (discrete, continuous) was counterbalanced between subjects.

A pelvis segment was modelled (C-Motion), and walking speed defined as the mean forward center of mass velocity of this segment through the collection volume. Walking speed variability was defined as the inter-trial variability of walking speed. Comparisons were made using repeated measures ANOVA, with sex and trial type as factors.

RESULTS AND DISCUSSION

Walking speed was significantly affected by trial types ($p < 0.001$, $d = 0.4$), with no effect due to sex. Participants walked, on average 0.06 m/s faster during the discrete trials. Walking speed variability was not affected by trial type or by sex ($p = 0.14$). There were no interaction effects between terms ($p = 0.33$).

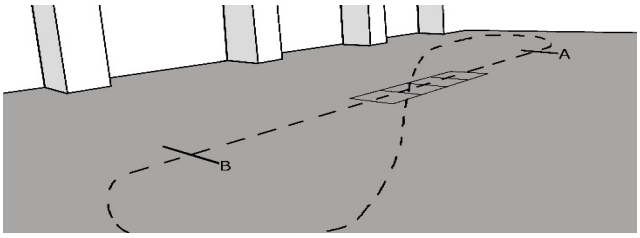

Figure 1: Laboratory schematic showing "figure of 8" walking pattern, and discrete walking pattern (between A and B).

Our initial hypothesis, that continuous walking would be faster than discrete walking was made due to the presence of gait initiation and termination phases during discrete trials, was not supported as participants walked significantly faster during the discrete trials. Although we do not have any data to explain why participants walked faster during discrete trials, we postulate that this increase may be a result of the control system used to determine self-selected walking speed, which we suggest is underdamped. In such a system, an initial overshoot, followed by modulation around the self-selected speed occurs. It is possible that the collection procedure was capturing a portion of such an initial speed overshoot.

Our second hypothesis, that walking speed variability would be higher in discrete trials versus continuous walking was also not supported, with no significant variability differences. This hypothesis was based, again, on the presence of the initial and termination phases of the cycle possibly introducing more variability into the data. Increases in variability can affect the statistics of outcome variables; however, regardless of the control mechanism governing walking, this demonstrates that inter-trial walking speed variability is not affected by trial type.

CONCLUSION

Significant differences in walking speed were found between the continuous and discrete trials, indicating that protocol may influence variables sensitive to walking speed, such as joint kinetics, ground reaction forces and minimum toe clearance.

INTRODUCTION

In human knee osteoarthritis (OA), local changes in bone mineral density in the tibia as measured by dual X-ray absorptiometry are suggested to be related to abnormal *in vivo* joint loading [1]. The relationship between in vivo measures of knee joint loading and changes in subchondral bone 3D microarchitecture, however, has not yet been explored. The subchondral bone, a shock absorber, protects the overlying cartilage against damage due to excessive loading. The aim of this study is to examine, on end-stage OA patients undergoing total knee replacement (TKR), the relationships between knee joint loads measured in vivo using gait analysis prior to surgery, and variations in bone microarchitecture of their excised knees quantified with 3D micro-computed tomography (micro-CT).

METHODS

Patients: Twenty-five knee-OA patients scheduled for TKR surgery (age 68±7 years, mass 92±18 kg) underwent pre-operative gait analysis. This study has received ethics approval from the Institutional Research Ethics Committees and all patients provided written informed consent.

Gait Analysis: The following kinetic variables were collected with 12 Vicon cameras and 4 force platforms and analysed with Visual3D v5 (C-motion Inc., MD, USA): knee external (ERM) and internal rotation moments (IRM), knee adduction moment (KAM) and knee adduction moment impulse, all normalized by bodyweight. The peak tibio-femoral joint contact force was calculated with a musculoskeletal model [2].

Micro-CT Analysis: After surgery the entire tibial plateaus were retrieved and scanned with micro-CT (17 µm/pixel, Skyscan 1076, Skyscan-Bruker, Belgium). The following subchondral bone 3D microarchitectural parameters were analysed in 4 cylindrical subregions of interest (ROIs, 10 mm diameter, 5 mm length) selected via software (CT Analyser, Skyscan-Bruker) in the antero-medial (AM), antero-lateral (AL), postero-medial (PM) and postero-lateral (PL) condyle (Fig. 1): bone volume fraction (BV/TV), trabecular thickness (Tb.Th), number (Tb.N), separation (Tb.Sp), and structure model index (SMI).

Statistics: Subregional differences in microarchitectural parameters were tested by Kruskal Wallis followed by Mann-Whitney U tests with Bonferroni correction. Associations between measurements from gait analysis and bone microarchitecture were investigated using Pearson's correlations.

RESULTS AND DISCUSSION

Statistically significant differences ($p< 0.05$) in subchondral bone microarchitecture were found among the ROIs. The AM ROI exhibited highest BV/TV (up to +75%, Fig. 1a), Tb.N (up to +41%), and lowest SMI (up to -69%), compared to the other three ROIs. The Tb.Th was greater (+26%), and Tb.Sp lower (-25%) in the AM than in the AL ROI. The BV/TV in the AM and PM ROIs was negatively correlated with the peak ERM ($r= -0.74$, $p< 0.01$, Fig. 2b, and $r= -0.56$, $p< 0.01$) and with KAM impulse ($r= 0.42$, $p< 0.05$ and $r= 0.42$, $p< 0.05$).

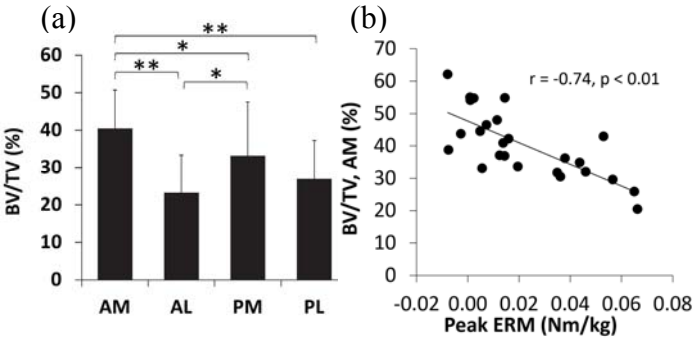

Figure 1: (a) average BV/TV and standard deviation (error bars) in the four proximal tibia ROIs (*$p< 0.05$, **$p< 0.01$); (b) Scatter plot with best fit line for 'BV/TV AM vs. peak external rotation moment (ERM)'

CONCLUSIONS

The four anatomical regions of interest showed significant differences in bone microarchitecture among each other. In particular, our results suggest that, during stance, the peak ERM is negatively related with BV/TV in the AM and PM tibial plateau. These significant associations with bone volume fraction found in the medial tibial plateau regions could be linked to a microstructural adaptation of the bone due to altered loading patterns that generate increased stresses in this condyle [3]. Analysis is ongoing to elucidate these relationships.

This study is the first to investigate relationships between measures of joint loading *in vivo* and knee bone microarchitecture, on the same patient. If confirmed, ERM could be suggested to be used as a non-invasive indicator of disease progression.

INTRODUCTION

As a result of injury or pathology, subjects frequently adopt altered gait modes [1] such as stiff knee gait (SKG) at lower velocities or slow running (SR) for higher velocities due to difficulty in performing normal gait (NG) or to preserve body physical integrity. Despite the large number of studies on normal gait and running [2,3] the effects of adopting adapted locomotion modes such as SKG and SR in relation to NG are not clear, especially in what concerns the changes on the pattern of lower limbs joint coordination. Recently, tools from dynamical systems theory, such as phase space analysis, have been contributing to the detection of limit cycle patterns whose variability points according to the level of detected order for the existence of chaotic behaviors of motor control. The aim of this study is to apply phase space analysis to assess specific subject joint coordination through hip, knee and ankle angular phase variability during SKG and SR when compared to NG.

METHODS

According to the interest on case study in pathology and lesion and the difficulty of the sample means in representing pathological cases and lesions, attention was focused on individual study of a subject. Data was obtained from simultaneous recordings during one stride of NG, SKG and SR of skin markers at right and left anterior superior iliac spines, thigh superior, knee medial and lateral, shank superior, ankle medial, lateral and toes recorded with 8 camera Qualisys system at 100 Hz. Stick figure model was morphed with Twente Lower Extremity Model (TLEM) to match size and joint morphology. Inverse kinematics was performed to obtain joint angles and dynamic analysis based on joint angles and kinetic boundary conditions. Phase angle was obtained from angle and angular velocity for hip, knee and ankle joints during NG, SKG and SR. Variability was assessed with continuous relative phase standard deviation (CRPsd) for each pair of hip, knee and ankle joints during NG, SKG and SR.

RESULTS AND DISCUSSION

SKG presents lower values of maximum hip and knee joint angles (0.48 and 0.70 rad) when compared to NG (0.65 and 1.06 rad), with similar maximum ankle joint angles (0.40 rad). Hip, knee and ankle present lower maximum joint angles at NG (0.65, 1.06 and 0.40 rad) and SKG (0.48, 0.70 and 0.40 rad) when compared to SR (0.63, 1.52 and 0.61 rad). SKG presents lower amplitudes of hip (-2.9, 2.9 rad/s), knee (-2.6, 4.6 rad/s) and ankle (-3.6, 2.5 rad/s) joint angular velocities when compared to normal gait and normal gait presents lower amplitudes of hip (-3.0, 3.5 rad/s), knee (-6.1, 6.0 rad/s) and ankle (-4.9, 2.9 rad/s) joint angular velocities when compared to slow running (-3.0, 5.0; -10.0, 7.5 and -6.7, 6.9 rad/s). SKG presents lower amplitudes of hip (-32.0, 39.0) rad/s^2, knee (-50.0, 52.0) rad/s^2 and ankle (-44.0, 84.0 rad/s^2) joint angular accelerations when compared to normal gait and normal gait presents lower amplitudes of hip (-34.0, 46.0 rad/s^2), knee (-72.0, 120.0) rad/s^2 and ankle (-54.0, 104.0) rad/s^2 joint angular accelerations when compared to slow running (-68.0, 46.0), (-118.0, 147.0) and (-109.0, 119.0) rad/s^2.

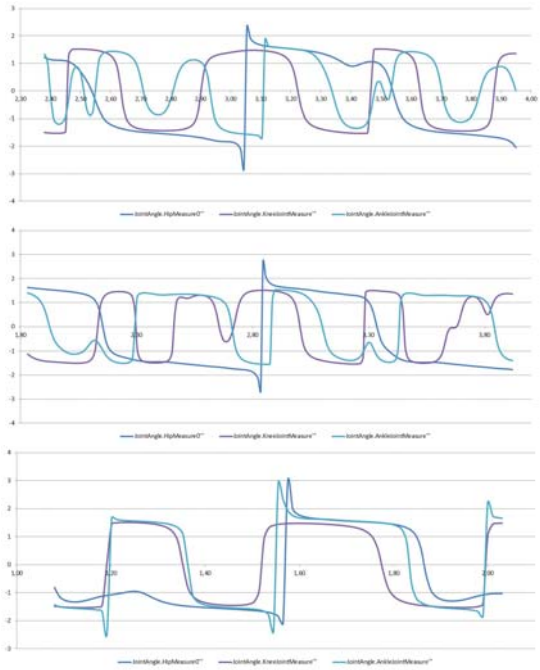

Figure 1: Angular phase of hip, knee and ankle joint during NG, SKG and SR.

At NG, SKG and SR the hip presented higher CRPsd than the knee. At NG the knee presented higher CRPsd than the ankle with SKG presenting similar CRPsd for this joints and SR presenting lower CRPsd at the knee in relation to the ankle joint. The higher CRPsd at the hip was observed during SKG whereas the lower CRPsd for the knee was observed at SKG. The higher CRPsd at the ankle was detected at SR

CONCLUSIONS

Phase space analysis presents as an adequate tool to assess lower limb joint coordination during altered gait modes.

INTRODUCTION

Different types of squat exercises under stable and unstable conditions are widely applied in fitness and rehabilitation training in order to improve or maintain individual performance levels. Trunk muscles and spinal stability are considered key factors of load support during squat exercises. Varying levels of stability while performing squats can notably affect core muscle activity [1,2] and training impacts. Thus, the purpose of this study was to examine whether different types of squat exercises under stable and unstable conditions alter lumbar spine curvature and trunk muscle activation.

METHODS

Healthy females (N = 6, age: 29.4 (SD 9.0) y, height: 169 (6) cm, body mass: 64.0 (7.1) kg) and males (N = 6, age: 28.8 (8.0) y, height: 178 (3) cm, body mass: 76.2 (6.6) kg) completed four repetitions of each squat type (back squat (BS), front squat (FS) and overhead squat (OS)) in a randomized order under stable and unstable conditions, barefoot, with additional external loads (female 12.5 kg / male 20 kg). An internal knee angle of 100° at the lowest point (turning point) and a 2 s up and 2 s down phase were required. After the stable trials were completed, unstable trials were performed with a reduced base of support by standing with the ball of their feet on a 1.6 cm high wooden board and their heels off the ground.

Surface electromyography of internal (IO) and external oblique (EO), rectus abdominus (RA) and erector spinae (ES) was recorded during each squat type and normalized to maximal voluntary isometric contractions performed in crunch and prone plank positions. 3-D motion of the participants was determined using an optoelectronic motion capture system with 56 reflective markers placed on lower limbs, hip, spine, thorax, shoulder and hands. Spine curvature was evaluated by measuring the angle between specific spinal segments at the start, turning point and end of the squat. Anterior-posterior motion of the centre of mass (COM) during squatting was also measured for all conditions. Two (condition: stable vs. unstable) × three (type: BS, FS, OS) repeated measures ANOVAs were calculated for each muscle, body sway and spine curvature at different squatting positions. The outcome measures were to evaluate trunk muscle activity, lumbar spine angle and body sway for the different squatting conditions.

RESULTS AND DISCUSSION

For all muscles significant condition-effects ($p<0.02$) with large effect sizes were observed for squatting down ($0.55<\eta_p^2<0.74$) and up ($p<0.03$, $0.49<\eta_p^2<0.80$) except for the rectus abdominis (Table 1). Significant differences between stable and unstable squatting were only observed for IO and ES during the downward movement. A significant stability (stable vs. unstable) × condition (squat types) interaction effect was only observed for IO (Table 1). Spinal curvature showed significant condition effects at all movement positions. COM motion during the downward phase showed increased motion in the stable compared to unstable underground ($p<=.001$).

Table 1: Muscle Activity of IO (internal oblique), EO (external oblique), RA (rectus abdominis) and ES (erector spinae) during different types of squatting (back, front, overhead) and stability (stable, unstable) with lumbar spine curvature measured as the angle between segments T12-L2 and L2-L4 and total motion of center of mass.

CONCLUSIONS

Trunk muscle activity is altered by performing different types of squatting exercise. However, only IO seemed to respond with higher muscle activation under unstable standing conditions compared to stable conditions. As squat conditions also influences spinal curvature and COM motion, the implications for the prescription of squat exercises to be performed during athletic training has to be considered differentiated with respect to trunk loading and trunk muscle activation.

INTRODUCTION

Higher brain centers are heavily involved in processing the sensory information available to plan and execute the best motor strategy for controlling upright posture [1]. Postural control demands attention in healthy young subjects [2] but it is known that additional cognitive loading affects balance stability [3]. The processing of painful stimuli is also cognitively demanding [4], and therefore, disrupts attention from other tasks [5]. The effects of pain, cognitive load and balance stability is still to be fully understood. The aim of this study is to quantify the effects a cognitive (dual) task on postural stability during pain.

METHODS

Fifteen healthy young adults (8 males, age=27.1±3.4 yrs; height=1.72±0.08 m; weight=72.2±10.9 kg) participated in the experiment (N-20120077). Pain was induced via intramuscular injection (1ml, 6% hypertonic saline solution) into the vastus medialis and vastus lateralis muscles subsequently (0.9% isotonic saline was used as control). Pain intensity was evaluated with a 10-cm visual analogue scale (VAS) immediately after each injection and balance measurement (0="no pain"; 10="maximum pain"). The participants stood still barefoot during 1 min on a force plate (Good Balance system, Metitur; 50Hz) with the feet placed in a tandem position. Center of pressure (COP) was recorded before and during each injection, during 2 cognitive tasks: (i) counting forward by adding one; (ii) counting backward by subtracting three. The order of injections and cognitive tasks was randomized.

COP total area (TA) of displacement and the COP velocity in anterior-posterior (APvel) and medial-lateral (MLvel) directions were extracted. Mean VAS scores were compared between conditions (isotonic or hypertonic injections) with paired T-tests. The difference between before and during both injections conditions for COP parameters where compared between cognitive tasks with repeated measures ANOVA. Bonferroni post-hoc tests were applied to correct for multiple comparisons ($p < 0.05$).

RESULTS AND DISCUSSION

Pain during hypertonic injections was significantly higher compared with isotonic injections (4.8±1.7 cm; 0.7±0.8 cm, p=0.011). Table 1 shows the results for the COP variables.

A significant interaction was found between the injection type and cognitive task for TA and MLvel. Post-hoc comparisons showed that both TA and MLvel was increased during backward counting in comparison to forward counting during pain ($p<0.05$). Both variables were reduced during pain in comparison to non-painful conditions when subjects were counting forward ($p<0.05$). MLvel decreased during counting backward in comparison to forward during control (non-painful) conditions, but not TA.

Postural sway during pain was affected by the difficulty of the cognitive task performed. When the subjects counted backwards (difficult task, requiring more cognitive resources), both COP area and velocity in the medial-lateral direction increased. This probably indicates that a significant amount of resources have shifted from postural control to the cognitive task, increasing postural sway. Interestingly, the direction where the control is altered by the cognitive load is the medial-lateral direction, which is prone to changes given the standing position (feet tandem) as it reduces the dimensions of the base of support in the same direction, making it probably more difficult to control.

CONCLUSIONS

These findings indicate that during pain postural sway increases during the performance of the more difficult cognitive task (counting backwards). Furthermore, performing a simple cognitive task during pain improved balance compared with control condition.

INTRODUCTION

Parkinson's disease (PD) is a progressive neurological condition, characterized by a dopamine deficiency causing tremor, rigidity, bradykinesia and gait problems mainly arising from dopamine deficiency [1]. Gait disturbance is a key component of motor disability in PD patients, therefore there is a wide literature describing walking abnormalities in PD, most often carried on through motion analysis techniques [2], despite this, works focused on surface emg (Semg) analysis are lacking. Hydrotherapy has been proposed as an innovative rehabilitative strategy for the treatment of motor symptoms and quality of PD. In particular water buoyancy abolishes gravity thus reducing the weight that joints, bones, and muscles have to bear; consequently, an underwater (UW) training allows early active mobilization and dynamic strengthening. This work aims to evaluate improvements in muscular activation and joints kinematics in 10 PD patients before and after a hydrotherapy program, and compared to healthy subjects (Control group=CG).

METHODS

20 subjects participated in the study divided in two groups: PD patients (mean ± standard deviation (SD) BMI: 28±3, age: 71±6 years), and CG (mean ± standard deviation (SD) BMI:28±3, age: 65.5±7 years). Subjects were asked to walk barefoot at their preferred walking speed on the gait laboratory of GVDR (Cadoneghe, Padova, Italy). A minimum of three walking trials per subject were collected. Gait analysis was performed with 8 cameras stereophotogrammetric system (300 Hz) synchronized with 2 force plates (BTS, Italy) and the protocol reported in Volpe et al 2016 [3] was applied. The electrical activity of 6 muscles for each lower limb were collected by means of a portable SEMG system (FREEEMG1000, 1000 Hz, BTS Padova) together with the ground reaction forces. Surface EMG signals of the following muscles were recorded: Rectus Femoris (RF), Tibialis Anterior (TA), Bicipes Femoris (BF) and Gastrocnemius Lateralis (GL). Sensors were positioned according to Blumenstein [4] after appropriately cleaning and preparing the skin. Sensors were 3 cm of diameter and positioned 1 cm apart. The right and left muscle activation patterns were analyzed and the envelope of the signal computed (the peak (POP) and the position of the peak with respect to gait cycle (POP%) [5].

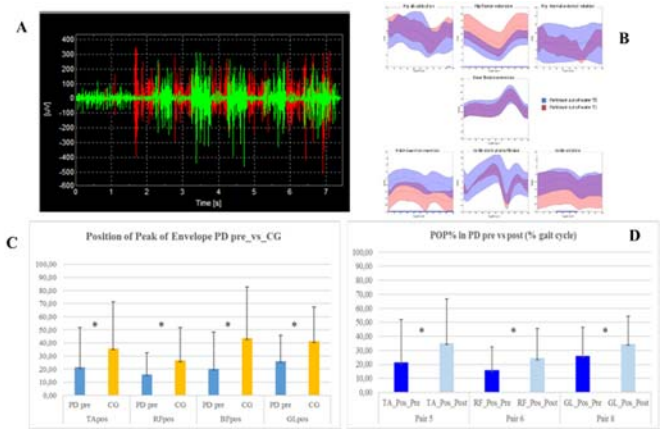

Figure 1: A) Example of superimposed raw signal of GL and TA of the same leg side, B) pre-post PD patients underwater gait normative bands vs CG, C) results of One Way Anova between: PD pre water training and CG, D) results of Paired Ttest between PD pre and post water training. *= $p < 0.05$

RESULTS AND DISCUSSION

A significant reduction in Joints kinematics differences was observed at all joints in the comparison between PD post and CG. sEmg results showed significant improvement in muscle activation timing after underwater training. A significant earlier activation was detected at all levels in PD patients, which was not present after the training period.

CONCLUSIONS

Underwater training played an important role in restoring a PD patients gait pattern not only in term of joints kinematics but also in term of muscles activation timing. These results may impact positively on the development of underwater gait treatments in PD.

P315 - TEMPORAL EFFECTS OF STABILITY WHILE SITTING ON A ROCKER BOARD

France Sevšek and Darja Rugelj
University of Ljubljana, Faculty of Health Sciences,
Ljubljana, Slovenia
Corresponding author email: france.sevsek@zf.uni-lj.si

INTRODUCTION

Balance boards of different types are routinely used to develop balance, motor coordination skills and core stability in young and older persons [1] as well as persons with low back pain [2]. Their functions and/or training progress are often estimated by the centre of pressure (CoP) movements as recorded by a force platform. Although this is a well-established method the exact experimental procedure still widely varies between the authors, especially regarding the time lengths of the measuring sequences, ranging from 7s [3] to 50 s [2], as well as the length of initial practicing trials.

For the planning of a reliable experimental procedure it was thus of great importance to study the learning effects as determined from the temporal behavior of CoP movements.

METHODS

For our purpose a simple rocker type of a balance board was chosen which allowed only one degree of movement. It consisted of a sitting platform mounted on two wooden rockers that were parallel to each other and parallel to the board's length. The rockers were semicircular with the radius of 18 cm thus allowing unstable medio-lateral movements of the sitting person. Rocker board was placed on a force platform which was positioned at the edge of a firm support 60 cm above the ground.

After they were seated on the board the participants were asked to put their hands on the thighs and the CoP recording was immediately started for one minute. The participants were instructed to maintain their balance while sitting. For each participant the same procedure was repeated five times with standing up and immediately followed by sitting down between the trials.

Fifteen healthy young persons participated in this study, 11 females and 4 males, aged 20.3 ± 1.9 years, with body mass of 70.81 ± 3.9 kg and height 172.6 ± 7.5 cm. They had no previous experience with sitting on balance boards.

Force platform Kistler 9286AA (Winterthur, Switzerland) with the corresponding data acquisition software served to assess the CoP movement during unstable sitting using 200 Hz sampling rate. The analyses of the acquired data were performed on a Linux server (Fedora 24) with a specially developed software [4].

RESULTS AND DISCUSSION

All participants managed to complete the sitting sessions without touching the supporting surface. The medio-lateral CoP path lengths (Figure 1) were analyzed using one-way repeated measures ANOVA. The comparison of the five consecutive measurements showed that at least two group means were statistically significantly different from each other ($F = 8.36$, $p < 0.001$). Post hoc test identified pairwise difference between the first and last three measurements ($p < 0.1$) and no statistical significant difference between the last three measurements ($p > 0.78$). These results indicate that persons adjust to sitting on the rocker board within first 60 to 120 seconds. Once the process of adjustment to a new postural experience is completed, the CoP movements become comparable (the third to fifth consecutive measurements).

To get additional information about the first two trials they were further divided into 20 s intervals. It was found that the CoP path lengths of only the last one differed from the previous ones ($F = 6.44$, $p = 0.006$). These results indicate that the first 100 s of rocker board sitting is dominated by learning effects and reflect the ability of initial postural stabilization while the rest is mainly related to the maintenance of sitting balance.

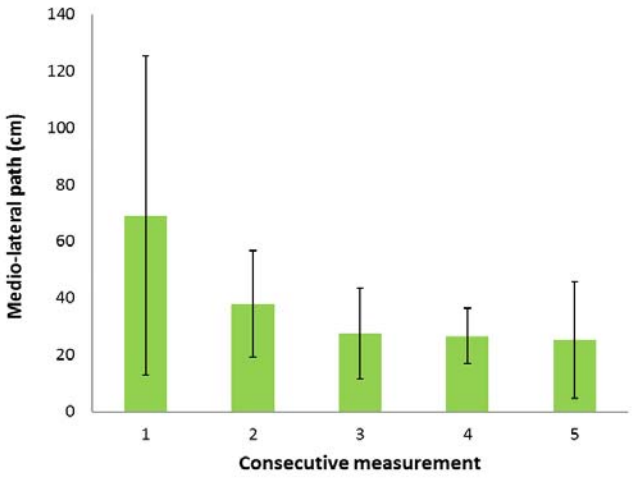

Figure 1: Average medio-lateral CoP path lengths for five consecutive 60 s measurements with standard errors.

CONCLUSIONS

At least 60 s, or even better 120 s, practice session of rocker board sitting is required prior to attain steady state results. Further research is needed to more precisely differentiate temporal effects.

P316 - THE IMMEDIATE INFLUENCE OF MANUAL MOBILIZATION OF ANKLE AND FOOT ON POSTURAL SWAY OF ELDERLY WOMEN

Darja Rugelj, Katarina Jenko and Urška Puh
University of Ljubljana, Faculty of Health Sciences
Corresponding author email: darja.rugelj@zf.uni-lj.si

INTRODUCTION

Manual mobilization of ankle and foot has been shown to influence proprioception [1], one of the important components of postural stability. However, there is a limited number of research investigating the role of manual mobilization techniques of feet and ankles on postural sway of elderly persons, and their results are inconclusive. In general, increased postural stability was often reported in more demanding conditions such as with eyes closed [2,3]. Therefore, the purpose of our study was to systematically investigate the immediate effect of manual mobilization of ankle and foot joints on postural sway of elderly community dwelling women in four sensory conditions. Additionally, the purpose was to define the sample size for a randomized controlled trial (RCT).

METHODS

Participants: 20 elderly women participated in the study (age 68.3 ± 6.2 years, BMI 26 ± 3.9).
Procedure: Mobilization of the foot included gliding of big toe, metatarsal, tarsal and talocrural joints and lasted for 5 minutes on each leg. A modified sensory interaction test (mSIT) on force platform was used to quantify postural sway in four sensory conditions [4]. The sequences of the trials were randomized, by using random blocks. The main outcome measures were mean velocity and medio-lateral sway of the center of pressure (CoP). Participants stood 60 seconds on a force platform (Kistler Winterthur, Switzerland), on a hard and compliant surface with their eyes open and closed. For the compliant surface a 40 x 60 x 6 cm Airex® mat was positioned on the force platform. All the analyses of CoP time series were performed with specially developed software [5]. The G*Power software [6] was used for sample size calculation.

RESULTS AND DISCUSSION

A 4 x 2 (sensory condition x pre/post treatment) repeated measure ANOVA was calculated comparing the sway velocity and medio-lateral sway of CoP. A significant main effect for the sensory condition was found indicating that there is an effect of sensory condition on the postural sway velocity and medio-lateral sway (F = 147.17, p < 0.001, and F = 138.22, p < 0.002) respectively. A significant main effect for the pre and post treatment condition was also found (F = 28.69, p < 0.001 and F = 19.84, p < 0.001 respectively), indicating an effect of treatment on postural sway. The interaction, however, was not significant (F = 1.039, p = 0.378), indicating that the effect of mobilization is significant in all test conditions and is not dependent on sensory condition. Detailed results are presented in Table 1.

The calculated sample size for the two postural sway variables for the 80 % power is 41 participants in opened eyes conditions and 58 participants in closed eyes conditions in both groups.

CONCLUSIONS

The results indicate that the immediate effect of manual mobilization of ankle and foot joints significantly decreased postural sway and was more pronounced in more demanding conditions, such as standing on a compliant surface. This results support the hypothesis that manual mobilization influences the joint position sense and thereby enhances peripheral mechanisms of postural control. To be able to generalize this observation a RCT with at least 58 participants is needed.

P317 - A SENSORIZED SMART SHOE FOR ESTIMATING FOOT PROGRESSION ANGLE WHILE WALKING

[1] Haisheng Xia, [1] Junkai Xu, [1] Jianren Wang, [2] Michael A. Hunt, [1] **Peter B. Shull**
[1]Shanghai Jiao Tong University
[2]University of British Columbia
Corresponding author email: pshull@sjtu.edu.cn

INTRODUCTION

Altering the foot progression angle during the stance phase of gait has been shown to reduce knee loading and pain for individuals with knee osteoarthritis in laboratory studies using motion capture systems [1,2]. To enable widespread benefits of gait retraining in practical applications, a portable solution is needed to accurately estimate foot progression angle outside the laboratory. The purpose of this paper is to present a customized smart shoe for estimating foot progression angle during walking for normal, toe-in, and toe-out gait patterns.

METHODS

A. Smart shoe design

An electronic module was inserted into the sole of a standard walking shoe (M18972, LZBU) (Figure1, top) and is composed of: microcontroller (STM32, STMicroelectronics), 3-axis accelerometer, 3-axis gyroscope and 3-axis magnetometer (MPU9150, Invensense), microSD card (microSDHC Class4, Transcend), 1000 mAh lithium-ion battery, and wireless charging receiver (Qi, WPC). The smart shoe charges wirelessly, the battery lasts 16 hours between charges, and 160 hours of continuous data can be stored on an 8GB microSD card. A foot progression angle algorithm [3] was programmed onto the electronic module to enable continuous foot progression angle measurements during walking while sampling at 100Hz.

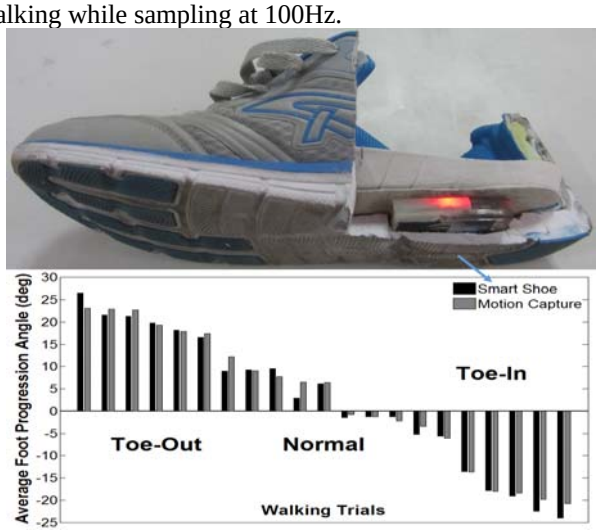

Figure 1: (top) Customized smart shoe made by inserting an electronic module in the sole of a standard walking shoe. (bottom) Average foot progression angle estimation from the smart shoe and motion capture system for all subjects for all walking conditions. Overall average absolute estimation error was 1.50±1.07deg.

B. Experimental validation

Seven participants (7 male, age 25.3±2.8 years, height 1.73±0.08m, mass 65.2±10.6kg, foot size 42.3±1.3EUR) participated in a treadmill walking trials. Raw sensor data from the smart shoe and motion capture data (Vicon, Oxford, UK) were both collected simultaneously at 100Hz as subjects walked on a treadmill (Bertec, Ohio, USA). Reflective markers were placed on the head of the second metatarsal and the calcaneous, and the difference between the line between these markers and the direction of forward progress was defined as the foot progression angle [2]. Participants performed three 2-minute walking trials (self-selected toe-in, normal and self-selected toe-out) in random order at a self-selected walking speed. One-way ANOVA was used to determine if there was any difference in absolute errors of foot progression angle estimation based on three different walking conditions ($p=0.05$).

RESULTS AND DISCUSSION

Average foot progression angle estimations from the smart shoe closely followed motion capture estimations for all subjects under all walking conditions (Figure 1, bottom). There were no significant differences in foot progression angle accuracy based on study condition ($p=0.75$).

Results demonstrated that the smart shoe accurately measured foot progression angle as compared to the "gold standard" motion capture system for all participants under all walking conditions. One limitation of this study is that we only tested healthy participants with normal gait patterns, thus the accuracy of the smart shoe for movement disorders involving abnormal gaits like foot drag or indistinct heel strikes remain unknown. Also, walking trials were only performed at subjects' self-selected speeds, thus it is possible that accuracy results could differ for significantly slower walking or faster walking and running gaits. More research is needed to explore smart shoe accuracy for different gait speeds and abnormal gait patterns.

CONCLUSIONS

This abstract presents a smart shoe for estimating foot progression angle, which could potentially be used for knee osteoarthritis or other clinical applications requiring foot progression angle assessment in daily life or in clinics without specialized motion capture equipment. Future versions of the smart shoe could potentially add feedback functionality through a wireless connected smart phone or embedded vibration devices in the shoe for real-time gait retraining to enable individuals to modify their gait outside of traditional laboratory settings.

P318 - CHILDREN WITH CP CAN IMPROVE KEY GAIT PARAMETERS WITH REAL TIME FEEDBACK

[1,2] **Adam T.C. Booth**, [2] Frans Steenbrink, [1]Annemeike I. Buizer, [1]Jaap Harlaar and [1]Marjolein M. van der Krogt

INTRODUCTION

Children with cerebral palsy often have limited walking ability and this is considered a key target of rehabilitation. While surgical intervention may improve gait, the extent of motor plasticity in children with CP is considered to be limited [1]. However, children with CP show the ability to adapt and improve hip and knee extension when challenged with real-time feedback during walking [2].

Virtual reality (VR) presents a promising platform for development of engaging and immersive rehabilitation, particularly for children, where interactive environments can maintain attention over a longer period. The GRAIL (Motekforce Link, Amsterdam) consists of an instrumented dual-belt treadmill, motion capture and VR screen. Gait parameters from biomechanical analysis can be calculated in real-time and displayed to the subject in VR. With the visualization of real-time feedback on gait performance, patients may be challenged to improve a range of key parameters such as knee extension, ankle power generation and step length.

The potential for training benefits of feedback are perhaps more apparent, however, it may also be a tool for advanced gait analysis through testing hypotheses of an individual's gait aetiology. Comfortable walking may allow for compensations that mask the gait limitation. By challenging specific aspects of gait, with feedback, the strategy used to reach the goal may highlight the gait limitation.

The aim of this research is to further explore the use of real-time feedback in children with CP to improve gait training and analysis.

METHODS

An real-time feedback game was developed for the GRAIL (Motekforce Link, Amsterdam). Gait was visualized by an avatar and allowed for feedback on a range of gait parameters often affected in CP (Fig. 1). Nine children with CP (Age: 10.5±3.3yrs/GMFCS: I-II) were included in an ongoing study. Baseline gait (BG) was initially measured and used to tailor feedback targets to an individual's ability. Targets were then adapted throughout feedback trials to maintain engagement. Three trials were then carried out with feedback on a single parameter; knee extension (KEFbk), ankle power (APFbk) and a further patient specific parameter (step length/pelvis tilt/foot progression).

Fig. 1. GRAIL with VR environment with step length feedback.

RESULTS AND DISCUSSION

With feedback on knee extension, children were able to reach clinically important [3] and significant improvements in peak knee extension around initial contact of 8° (BG:30.0±11.9°, KEFbk:22.0±12.0°, p=0.005, Fig. 2) . In response to feedback on ankle power, peak ankle power at push off increased significantly by 54.5% (BG:0.75±0.34 N/m^2, APFbk: 1.20±0.64 N/m^2, p=0.003). With patient specific feedback, improvements were found in 5° reduced anterior tilt, step length increased 10.8% and a modest improvement of foot progression during stance (2.4° reduced out-toeing).

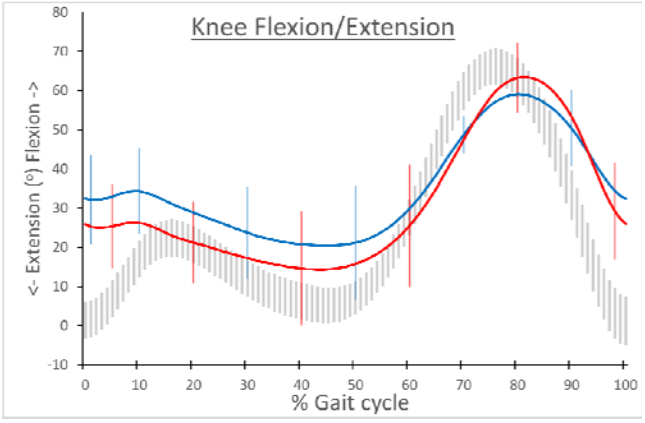

Fig. 2. Group mean knee flexion/extension during BG (blue) compared to KEFbk (red), vertical bars show SD. (Shaded: typically developing children ±SD)

CONCLUSIONS

This study demonstrates the potential for real-time feedback during treadmill walking to drive clinically relevant improvements of a range of key gait parameters in children with CP. This short term adaptability suggests some motor plasticity may be retained in children with CP. Future research should investigate if this improvement can persist to over ground walking with a feedback enhanced gait training programme. Additionally, patient specific compensations that may have clinical diagnostic importance were observed during some trials.

P319 - LONG-TERM ADAPTIONS DURING GAIT AFTER ACL RECONSTRUCTION: THE EFFECT OF SPEED

[1]**Karine Josibel Velasques Stoelben**, [2]Evangelos Pappas, [3]Mateus Correa Silveira and [1]Carlos Bolli Mota
[1]Federal University of Santa Maria
[2]Unversity of Sydney
[3] Federal University of Paraná

INTRODUCTION

Several studies have demonstrated that after anterior cruciate ligament (ACL) reconstruction gait deficits persist more than 3 years after surgery [1-3]. Reconstructed knee showed lower flexion [4] and extension [4,5] moment than healthy knee, lower flexion [5], adduction [2,5] and external rotation [5] moment than individuals without lesion.

However, it is unclear if joint moments are affected by gait speed differently in ACL reconstruction individuals. The purpose of this study was to compare peak joint moments of all lower limb joints in two gait speeds between a control group and a group of participants who had ACL reconstruction more than 4 years ago.

METHODS

Twenty-four men between 30 and 45 years old took part in the study. Twelve of them had ACL reconstruction between four and eight years ago (ACLG) and twelve men did not have any lesion in lower limbs (CG). Participants were asked to walk on a 10m walkway at two different velocity conditions: their preferred walking speed and 30% faster than the preferred speed.

Six infrared cameras (VICON system) captured the motion of 16 markers (PlugInGait Model) attached to body landmarks with acquisition frequency set at 200 Hz. Two force plates (AMTI) recorded the kinetic data at 1000 Hz sampling rate. Kinematic and kinetic data were filtered by a 4th order Butterworth low pass filter, with cut-off frequency of 6 Hz. Walking speed was monitored during the data collection using two photocells positioned six meters apart but also assessed by tracking the average velocity of a hip marker.

Three successful trials (total landing of the foot upon the force plate and gait velocity within 5% of target) for each condition were used in the analysis. Joint moments were calculated with inverse dynamics equations of motion (NEXUS 1.8.5, VICON) and were normalized to body weight. Two peaks (1st and 2nd half of stance) that characterized the maxima of each of the three moment components (adduction/abduction, flexion/extension, external/internal rotation moments) were analyzed for all lower limb joints.

Descriptive statistics (mean and SD) were produced for all peak moment. The data were inspected and tested to ensure that the assumptions for data sphericity were not violated. One repeated-measures MANOVA procedure was conducted for each joint, to determine the effects of the independent variables (leg, gait speed and group) on the dependent variables (peak moments in all planes for the hip, knee and ankle joints). ANOVA tests were performed if the MANOVA reached statistical significance ($p \leq 0.05$) to identify the significant kinetic variables. The α level was set a priori at 0.05.

RESULTS AND DISCUSSION

The MANOVA was statistically significant for the effect of speed for knee ($p = 0.023$) and hip ($p \leq 0.001$). Univariate repeated-measures ANOVA tests were performed for speed. They revealed that gait speed had a significant effect in the ACLG on flexion, extension and abduction in knee ($p \leq 0{,}004$), and flexion, extension, adduction, external and internal rotation in hip ($p \leq 0.016$); in the CG on flexion, extension, adduction and external rotation in hip ($p \leq 0.029$). All variables were greater in fast speed.

ACLG showed gait patterns different than CG when gait speed increased, suggesting different joint compensation. Kuenze et al. [3] found exercise-related adaptations in hip and knee biomechanics different in individuals with a history ACLR when compared with healthy controls despite a return to recreational activity, suggesting one potential source of elevated knee injury risk and reduced long-term knee joint health after ACLR.

Patients after ACL reconstruction present greater risk of re-injury, increase of cartilage degeneration, affecting athletic activities [6]. Elevated joint moment during tasks can be contributor for this evolution [7]. In this study, while CG showed difference only in hip, ACLG showed difference in knee and hip when speed was increased. This can be a possible responsible for the degeneration process.

CONCLUSIONS

The ACL reconstruction generates different long-term gait patterns when the speed is increased than healthy individuals, suggesting protection mechanism.

INTRODUCTION

The measurement of human kinematics is fundamental in rehabilitation, training, and injury prevention. Inertial Measurement Units (IMUs) are a promising and less resource-demanding alternative to stereophotogrammetry motion capture systems. However, their use is still limited because of the inaccuracies in the estimation of joint angles. A possible source of error is the use of simplified anatomical models that do not correctly reflect the real kinematics of human joints. Also, orientations calculated from IMUs are often directly applied to the model segments in a direct kinematics fashion [1], which can be susceptible to noise and errors in IMU placement and registration. Alternatively, inverse kinematics (IK) algorithms use a global optimization to estimate joint angles and overcome the major limitations of direct kinematics [2]. However, IK is commonly used to track the three-dimensional (3D) position of markers [2], and its potential in tracking 3D orientations from IMUs to estimate human kinematics is largely unexplored.

OpenSim [3] is a popular open-source software for biomechanical analysis that permits using realistic representations of joint kinematics and personalized musculoskeletal anatomy [4]. This study is (1) developing an OpenSim plugin to estimate joint angles in the lower limbs by solving IK from 3D orientation provided from IMUs, and (2) evaluating the proposed method by comparing orientation-based and marker-based IK estimates of joint angles during gait in the lower limbs.

METHODS

A single healthy subject was recruited for this study. Eight IMUs (Noraxon, Scottsdale, AZ, US) were placed each on a single body segment (thorax, pelvis, thighs, shanks, and feet). Reflective markers were placed on the subject's bony landmarks and rigid clusters of 3 markers were attached to each IMU. A 12-camera motion capture system (Vicon, Oxford, UK) was used to collect marker trajectories through Vicon Nexus (v. 2.3), while IMU orientations were acquired through Noraxon myoRESEARCH (v. 3.8) software and exported as quaternions. Marker and IMU data were synchronously collected via a common trigger signal, and sampled at 200Hz and 100Hz, respectively.

The standard OpenSim *gait2392* model was scaled to match subject's anthropometry using bony landmark markers from a static pose trial. Position and orientation of IMUs were registered to the model using the data from the marker clusters. IMU orientation-based IK [5] was implemented in an OpenSim plugin in which a global optimization calculates joint angles minimizing errors between experimental IMUs and virtual IMUs placed on OpenSim model.

Hip and knee flexion-extension, and ankle plantar-dorsiflexion angles were estimated for seven gait cycles using both IMU orientation-based and marker-based IK and then time normalized to the gait cycle. Root Mean Squared Error (RMSE) and coefficient of determination (R^2) were used to compare the results. Averages and standard deviation (SD) were reported in a plot as time-series.

RESULTS AND DISCUSSION

Sagittal plane joint angle estimates from IMU orientation-based and marker-based IK showed good agreement (Figure 1), with RMSE±SD of 4.34±0.56 deg for hip, 6.18±1.62 deg for knee, and 4.29±1.11 deg for ankle; and with R^2±SD of 0.93±0.03 for both hip and knee, and 0.75±0.08 for the ankle. Further investigations are required to assess the IMU orientation-based IK in other planes of motion and during different tasks. Also, more care in avoiding magnetic interference during data collection (i.e. force platforms) will potentially improve the quality of the results.

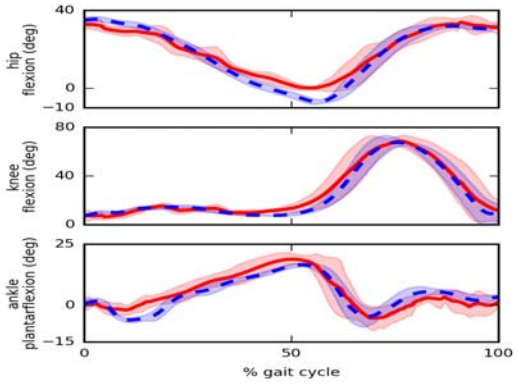

Figure 1: Joint angles: marker-based IK (blue) and IMU orientation-based IK (red) averages. Standard deviations are shown as shaded bands.

CONCLUSIONS

During gait, sagittal plane joint angles estimated via the IMU orientation-based IK OpenSim plugin closely matched results from marker-based IK. While further validation is needed, these results could lead to exciting and innovative out-of-the-laboratory applications.

P321 - SIMULTANEOUS WIRELESS MEASUREMENT OF LOWER LIMB MUSCLE ACTIVIES AND GAIT KINEMATICS USING EMG TELEMETER WITH H-GAIT SYSTEM

[1]**Ryo Takeda**, [1] Yoshihiro Seki, [1]Masahiro Todoh, [2]Masahide Harada, [1]Harukazu Tohyama and [3]Shigeru Tadano

INTRODUCTION

Gait analysis is a widely used clinical tool for quantifying human walking ability. Recently, the authors have developed a wireless three-dimensional gait analysis system using wearable inertial sensors based on quaternion calculations (H-Gait, Hokkaido University) [1]. This system proved useful in clinical situations where it was capable of quantifying differences in various spatio-temporal parameters of normal and pathological gait [2]. However, the physiological causes for these differences were not fully explored.

EMG is a popular method for recording the electrical activity of skeletal muscles during human motion. Since walking motion relies on the selective timing and intensity of appropriate muscles of the lower limb at various phases within a gait cycle, EMG can be used to associate muscle activity to gait parameters. However conventional methods using EMG and gait analysis systems were limited to short walking distances and few number of EMG electrodes due to the usage of camera based motion analysis and wired EMG setups. Thus, measurement in everyday environments proved difficult.

As a solution this problem, the current study combined the previously mentioned wireless gait analysis system and a wireless multi-channel surface EMG telemeter system. The objective of this work is to propose a novel system capable of simultaneous measurements of gait analysis and EMG to associate muscle activity timings and intensity to lower limb postures during various phases of a gait cycle.

METHODS

Three healthy volunteers were recruited for this study. Seven H-Gait sensors were attached to seven lower limb body segments (pelvis, both thighs, both shanks and both feet) (Figure 1: S1-S7). The EMG telemeter bipolar surface electrodes were attached to seven muscles of the lower legs (gastrocnemius lateralis (GL), gastrocnemius medialis (GM), biceps femoris (BF), semitendinosus (Sem), vastus lateralis (VL), vastus medialis (VM) and rectus femoris(RF)), the ground(GND) was attached to the patella (Figure 1).

The acceleration and angular velocity data of each sensor were measured at a sampling rate of 100Hz, while the EMG of the seven muscles were measured at 1000Hz during level walking. Three-dimensional kinematic parameters of the volunteers were obtained from the H-Gait system and heel contact timings were used to divide the measurement data into gait cycles[1,2]. Synchronization of the H-Gait system and EMG telemeter in the time domain was achieved via electrical triggers at the start and end of the swing phase.

RESULTS AND DISCUSSION

The activity of the seven muscles during a gait cycle of a volunteer are shown in Figure 2. BF and Sem were active at the initial stance phase. VL, VM and RF were active at the mid-stance phase. GL and GM were active during toe off.

CONCLUSION

The results proved that the proposed system was capable of associating timing and intensity of clinically relevant muscles activity to lower limb postures at various phases within a gait cycle. The findings of this study were as follows: BF and Sem function to stabilize posture during early stance, while VL, VM and RF resist body weight in mid-stance. This method has the potential of assessing muscle activity differences to pathological gait abnormalities and also evaluate the risk of fall during specific gait phases.

Figure 1: EMG electrode and sensor attachment locations.

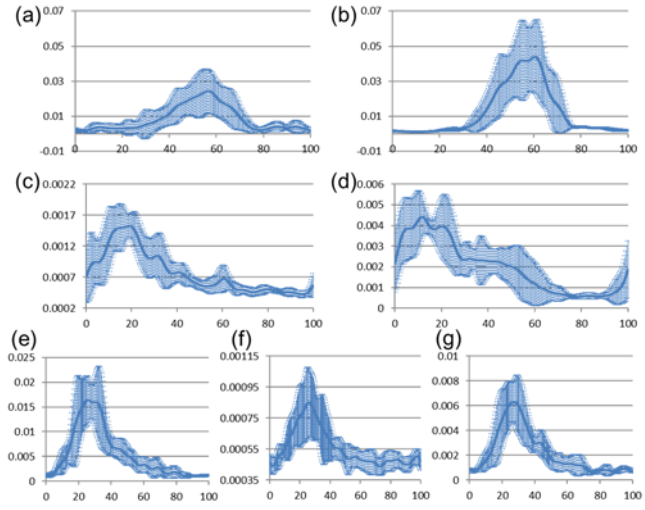

Figure 2: Surface EMG normalized into 1 gait cycle. (a)GL, (b)GM, (c)BF, (d)Sem, (e)VL, (f)VM and (g)RF.

P322 - THE STABILITY OF THE LOWER LIMBS DURING STEPPING MOTINON

Hai-peng Tang[1], Shintaro Toyoshima[1] and Xiu Deng[2]

School of Education and Welfare, Aichi Prefecture University, Nagakute, Japan[1]

School of Human Science and Environment, University of Hyogo, Hyogo, Japan[2]

INTRODUCTION

Variability always exists during human movement, therefore it is difficult to repeat the same movement exactly each time. Such variability can be observed not only in the inexperienced movement, but also in the reaching movement performed by arms, as well as in the locomotion of walking or running performed by the lower limbs. Such kind of variability in movement is regarded to be the stability of motion. The improvement of stability had a great influence over the locomotion of the lower limbs both in daily life and in sport activities. Up to now, there has been a large body of literature related to spatial stability, but only a few reports have focused on time stability in the lower limbs during dynamic tasks. The purpose of this study is to evaluate the time stability and spatial stability of the lower limbs during steeping motions, and the influences on these two stabilities were analyzed and compared by groups of sex, age as well as muscle strength.

METHODS

The motion stability test was conducted by examining 82 subjects ranging from teenagers to the elderly, both male and female. In order to evaluate the influence on motion stability by the process of aging, a wide range of age groups of subjects was assessed. The test was conducted in stepping motion in place with the highest speed for 15 seconds. Since the elderly were included in the test subjects, instead of fast running, a safer way of stepping motion was used. Each subject was videotaped with a video camera operating at 60Hz set about 10m in front. The stability of time and the stability of space were evaluated by the change of coefficient of variation of the knee joint during the stepping motion. The time coefficient of variations (TCV) was calculated on the ratio of the standard deviation to the mean time of the knee joint reached at each step. The TCV was compared with the DCV (The distance coefficient of variations) that reported by Tang et al.

RESULTS AND DISCUSSION

Compared with youth and middle-aged groups, the TCV appeared bigger in teenager and the elderly groups for both male and female. On the other hand, no significant differences could be observed in all male and female in all age groups. The results also indicated that significant differences of TCV could be not be observed relating to muscle strength both in males and female. The means of TCV of male group appeared bigger in significance difference in female groups , which proved that sexual differences exist between male and female groups.

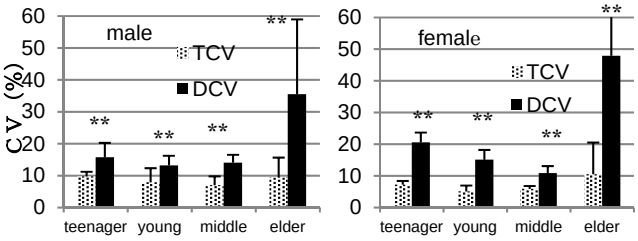

Figure 1: Corporation of the TCV and DCV

From Figure 1, the value of DCV was bigger than the TCV. For the teenager group, its value appears to be three times bigger than the middle-aged group, and about four times bigger than the elderly group. Furthermore, significant differences were recognized in all age groups.

This study proved that changes of muscle strength have no influences on the time stability, and the superiority of time stability is obvious in high-speed motion. From the results, among all the different age groups both for male and female, no any significant differences could be observed in time stability, it means, the time stability kept unchanged in spite of different ages and sexes. In contrast according to Tang el al［1］ report, the spatial stability declined together with the decline of the body functions due to aging. There have also been a lot of studies about the big influences in body movement of muscular strength. Consequently, the study suggested that in order to prevent the loss of body balance in movements, the human body system prefers to keep time stability than to keep spatial stability which appears to be less important in keeping body balance.

CONCLUSION

The study result showed that the muscle strength and body decline due to aging have little influence on the time element. That is to say the time element kept to be more consistent than spatial element in movement. Such phenomenon of spatial stability and time stability can be regarded as one of the important basic characteristics of human physical movement.

P323 - ECONOMY, BIOMECHANICS AND PERFORMANCE IN FEMALE MIDDLE-DISTANCE RUNNERS

[1] **Danielle Trowell**, [1]Elissa Phillips and [2]Jason Bonacci
[1] Movement Science, Australian Institute of Sport, Australia
2 School of Exercise and Nutrition Sciences, Deakin University, Australia
Corresponding author email: Danielle.Trowell@ausport.gov.au

INTRODUCTION

In track and field, 'middle-distance' events include races that cover between 800m and 3000m. Despite established research on long-distance runners (>10km) and male-only athletes [1-3], there is a dearth of knowledge related to the running technique of female middle-distance runners. Even fewer studies have investigated how specific kinematics and kinetics interact with economy and performance among this cohort. To improve current training programs among middle-distance runners there is a need to enhance our understanding of the biomechanical factors associated with superior performance. For developing athletes, the identification of representative or efficient movement patterns could be used to guide technique training. At a more competitive level, identifying differences in running mechanics among varying levels of runners may provide an opportunity for additional performance improvements once the rate of physiological adaptations begin to plateau. Therefore, this study aimed to identify movement patterns most related to performance and economy among trained female middle-distance runners.

METHODS

Nine female middle-distance runners participated in this study (age: 21 $\pm$ 3 years, body mass: 53.3 $\pm$ 4.1 kg, height: 167 $\pm$ 0.03 cm). Biomechanical data were collected using a VICON motion analysis system (Oxford Metrics Ltd, Oxford, UK) and in-ground Kistler force plates (Kistler, Winterthur, Switzerland). Athletes completed trials at a representative race pace (6.84 $\pm$ 0.65 $m \cdot s^{-1}$) and speed effects were controlled for. This data was then compared in relation to athletes 1500m race time (4:23.31 $\pm$ 9.65 min), as well as their running economy. Running economy was determined by measuring submaximal VO_2submax at 16km/h, using a customized, indirect calorimetric system and motorized treadmill. Sixty-four kinematic and kinetic variables occurring in the sagittal plane were included in the analysis. A paired-samples t-test ($p > 0.05$) was used to establish gait symmetry; and the right side was used for further analysis. A Partial Least Squares Regression was used to reduce data down to a subset of variables with the best predictive power for race time or running economy. Variable subsets were analyzed using multiple regression to determine the strength and predictive power of each model.

RESULTS AND DISCUSSION

The results of this study showed that running economy measured at 16km/h on a treadmill cannot predict 1500m race performance among our sample of trained female middle-distance runners ($R^2 < 0.00$, $p = 0.97$). Consequently, no biomechanical variables could mutually predict both 1500m performance and running economy. This unexpected finding may be a negative outcome of using running economy to measure middle-distance runners' overall efficiency, since middle-distance runners depend on unique contributions from the aerobic and anaerobic energy systems during racing [3]. Alternatively, athletes may not have run a race time that was a true indication of their physiological capacity in a time frame close enough to the physiology testing session. Consequently, their running economy was associated with a slower race time.

Similarly, no individual variable or linear combination of variables could account for the variation in female performance when significance was set at $p < 0.05$. In contrast, a range of individual variables demonstrated significant relationships with running economy. More economical runners demonstrated a larger plantarflexion ankle angle during stance ($R^2 = 0.51$, $p = 0.07$) suggesting that efficient athletes tend to run with more of a forefoot strike than a neutral foot strike. This is in agreeance with past research [4], and may improve efficiency by facilitating the ankle joints ability to absorb, store and return elastic energy. Economical runners also had a slower flexion velocity of the hip during swing ($R^2 = 0.67$, $p = 0.03$) and flexed their knee less during swing ($R^2 = 0.75$, $p = 0.01$). This may suggest that these runners minimize unnecessary concentric movements in the sagittal plane following toe-off, thus lowering the energy required to bring the leg forward in preparation for ground contact. Finally, more economical runners also had a smaller total range of thorax motion ($R^2 = 0.65$, $p = 0.03$), which is in contrast with past research [1]. It appears that reducing excessive movements in the sagittal plane may play a role in reducing the energy demand during running.

A range of nonsignificant trends were also identified in this study, which may be the consequence of our small sample size. Future research is needed to investigate these trends and their potential impact.

CONCLUSIONS

The results of this study provide the first substantial evidence for the relationship between running mechanics and economy among female middle-distance runners. Future research should aim to address the limitations in this studies design to determine if nonsignificant trends represent a legitimate relationship with female performance and/or economy.

P324 - FRACTAL DYNAMICS OF HUMAN GAIT ARE RELATED TO PROPERTIES OF KNEE EXTENSION MUSCLE IN OLDER ADULTS

[1] **Naomi Tsugita**, [2] Yuya Watanabe, [1] Emi Yamagata, [3] Misaka Kimura, [4] Motoki Kouzaki and [1] Yasuko Okayama

INTRODUCTION

The gait rhythm is generated by the function of the central nervous system and is included the fractal fluctuations. Age-related changes in fractal fluctuations in stride time interval will cause instable gait. Since the gait stability is established by mutual cooperation between the musculoskeletal and the central nerve function, these two factors need to be evaluated together.

The purpose of this study was to examine the relationship between the fractal fluctuations of stride interval and both quantity and quality of the quadriceps muscle.

METHODS

The subjects were 18 healthy older women with regular exercise habits (Mean age 72.5 ± 5.6 years) (Table 1). Subjects were instructed to walk continuously on level ground at their self-determined usual pace for 4 min. Foot switches were taped beneath both shoes to measure the stride interval. The data from sensors was recorded at 1000 Hz on a data logger fixed on the waist with a belt. To evaluate the gait rhythm, the fractal fluctuations was evaluated using the scaling index (α) as calculated with detrended fluctuation analysis method for stride time interval. The α value closer to 0.5 represents a complete randomness (white noise) of the gait rhythm. Long-range correlation is presented when α value is between 0.5 and 1.0 [1]. To minimize any start-up effects, we removed the first 10-stride of all subject's time series.

Transverse images of the anterior compartment of the right thigh were obtained with a B-mode ultrasound imaging device. An electric caliper was used to evaluate the muscle thickness (MT) of the anterior compartment of the thigh on the resultant transverse ultrasound images. MT was defined as the sum of the thickness of the rectus femoris muscle and the vastus intermedius muscle. Echo intensity (EI), defined as the mean pixel intensity in the muscle, of the rectus femoris muscle was assessed from the ultrasound images. The value for EI was determined by gray scale analysis using the standard histogram function. Higher EI values are considered to reflect higher proportions of non-contractile elements (e.g., fat and connective tissue) in the muscle [2].

Table 1: Summary of the results.

N=18

	Mean ± SD	Range
Height (cm)	151.5 ± 6.6	134.5 - 163.5
Weight (kg)	53.9 ± 7.8	38.5 - 67.0
BMI	23.5 ± 3.0	18.6 - 30.6
Muscle thickness (cm)	4.41 ± 0.36	3.82 - 5.09
Echo intensity	25.95 ± 4.48	17.73 - 33.0
Stride time (msec)	970.1 ± 59.3	884.9 - 1126.6
Fractal index (α)	0.66 ± 0.34	0.07 - 1.29

RESULTS AND DISCUSSION

The scaling index (α) of stride time interval during gait widely ranged from 0.07 to 1.29, indicating that individual variability of α is large for older adults. The relationships between α and MT, and EI across all subjects were shown in Figure 1. There was no significant correlation between α and MT (p>0.05, left panel), whereas a significant negative correlation was found between α and EI (r=-0.618, p<0.01, right panel). The finding that fractal fluctuations during gait were not correlated with MT suggests that muscle quantity does not contribute to gait rhythm in older adults. However, the finding that fractal fluctuations during gait were negatively correlated with EI, which is a measure of muscle quality, suggests that high quality muscle contributes to a stable gait in older adults. Thus, interventions aimed at improving muscle composition may assist in maintaining gait stability in older persons.

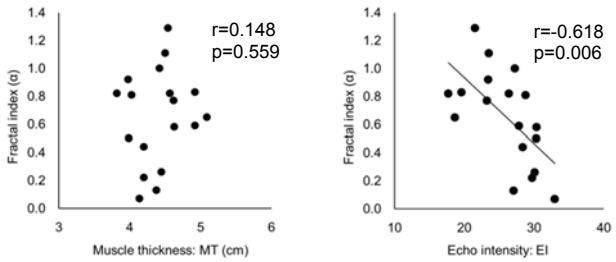

Figure 1: Relationship between α and MT (left), EI (right) in older adults.

CONCLUSIONS

In conclusion, fractal fluctuations in gait were not correlated with MT but with EI of the quadriceps muscle in older adults. These findings suggest that gait stability for older adults is related not to muscle quantity but to muscle quality.

P326 - ALTERED INTEGRATION OF PROPRIOCEPTIVE INFORMATION FOR BALANCE CONTROL IS ASSOCIATED WITH PROSPECTIVE FALLS

INTRODUCTION

Control of standing requires feedback from a variety of sources including the visual, vestibular and proprioceptive systems. To control balance, sensory information is dynamically weighted and interpreted against an internal upright reference [1]. Ageing is associated with diminished somatosensory functioning and elderly take longer to adapt in changing sensory conditions [2]. Both would affect balance control and increase falls risk.

Vibration of postural muscles is a potent stimulus (perturbation) of proprioception, resulting in an illusion of muscle lengthening [3], and posture is adapted to counteract illusory movement depending on the weight assigned to proprioception [4]. In an optimally functioning system the unreliable postural information from proprioception during and after vibration (post vibration effects) would lead to reduced weighting of distorted proprioceptive input to maintain balance.

We hypothesized that elderly may have two changes in proprioceptive function; reduced sensitivity and reduced capacity for reweighting. In comparison to young individuals, this would present as both lesser response to vibration to the ankle or lumbar muscles, and poorer quality of balance control during the period after vibration in elderly individuals. We further hypothesized that these differences between elderly and young would be emphasized more in individuals who go on to fall than those who do not

METHODS

Twenty-one young (21(2) years), and 106 elderly (78(16) years) people volunteered to participate. Elderly were followed for 1 year to assess falls incidence. Forty-four elderly reported 1 or more falls (fallers), and 62 reported no falls (non-fallers). Analysis was focused on AP movement.

Participants stood barefoot, blindfolded on a force plate for 135s. Vibrators (60Hz, 1mm) attached to triceps surae or lumbar erector spinae were activated twice for 15s, after 15s and 75s (45s for recovery). Center of pressure (CoP) excursion was assessed at baseline (15s) and during vibration (15s). A 1-s sliding window (15s) was used post vibration to assess recovery.

Recurrence Quantification analysis (RQA [6]) assessed the deterministic (DET) and laminar (LAM) structure of CoP. Higher laminarity relates to balance states that do not change, or change little over time. Entropic half-life [6] assessed temporal correlations of CoP in each 15-s window. Differences between groups were assessed using wavelet based one-way ANOVA. Relative proprioceptive weighting was expressed as amount of CoP displacement during vibration (compared to baseline) relative to the summed CoP displacement during ankle and lumbar vibrations.

RESULTS AND DISCUSSION

At baseline (first 15-s before vibration), compared to the elderly, the CoP of the young was more deterministic and laminar, and Entropic half-life was ~0.04s longer (more temporal correlation). Fallers and non-fallers were not significantly different at baseline.
CoP displacement due to ankle vibration was not different between groups. CoP in elderly moved less during lumbar vibration than young, i.e. young weighted lumbar proprioception more than elderly. Relative proprioceptive weighting between ankle and lumbar regions was not different between fallers and non-fallers ($P>0.05$).

Most differences between fallers and non-fallers were observed after the 2nd ankle vibration and after the 1st lumbar vibration; fallers exhibited lower DET (for 11 and 7 15-s windows after ankle and lumbar vibration, respectively) and lower LAM (for 7 and 9 15-s windows after ankle and lumbar vibration, respectively) than non-fallers. Young exhibited significantly higher DET and LAM, and significantly lower entropic half-life than elderly during these time windows. Taking the lower temporal correlations in consideration in elderly compared to young, lower DET could be interpreted as more disorderly balance control in elderly than young.

CONCLUSIONS

Fallers and non-fallers displaced CoP similarly with both ankle and lumbar vibrations suggesting that peripheral proprioceptive function was not different between these groups. Post vibration differences suggest that the reweighting of proprioceptive information was affected in elderly. In elderly compared to young, control was more random (lower DET), and observed lower LAM might be interpreted as balance control with a degraded sense of internal upright reference or lesser control about this internal reference. These differences between young an old are more emphasized in fallers than non-fallers post vibration.

P327 - HILBERT TRANSFORM AND GAIT ANALYSIS: A NEW METHOD TO EVALUATE GAIT VARIABILITY

[1]**Gustavo S. Souza**, [1]Georgia C. Lehnen, [1]Rina M. Magnani, [1]Fábio B. Rodrigues, [2]Adriano O. Andrade [1]Marcus F. Vieira

INTRODUCTION

Gait variability has been used to evaluate the ability to optimally control gait from one stride to the next [1]. Many studies tested gait variability under different conditions, such as different walk speeds or age groups [2], or to evaluate the impacts of impairments or diseases in human gait [3].

The aim of this study was to develop a new method focused on evaluating gait cycle variability using Hilbert Transform's property of easily creating a bi-dimensional space from a single time series.

METHODS

The proposed method was validated by comparing its results with a control method, by using a data set of a previous study concerning gait on inclined surfaces. The control method used was the one presented by Dingwell et al. [4]. This data set comprised 49 healthy young subjects (26 males and 24 females, 24.5±5.5 years old, 68.1±10.8 kg, 1.70±0.08 m). Reflective markers were attached to the heels, and spinous process of the first thoraric vertebrae (T1) of all subjects. The reflective markers were used for movement registration with a 3D motion capture system using ten infrared cameras operating at 100 Hz (Vicon Nexus, Oxford Metrics, Oxford, UK).

Subjects walked on a level and inclined treadmill at their preferred walking speed. Then, the subjects performed seven trials of 4 min in -10%, -8%, -6% (walking down), 0% (horizontal), 6%, 8% and 10% (walking up) treadmill inclinations. Subjects rested 2 min between trials.

Before data analysis, kinematic data were low-pass filtered with a fourth order, zero-lag Butterworth filter with a cut-off frequency of 6 Hz. The initial and final strides were discarded in order to select the middle 150 strides of each trial. The right leg heel-strikes, which were detected as the zero-cross of its heel markers velocity determined the gait cycles.

In order to remove the drift of the signal, the medial-lateral (ML), anterior-posterior (AP) and vertical (V) T1 marker velocity was calculated using the three points method from the T1 marker position data. Then, the Hilbert Transform [5] is calculated for each T1 direction velocity series. A plot of this transformed signal in a real vs imaginary axis forms a circular shape that represents each stride.

The center coordinates of each one of these circular shapes were estimated as the mean of each cycle's real and imaginary parts. In addition, the center coordinate of the mean stride cycle was estimated as the mean of the real and imaginary components of the time series. Finally, the Euclidian distance of each stride's center coordinate to the mean stride cycle's center coordinate was calculated. This result shows the dispersion of each cycle in relation to a mean cycle along the trial. The mean distance along the 150 cycles was then used to evaluate gait variability.

RESULTS AND DISCUSSION

Results were normalized to better comparison of both methods in a single plot. As seen in Figure 1, the proposed method showed very similar results to the control one. The same "V" pattern found in the inclined surface data set is observed using both the proposed and control method.

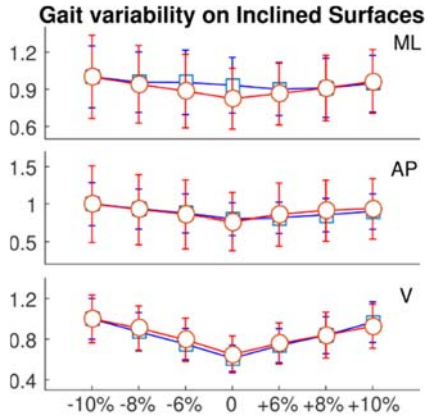

Figure 1: Comparison of gait variability on inclined surfaces, obtained using the proposed method (blue-squares) and control method (red-circles) [4].

CONCLUSIONS

Although both methods showed similar results, it is important to notice each one have its own focus. While the proposed method focus on analyzing variability of each gait cycle, the control method focus on the variability within gait cycles. The proposed method, however, showed smaller standard deviation and it is a good alternative to evaluate gait variability.

P328 - NONLINEAR ANALYSIS OF POSTURAL CONTROL BEFORE AND AFTER DISTURBANCE

INTRODUCTION

The structural and temporal characteristics of center of pressure (COP) sway data are often visually apparent, but not captured by conventional measures such as the area of confidence ellipse or average amplitude of the signal. COP sway can show a scale invariant structure so that the structure repeats itself on subintervals of the signal [1]. The scale invariant structures of physiological phenomena like inter-spike-interval of neurons [2], inter-stride-interval of human walking [3] and inter-beats of the human heart [4] have been previously and successfully assessed in order to differentiate healthy from pathological conditions. In this study, we computed multifractal detrended fluctuation analysis (MDFA) and multiscale entropy (MSE) as measures of nonlinear variability of COP sway to test the postural control in response to disturbance during bipedal standing of healthy young individuals.

METHODS

Thirty healthy and active young individuals (23.0±4.7 years old, 67.4±16.1 kg, 1.71±0.10 m) gave written consent to participate in this study. The participants stood on an AMTI force plate operating at 100 Hz and were exposed to an external disturbance induced by a pendulum. A load (3% of body weight) was attached to the extremity of the pendulum [5]. The participants were required to receive the pendulum impact, applied in anterior-posterior direction, with their upper limbs extended at the shoulder level. COP sway was acquired during 120 s before and 120 s after the disturbance. The participants performed three trials. Fractal dimension was estimated by using MDFA; regularity of COP sway was tested using MSE. For MDFA calculation, we have used intervals ranging from 12 to data length/4 data points and 7 time scales [6]. For MSE (12 time scales), we used an adapted practical solution [7] for the determination of the suitable parameters. We found $r=0.2$*data standard deviation, $m=3$, and $\tau=12$. The data were analyzed in four 60-s time intervals before and after the disturbance: 1 to 60 s, 21 to 80 s, 41 to 100 s and 61 to 120 s. A customized MatLab code was written to calculate the variables. Significant differences between before-after disturbance conditions and among the four 60-s time intervals were analyzed by repeated measures ANOVA, with $p<0.05$.

RESULTS AND DISCUSSION

MDFA was significantly larger (Fig. 1A) and MSE significantly smaller (Fig. 1B) after than before disturbance, i.e. COP sway is less random and more regular after than before disturbance. MDFA was significantly different among time intervals ($p=0.003$), with significant interaction effect between before/after disturbance and time intervals. Pairwise comparisons revealed that MDFA after disturbance was significantly larger during 21 to 80 s, 41 to 100 s and 61 to 120 s time intervals compared to the remaining ones ($p=0.003$).

The results suggest that after disturbance there is an active effort to stabilize the body, leading to a less random and more regular and long-range correlated COP sway.

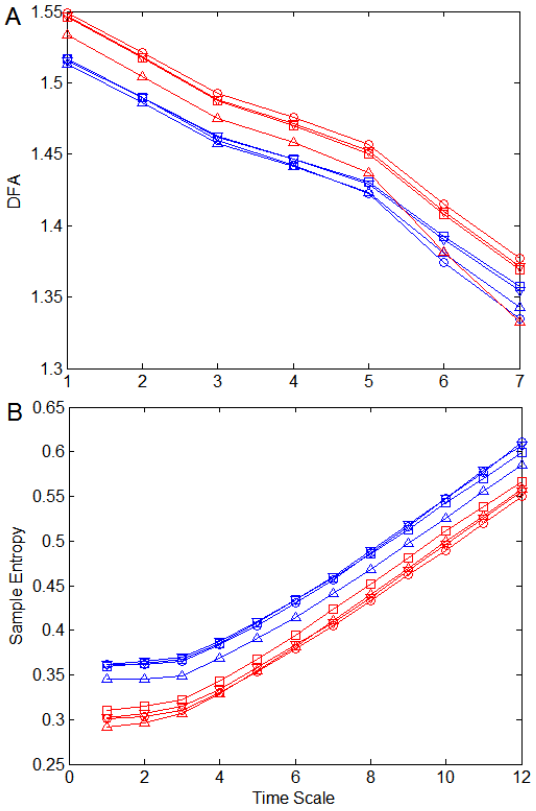

Figure 1: (A) MDFA curve. (B) MSE curve. Blue: before, Red: after disturbance. Δ: 1 to 60s, □: 21 to 80s, ∇: 41 to 100s, and o: 61 to 120s time intervals.

CONCLUSIONS

The disturbance appears to lead to a more active and long-range correlated control of upright posture that lasts 2 min after disturbance.

P329 - INFLUENCE OF GAIT SPEEDS ON KNEE JOINT CONTACT FORCES

[1] **Xin Wang**, [2]Yue Ma and [3]Wing Kai Lam

INTRODUCTION

Speed walking, which is the walking with a speed at the upper end of the individual range, is a popular fitness exercise in many cities in China. However, most participants only concern about the gait speed but receive little attention on knee joint loading, which may result in higher risk of knee joint injuries. The researchers [1,2] have found that when walking at fast gait speed, the walking kinematics and kinetic would be changed. In brief, higher gait speed was associated with larger step length, knee flexion angle, and peak plantar pressure, but smaller ankle angle and shorter stance and total contact times.

Nevertheless, TF is the resultant knee force (KF) exerted on the knee, it is believed that three-dimension KF information can provide additional information for better estimation of knee joint loadings during walking of different speeds.

METHODS

Fifteen young healthy male participants (mean age 24.6 ± 1.19 years; height 1.76 ± 0.02 m; 68.3 ± 1.72 kg) and fifteen female participants (mean age 24.8 ± 1.13 years; height 1.64 ± 0.02 m; 54.0 ± 1.92 kg) were recruited to perform five successful barefoot walking trials in different speeds (normal 1.1 m/s, medium 1.4 m/s, and fast 1.7 m/s). Ground reaction forces were recorded at 1,000 Hz using force plate (AMTI, Watertown, MA, USA), Synchronized motion data were captured at 250 Hz using Codamotion infrared capturing system. All the GRF and lower limb kinematics information were input to determine 3 dimensional knee joint forces using the AnyBody musculoskeletal model (AnyBody Modelling System v.6.0.3, Anybody Technology A/S, Aalborg, Denmark) in all speed conditions.

In order to minimize the body mass effect, we normalized all KF with body mass. All statistical analyses were performed with SPSS 19.0 (SPSS, Chicago, IL, USA). We performed one-way repeated measures ANOVA to assess the speed effect on each of the KF components. All data were presented as mean ± SD and Significant level was set at $P = 0.05$.

RESULTS AND DISCUSSION

Table1 showed that participants walking at fast speed experienced higher both proximo-distal and anterior-posterior KFs during early heel contact phase compared to the normal and medium speed conditions ($P < 0.01$). However, medial-lateral KF was not different among speed conditions ($P > 0.05$).During fast walking, the proximo-distal and anterior-posterior KF were more than 3 and 1 BW in the present study, which is in line with Derek and Haight [2] study, which had obese and non-obese participants walking at fast speed (1.75 m/s) and at slow speed uphill (0.75 m/s, 6°) and results in peak TF with 3.12 BW.

Table1. The peak knee contact forces in different walking speeds

Force	Normal (1.1 m/s)	Medium (1.4 m/s)	Fast (1.7 m/s)
Proximo-distal KF(N/BW)	2.12±0.51	2.56±0.48$^{\triangle\triangle}$	3.49±0.53**
Anterior-posterior KF(N/BW)	0.70±0.15	0.81±0.17$^{\triangle\triangle}$	1.23±0.26**
Medial-lateral KF(N/BW)	0.43±0.09	0.45±0.12	0.45±0.10

In addition, the present findings showed the maximum knee contact force had two obvious peaks, which supported the findings measured using embedded sensors [3, 4]. With the increase of walking speed, the KF become larger and time for reaction become shorter, which is challenge for skeletal muscle system to react and attenuate impact forces. From this perspective, the participants might expose to higher risk of knee joint. If one 70 kg-person walks at the high pace for an hour every day, the distance is equivalent to 8000 steps and his knee joint would sustain more than 2,000 N per a step (or 1,600 tons/hour).

CONCLUSIONS

Fast walking characterizes as longer step length, faster step frequency, and shorter stance time. With the increase of gait speed, both proximo-distal and anterior-posterior GRFs were increased significantly, which suggests that the stability is more demanding and therefore require stronger muscle forces. Although fast walking is encouraged for building up fitness, the potential risk of knee cartilage and ligament injuries associated with increased knee contact forces should require further attention.

P330 - QUANTIFICATION OF SOFT TISSUE ARTIFACTS IN CANINE HINDLIMB DURING PASSIVE STIFLE ACTIVITY

[1]**Ching-Ho Wu**, [2]Cheng-Chung Lin, [1]Chia-Lin Chang, and [3]Tung-Wu Lu

INTRODUCTION

Skin marker-based stereophotogrammetry has been widely employed in dogs for the quantitative assessment of orthopedic abnormalities and treatment outcomes. However, soft tissue artifacts (STA) as a result of the movement of the skin surface relative to the underlying bones have been a major source of error [1]. While the STA of the human lower limbs have been well quantified and shown to affect the outcome of motion analysis [2], the STA in dogs were typically neglected in most skin marker-based studies. Only a limited number of studies reported that STA does exist and should be taken into account in canine kinematics analysis [1, 3]. Therefore, it is essential to quantify the STA and their influence on estimating joint kinematics in dogs for clinical applications.

The objective of this study was to assess *in vivo* the 3-D displacements of skin markers attached on the anterior-lateral aspect of the thigh and shank of dogs with respect to the underlying bones during passive stifle movement.

METHODS

Nine healthy, adult, mixed breed dogs (body weight: 22.7±3.2 kg; age: 55.9±24.1 month) were recruited in the study. An 6-camera infrared motion capture system (Bonita 10, VICON, UK) was used to measure the skin marker coordinates. A C-arm fluoroscopy (Arcadis Avantic, Siemens, Germany) was used to acquire simultaneously the x-ray images of the stifle motion. Dog subjects also underwent CT scan to collect volumetric images of the right hind limb.

All subjects were anesthetized with inhalant anesthetics and their stifle joints were passively extended from fully flexion position during data acquisition. Nineteen infrared retro-reflective markers were attached to the thigh and shank and were captured using the motion capture system. A model-based tracking technique was employed to determine the STA-free 3-D poses of the femur and tibia by registering the CT model to the fluoroscopic images [4]. The position vectors of each marker relative to the underlying bone coordinate system, $\boldsymbol{p}_i$, during the entire motion task were derived. For each subject, root-mean-squared amplitude (*rmsd*) and peak-to-peak amplitude (*ppd*) of $\boldsymbol{p}_i$ across all x-ray image frames were computed.

RESULTS AND DISCUSSION

Considerable movements of the skin markers with respect to underlying bone segments were observed. The lateral thigh markers were displaced mainly along the anterior-posterior (AP) axis of the femur while the anterior thigh markers moved along proximal-distal (PD) direction (Fig. 1). On average, the anterior thigh markers showed *rmsd* less than 9.4±2.1 mm and *ppd* less than 29.1±6.3 mm. The lateral thigh markers showed smaller errors in comparison to anterior markers. The primary STA of the shank appeared on the lateral side (Fig. 1), which gave a *rmsd* and a *ppd* less than 7.9±3.1 mm and 23.9±10.2 mm, respectively. In general, the displacement amplitudes of thigh markers were greater than those of the shank markers. The anterior thigh and lateral shank were possibly the areas with largest STA in dogs, which were different from the STA distribution in the human lower limb.

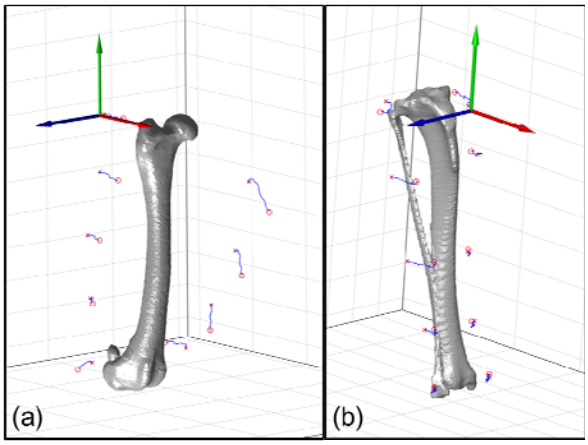

Figure 1: Distribution of the soft tissue artifacts of the thigh and shank of a canine subject during isolated stifle motion.

CONCLUSIONS

The study documented for the first in the literature the 3D displacements of skin markers with respect to the femur and tibia by means of a model-based tracking method using fluoroscopy. The findings demonstrated that the skin markers on the anterior thigh and lateral shank were both subject to significant STA. The area with large skin-bone displacements may not serve as ideal selections for marker placement. The current results will be helpful for better determination of marker positions used for kinematic models and for the development of STA-compensation models in canine gait analysis.

INTRODUCTION

Osteoarthritis (OA) is one of the most common musculoskeletal disorders. Mechanical stress has been closely linked to the onset and progression of knee OA. The varus moment is measured using three-dimensional motion analysis as a measure of mechanical stress. Changes in varus moment with respect to the progression of the knee OA have been reported. However, there is no report on the change of varus moment in individuals without OA and how this relates to development of knee OA. This study aimed to provide standardized data of the varus moment of young healthy individuals to provide a foundation for a longitudinal study. We report that we have found a characteristic knee varus moment waveform that appears to differ from that expected in individuals without knee OA..

METHODS

We recruited six young healthy subjects from Kio University for this study. The mean and standard deviation (SD) of age, weight, and height were 21.8±0.8 years, 64.2±14.1kg, 1.70±0.06m, respectively.

Participants gave their written consent to participate in this study, which was approved by institutional ethics committees. The task was to walk 10 meters at optimal speed, for six repetitions. The ground reaction force and the varus moment applied to the right knee joint were measured using a three-dimensional motion analysis system (VICON, Oxford Metrics, Oxford, UK) and and AMTI force plate system (AMTI, Inc, Nerton, MA). All data was taken into MATLAB R2010a (Mathworks Inc.; MA, USA) using a program developed by the Department of Applied Physics, University of Eastern Finland and analyzed.

RESULTS AND DISCUSSION

The ground reaction forces of all six people were similar. The internal knee joint moment showed similar waveforms by 4 persons, and 2 persons showed different waveforms. The ground reaction forces of all six participants showed the same tendency, but the varus moment of two of the six people appeared immediately after the heel contact and changed in the valgus direction during the midstance phase. This indicates that the knee joint moves once in the varus direction due to the impact of the heel contact, but then the knee joint is moving largely in the opposite direction. This indicates that the knee joint dynamics is different from normal during the midstance phase to the late stance phase. As Iijima et al (2015) reported that the thrust of the knee joint is related to pain, such features may lead to the identification of the cause of knee OA onset. In the future, it is necessary to increase the number of subjects to standardize knee joint dynamics and investigate in detail the whether this pattern of knee joint dynamics leads to onset of knee OA, and what kind of person's characteristics will change.

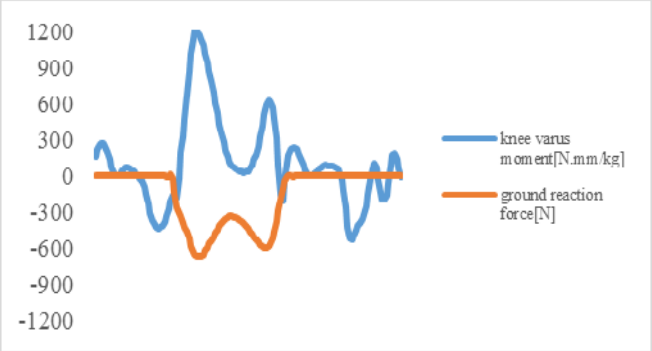

Figure 1: Typical ground reaction force and varus moment of young healthy subject

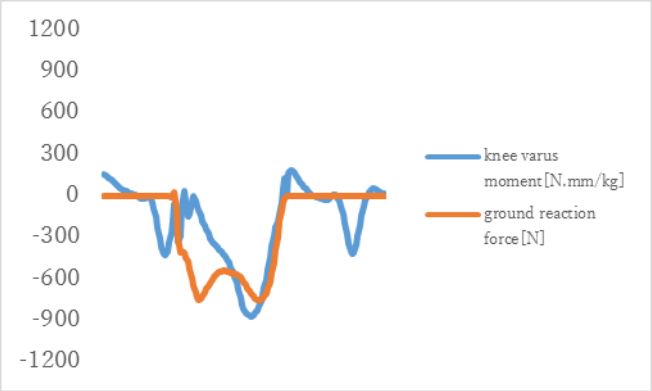

Figure 2: Ground reaction force and varus moment different from typical examples of young healthy subject

CONCLUSIONS

In this study, we found that some people move the knee joint largely in the valgus direction in the midstance phase to the late stance phase of gait. Paying attention not only to the knee joint dynamics at the initial stance of gait, but also to it after the midstance phase may lead indenfitication of features that could be related to development of knee OA. This may be useful for future development of prevention strategies.

INTRODUCTION

Flatfoot, as a typical consequence of foot deformity, presented an increased incidence rate in obese children. Although flatfoot has presented a very high incidence rate in obese children, previous studies which investigated the foot biomechanics and foot structure of obese children rarely calculated the footprint parameters to define flat arch, lowered arch, intermediary arch and normal arch foot types as a screening criterion of subjects.

The purpose of this study was to determine whether it is essential to define lower arch foot type as a subject screening criterion to control the variable factor of experimental group in the foot biomechanics research of obese children by comparing the dynamic plantar pressure distribution, gait cycle and center of pressure of obese children with flatfoot to obese children with normal arch foot and normal-weighted children with flatfoot respectively.

METHODS

All the subjects participated in the study were selected from a foot morphology database of 551 Chinese children (280 boys and 271 girls) .Foot types of subjects were classified by Foot Angle (FA) and Chippaux-Smirak Index (CSI) using Bauerfeind® footprint plate.

Totally 21 obese children with flatfoot (OF group) (12 boys and 9 girls) and the matched control groups named obese children with normal arch foot (ON group) and normal-weighted children with flatfoot (NF group) were selected from the database. Data of pressure parameters and its relative gait data, including peak pressure, load rate, force-time integral, pressure-time integral, relative impulse, relative area, center of pressure (COP) and gait cycle, of all subjects were recorded by Footscan® plate system. All subjects walked across the plate barefoot to collect the data.

Statistical analysis was conducted by SPSS17.0. The level of $\alpha = 0.05$ (p value ≤ 0.05) was perceived as significant for statistical analyses.

RESULTS AND DISCUSSION

The results of plantar pressure distribution demonstrated that obesity resulted in increased peak pressures, load rates, force-time integrals and pressure-time integrals beneath 1st-5th metatarsal, midfoot, medial heel and lateral heel regions, while flatfoot resulted in decreased foot loading pattern beneath 4th metatarsal and 5th metatarsal regions. The relative area of OF group beneath midfoot region (AI) was significantly larger than that of ON group ($p<0.001$). COP trajectory of OF group displayed a significant decrease of medial shift in medial-lateral direction during duration of forefoot contact phase compared to ON group (Figure 1). A previous research of Dixon et al. [1]indicated that the COP displacement in medial-lateral direction, especially during initial contact phase and forefoot contact phase, could be an indication of foot loading pattern and incidence of lower extremity overuse injuries.

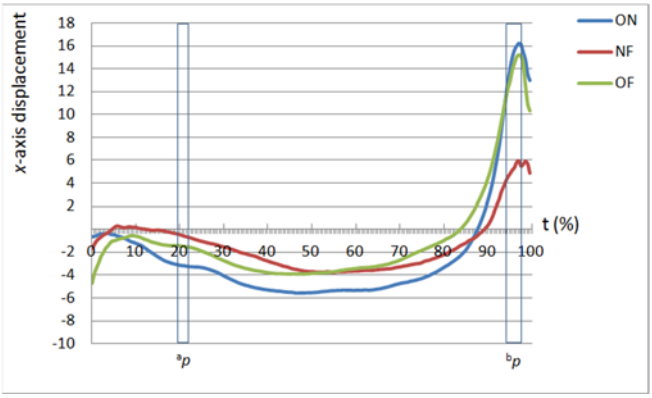

Fig. 1. COP displacement in medial-lateral direction (x-axis) and anterior-posterior direction (y-axis) of ON, NF and OF. t, % duration of gait cycle; ^{a}p, significant difference for x-axis displacement between ON and OF; ^{b}p, significant difference for x-axis displacement between NF and OF.

CONCLUSIONS

It could be assumed that obese children with flatfoot could be at a lower risk for lateral metatarsal stress fractures and a lower incidence of foot everted position when compared to obese children with normal arch foot. Due to the significant differences between OF group and control groups, the current study suggested that lower arch foot type should be defined in the future foot biomechanics research of obese children as a subject screening criterion due to its confounding effect on the plantar loading characteristics.

ACKNOWLEDGEMENTS

The present study obtained financial support from National Natural Science Foundation of China, grant number: 11502154. The authors would like to acknowledge all the experimenters for subject recruitment and data collection, and to acknowledge all of the participants who were made this study possible. P333 - SQUATTING PERFORMANCE AND BIOMECHANICS ACROSS FEMALE OF DIFFERENT AGES

[1]**Sha Qu**, [2]Yi Qu, [2]Wing-Kai Lam, [3]Yongdan Du and [1]Dongmei Luo
[1] Beijing Sports University, Beijing, China

INTRODUCTION

The lower limb motor function of the elderly declines with age, which increases the risks to fall injuries that might lead to bone fracture and poorer performance in various daily activities [1]. Squatting up and down is a critical ability in many daily activities such as squatting in bathroom and rising from chairs.

Previous research on the squatting mechanism of elderly falls has been focused in physiological and biochemical perspectives[2], but little effort was done on the motor control ability. Therefore, this study was to compare the total time, kinematics and ground reaction force (GRF) during squat across female of various age groups.

METHODS

140 women community walkers were assigned into 20, 30, 40, 50, 60 and 70 aged groups. All subjects reported no obvious trauma and diseases which affect balance and squatting performance. The subjects were asked to perform squatting upward and downward on Kistler force platform (Kistler, Amherst, USA) to record GRF. A SONY camera was used to determine total movement time and maximum hip, knee and ankle angles during squatting.. One-way ANOVA was performed to examine if there is significant different between age groups. Significant level was set at $P < 0.05$

RESULTS AND DISCUSSION

In Table 1, longer total squatting time was required in 50, 60 and 70 aged groups compared with 20 aged group ($P < 0.05$).

Moreover, 50 aged group had smaller maximum hip flexion angle than 20 aged group ($P < 0.05$). Maximum knee flexion angle were smaller in 50, 60 and 70 aged groups compared with 20 and 30 aged group ($P < 0.05$). Maximum ankle flexion angle was smaller in 50, 60 and 70 aged groups compared with the 20 aged group ($P < 0.05$).

Furthermore, smaller peak GRF and maximum contraction index was found for 50, 60 and 70 aged groups compared with 20 and 30 aged groups ($P < 0.05$)

CONCLUSIONS

Beyond age of 50 years old, female subjects characteristics as longer total squatting time, smaller angle range of motion, and smaller generation strength and power when compared to younger females (i.e. 20, 30, 40 aged groups) .This may be explained by poor quadriceps strength and power (e.g., Table 1) as well as limited joint flexibility and poor proprioception. Therefore, muscle strengthening exercise, stretching and proprioception training seems to be the necessary remedies for the elderly to improve their squatting ability[3]. This would improve the mobility of daily living.

When observing from the tested variables, 50 years old would be a turning point of motor control. Females at the age of 50 years old should pay particular attention to maintain their fundamental motor ability and require medical care as indicated by significant decline of squatting performance[4]. Further study should investigate other motor tasks to have a comprehensive evaluation of aging.

P334 - A SIMULATION STUDY ON THE SCALE EFFECTS ON THE GAIT OF IMAGINARY BIPEDS

Makoto Yoshida, and Kazunori Hase
Tokyo Metropolitan University
Corresponding author email: yoshida-makoto@tmu.ac.jp

INTRODUCTION

The effect of different body sizes on the gait of bipeds is investigated. The subject of the study is not restricted to real humans, but we also aimed to investigate the gait of imaginary bipeds such as giants and dwarves. Investigating the gait of these imaginary bipeds might enable a more realistic visual expression, which would be useful in the entertainment industry. This study might also provide evolutionary insight, since biomechanical features depending on the body size are of course subject to natural selection.

We employed a simulation framework of a simplified whole body model of the musculoskeletal system of human, controlled by a network of neural oscillators with a sensory feedback system [1].

On constructing models of imaginary bipeds with various body sizes, we assumed the simplest scaling laws to our knowledge; the mass is proportional to the volume, *i.e.* proportional to the length to the power of three, and the force exerted by a muscle is proportional to its physiological cross-sectional area (PCSA), *i.e.* proportional to the length to the power of two.

The above assumptions imply that the balance between the mass of body parts and the muscle force will change as the body size changes. We observed the changes in the gait pattern as functions of the height of the biped model.

METHODS

A model of an average-sized human with the height of 1.75 m and the weight of 72 kg was constructed. This model was scaled with the simple scaling laws described above. We employed genetic algorithm (GA) to obtain the parameters of the network of neural oscillators that controls properly a given musculoskeletal system. As an initial conjecture of the neural parameters, which is subject to optimization by GA, we employed an optimal neural parameters for a similar body size.

RESULTS AND DISCUSSION

We were able to obtain a stable gait pattern for each biped with the height ranging from 1.25 m to 2.25 m. The stride length, the distance travelled during a single gait cycle, was longer for the taller biped models. The gait cycle was longer for the taller biped models.

The dependencies of the performances of the gait on the height of the biped models are shown in Figure 1. The walking speed converged to a similar value, irrespective of the body size, which might be of evolutionary significance. The specific power, the energy consumption per unit mass of the body per unit distance of locomotion divided by the gravitational acceleration, became smaller as the biped became taller. This tendency roughly agrees with that reported for tetrapod mammals [2]. Since all of the body segments are scaled proportionally to the height of the biped model, the length of every muscular contraction, which causes every body movement, is also scaled proportionally to the height. Since the force exerted by a muscle is assumed to be proportional to its PCSA, the work done by this muscle, muscular force multiplied by the length of muscle contraction, should be proportional to the volume of the muscle. That the PCSA's of the muscles were scaled proportionally to the length to the power of two implies that the volumes of the muscles are proportional to the mass of the whole body, which was scaled proportionally to the length to the power of three. Thus, the energy consumed during a single cycle of gait motion per unit mass should be constant irrespective of the body size. Therefore, since the stride length increased with the height, the locomotion should be more efficient for the taller biped models.

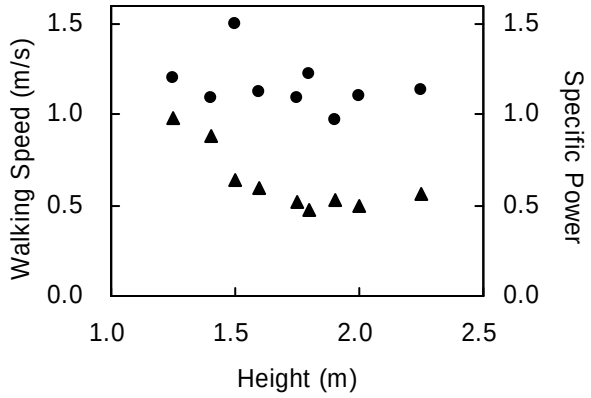

Figure 1: Performances of the gait as functions of the height. The speed (circles, left ordinate) and the specific power (triangles, right ordinate) of the gait are plotted as functions of the height of the biped models.

CONCLUSIONS

That we were only able to obtain stable gait pattern with those with the height within a certain range might be due to the limitations of the scaling effects. Nevertheless, we are continuing to search for the stable gait patters yet to be discovered for giants and dwarves, since we might have not invested enough computational power so far.

P335 - BACKWARD WALKING IN PATIENTS ACCORDING TO THE SEVERITY LEVELS OF PARKINSON'S DISEASE

Minji Son, Changhong Youm*, Myeounggon Lee, Hwayoung Park
University of Dong-A, Busan, Korea
*Corresponding author's email: chyoum@dau.ac.kr

INTRODUCTION

Parkinson's disease (PD) is characterized clinically by progressive deterioration of the central nervous system and pathologically by depigmentation of the substantia nigra and the presence of Lewy bodies [1]. Patients with PD experience problems, such as falls, and freezing of gait during walking in daily activities [2]. Specifically, the elderly experience falls in perturbations or movements that require a person to move backwards. Particularly, a backward walking relies more on proprioception than forward walking [3]. Characteristics of backward walking in PD patients with increased disease severity are still unclear. Therefore, the purpose of the study was to investigate backward walking characteristics according to the severity levels of PD patients using 3-D motion analysis.

METHODS

This study enrolled a total of 62 PD patients. Twenty-one patients exhibited H&Y stage 3.0 PD, 16 patients exhibited H&Y stage 2.5 PD, and 25 patients exhibited H&Y stage 2.0 PD, based on the Hoehn and Yarh scale. All patients with mild to moderate stages of PD were recruited from outpatient clinics, and all patients were tested during defined off-states for a minimum of 12 h before the trial. The backward walking was captured on an 8 m walkway using a motion capture system comprising six cameras (VICON Motion Systems Ltd., UK). The outcomes from three successful trials were averaged and used in the statistical analyses. Spatiotemporal variables included the walking speed, stride time, stride length, the asymmetry index of the step time and length, and the toe clearance height. Furthermore, kinematic variables were the ROM of hip, knee, and ankle, in the sagittal plane. Each step was classified into a more affected side (MAS), and a less affected side (LAS), according to the dominant side of symptoms in PD.

All statistical analyses were performed using SPSS (Version 21.0, SPSS Inc., Chicago, IL). The normality was verified using the Shapiro–Wilk test. One-way ANOVA tests were used to determine significant differences among the groups with the Scheffe significant difference post-hoc test and t-tests for paired samples. The statistical significance was set at $p<0.05$.

RESULTS AND DISCUSSION

There was no difference in demographic and clinical characteristics in sex, age, height, body mass, MMSE, LED, and duration of the symptoms between groups. However, the UPDRS stage III and the UPDRS total scores, significantly differed between groups (Table 1).

Step length, stride length, walking speed, foot-clearance height, ROM of hip and knee joints, and asymmetry of step length, exhibited a significant difference between groups. In addition, step length, and ROM of knee and ankle joints, exhibited a significant difference between steps.

Step time, stride time, and the asymmetry index of the step time exhibited nonsignificant differences in both groups and steps.

Table1. Physical and clinical characteristics of participants

	H&Y 2.0	H&Y 2.5	H&Y 3.0	F-value
Sex (M:F)	14:11	9:7	9:11	-
Age (yrs)	68.20 ± 5.67	71.76 ± 5.66	69.96 ± 4.49	2.238
Height (m)	158.52 ± 8.48	155.20 ± 9.44	156.58 ± 9.22	0.701
Body mass (kg)	62.09 ± 7.44	57.56 ± 10.95	58.01 ± 7.15	1.948
MMSE (score)	28.00 ± 2.51	27.31 ± 1.35	27.24 ± 1.70	0.994
UPDRS stage III (score)	30.32 ± 7.01	32.25 ± 7.38	37.93 ± 4.82	8.255*
UPDRS total (score)	42.14 ± 8.73	47.75 ± 10.15	53.14 ± 11.55	6.763*
LED (mg/day)	469.4 ± 202.9	674.1 ± 438.6	671.6 ± 355.3	2.841
Symptom duration (yrs)	4.84 ± 4.00	7.62 ± 5.53	6.35 ± 5.10	1.69
H&Y (stage)	2.00 ± 0.00	2.50 ± 0.00	3.00 ± 0.00	-

All data are given as mean ± standard deviations. MMSE: Mini mental state exam, UPDRS: Unified Parkinson's disease rating scale, LED: L-DOPA equivalent dose, H&Y: Hoenh & Yarh stage. * Significance was assessed using one-way ANOVA tests ($p< 0.05$).

CONCLUSIONS

The results of this study indicated that H&Y 3.0 and H&Y 2.5 were less than H&Y 2.0 in step length, stride length, walking speed, foot clearance height, ROM of hip and knee joints, and asymmetry of step length. Therefore, we found that each group of PD patients showed different characteristics during backward walking. Furthermore, these results might suggest that forward walking could be helpful for measurement and analysis of gait characteristics in PD.

INTRODUCTION

Alterations in knee adduction moment (KAM) has been suggested as a surrogate measure of medial compartment (1). It has two peaks; the first peak has been correlated with the progress of knee osteoarthritis (OA) that is more common in elderly population (2). Individuals with OA suffer to the limit of functional mobility including walking. Walking involves cognitive processes related to planning and performing actions. With advancing age, reduction in the cognitive functions related to walking has been noted (3). As OA is an age-related condition, it is therefore, necessary to consider OA gait assessment whilst individuals performing additional cognitively engaging tasks. There is, to the best of our knowledge, no published research examining the effects of concurrent cognitive tasks during walking on KAM. The aim of this study is to explore whether introducing cognitively engaging task during walking would affect the first peak of the KAM in healthy individuals.

METHODS

Twenty-three healthy male subjects (age: 34.56 + 5.12 years) walked on a GRAIL system (Gait Real-time Analysis Interactive Lab, Motek Medical B.V.) at two days, separated by 5 ± 3 days. The GRAIL consists of an instrumented dual-belt treadmill and a 12-camera Vicon tracking system (Oxford Metrics, UK). Using the self-paced mode with virtual-endless scene, they walked under three conditions in random order: 1) Free walking (FR); 2) while performing one back auditory memory test (OB); and 3) while performing two-back auditory memory test (TB).

The average the first peak of KAM, range-of-motion (ROM) of KAM and foot progression, and walking speed across 100 consecutive gait cycles were calculated. A repeated measures ANOVA was used to explore the effect of memory tasks on these outcomes. The level of statistical significance was set at $p<0.05$.

RESULTS

Descriptive statistics for KAM and its ROM, walking speed, and ROM of foot progression are presented in Table 1. The mean of KAM and foot progression of the 23 subjects for each walking condition is illustrated in Figure 1. There was no significant decrease (Figure 1) in these parameters while performing OB and TB tasks within a session and between days.

DISCUSSION AND CONCLUSIONS

Although there was no significant effect of the working memory task on the reported gait parameters, participants walked slower ($p=0.068$) while performing OB and TB. In general terms, walking slower while performing another cognitive task is suggested in literature (3). Our findings show that the memory tasks caused participants to walk with only a slight reduction in both the first peak of the KAM and external foot progression (it can be used to reduce KAM (4)) (Figure 1). This is expected since control of gait requires minimal cognition; healthy subjects should therefore have sufficient residual cognitive capacity to maintain gait control even whilst performing additional cognitively engaging tasks (e.g. a working memory task). The results are based on much more strides compared to literature, therefore, learning effects might be reduced in our study. Future research should examine the effect of our concurrent paradigm on KAM and other gait parameters related to knee unloading in knee OA patients.

P337 - THE PARAMETERISATION OF THE CAVITY FORMATION IN SUBSTITUTE MATERIALS FOR NORMALISED AND SPECIAL MILITARY AMMUNITION

[1] **Richard Billich**, [1]Frantisek Lopot, [1] Ondrej Fanta, [1] Petr Kubovy, [1] Karel Jelen
[1] Charles University in Prague, Faculty of Physical Education and Sport,
Department of Anatomy and Biomechanics, Prague, Czech Republic

INTRODUCTION

Gunshot wounds are generally characterised by the permanent cavity which can be defined as the bullets wound track and is observed as a hole or damaged area in tissue formed after projectile penetration. The data obtained are used to assess the risk through the so-called gunshot wounding criteria. There are a number of different injury severity scoring systems in use by the medical fraternity to triage patients with gunshot wounds and other trauma. These systems rely on assessment of actual injuries rather than the type of bullet creating the wound/s.

METHODS

Standard 9 mm ammunition - Luger FMJ; .357 Magnum FMJ and a modern bullet with a high performance expansive projectile .357 Magnum GOLD DOT were selected.

The substitute materials - glycerine soap and 20% gelatine, play a vital role in the data processing and design of own criteria for quantifying the actual wounding effect (**$WE_{1/2}$**). Parameter **WE_1** is possible to understand as the contractual density of the loss of projectile kinetic energy due to the ballistic gelatine volume block. The paramater **WE_2** is defined by using the volume of the permanent cavity in a block of glycerine soap. The parameters **PA_1** and **PA_2**, which are quantified by the projectile's ability to penetrate the test material. Consistent with the literature [1,2], we expect that this property is highly dependent on the environment in which the projectile moves, which plays an irreplaceable role in the overall shot hazard assessment. Parameter to quantify the shot potential to wound (**WP**) is defined as the contractual areal density energy of the bullet.

All the parameters are designed to have a clear physical interpretation in the form of planar or volumetric energy densities and optionally a clear mathematical interpretation in terms of variable characters.

RESULTS AND DISCUSSION

Table 1. provide a summary of the internationally recognized criteria according to and our introduced parameters. The table, next to the numeric values of individual criteria, always specifies the likely wounding effects in order from I (least) to III (most).

Our parameters **WP** and **WE_2** correspond well with the generally accepted criteria. The visible differences in parameters **WE_1, PA_1** and **PA_2** these criteria identify the evaluated bullet characteristics which, otherwise, remain unaffected.

The bullet of the 357 Magnum Gold DOT type will likely be captured by the protective utility and the trauma now will be caused by the blunt impact on quite a large area of protective equipment to the tissue beneath. The bullet of the 357 Magnum FMJ type, with a high penetration ability.

In this type of charge, however, there is no deformation of the shot, consequently, the protective equipment working surface will be smaller and the mentioned dangerous areal density of the impact kinetic energy to the tissue will be, by contrast, higher. In this case, we consider this bullet to be more likely to cause serious trauma.

Table 1. Quantification of wounding effects caused with pistol shots based on internationally accepted wounding criteria supplemented with criteria WE, $WE_{1,2}$ and $PA_{1,2}$.

Legend: StP – Stopping Power; **RSP** – Relative Stopping Power; **W_κ** – Effectiveness Criterion; **W_{TH}** – Effectiveness Criterion; **PIR** – Power Index Rating; **KO** – Knockout Value; **OSS** – One Shot Stop; **WP** – Wounding Potential; **$WE_{1/2}$** – Wounding Efficiency; **$PA_{1/2}$** – Penetration Ability

CONCLUSIONS

The objective of the study was to highlight, in an understandable way, the difference between the wounding potential of shot (**WP**) to injure and their actual wounding effects (**WE**), which is, with respect to the environment type penetrated by the shots, based on its destructive and/or a penetration ability.

INTRODUCTION

Osteoarthritis (OA) is a degenerative joint disease involving the breakdown of articular cartilage, which is common after injury or with aging. Partial anterior cruciate ligament (p-ACL) ruptures are commonly seen clinically, making up between 10-28% of all ACL tears [1, 2]. Following knee injury, sheep develop OA at a slightly accelerated rate compared to humans but with some similar patterns [3]. In an ovine knee injury model [4], altered gait mechanics and degradation of the cartilage have been observed 20 weeks post ACL transection (Tx) surgery. However, potential alterations in *in vivo* joint kinematics at 20 and 40 weeks post p-ACL Tx surgery remain to be determined in an animal model. Therefore, the objective of this study was to investigate the *in vivo* kinematics of the ovine stifle joint over time following p-ACL Tx.

METHODS

Five skeletally mature female Suffolk-cross sheep had bone plates implanted onto their tibia and femur of their right hind limb, four weeks prior to kinematic testing. Briefly [4], on the day of kinematic testing, a stainless steel post was attached to each plate and an instrumented spatial linkage (ISL) was mounted between them. The ISL consists of six rotational encoders providing six degrees of freedom (6-DOF) to its motion. The 6-DOF *in vivo* kinematics of the stifle joint were measured during "normal gait" while the animal walked on a treadmill at 2 mph (0.89 m/s). Each animal then underwent arthroscopic p-ACL Tx surgery. The *in vivo* gait kinematics were measured again at 20-21 weeks and 40 weeks following p-ACL Tx. Following kinematic testing at 40 weeks, the animals were euthanized and their hind limbs were disarticulated. Throughout tissue dissection, gross morphological grading was conducted by one expert observer for gross defects [5], osteophyte formation [6], and meniscal damage [7]. A Mann-Whitney statistical test was used to determine differences in gross morphological score between groups, and was calculated using Prism 7 GraphPad and significance was accepted at $p \leq 0.05$.

RESULTS AND DISCUSSION

The 6-DOF *in vivo* kinematics for all five animals are presented in Figure 1. The most noticeable finding of this study was the considerable kinematic inter-subject variability. There were consistent changes in medial-lateral, posterior-anterior, and inferior-superior translations at 40 weeks from intact to after p-ACL Tx in most animals. p-ACL Tx led to significantly more gross damage than the non-operative controls ($p=0.008$). There was considerable meniscal damage and osteophyte formation in the 40 weeks post p-ACL Tx group, whereas the control group rarely exhibited osteophyte damage and sustained no meniscal damage. To our knowledge, this is the first study that has quantified *in vivo* kinematics in a p-ACL rupture model. This inter-subject variability could be due to several contributing factors: bony and meniscal shapes, musculature and neuromuscular control mechanisms, and biological changes to tissues after p-ACL Tx. Two strengths of this study are that it quantifies gait longitudinally over 40 weeks following partial knee injury and that it allows animals to be compared to themselves, so that trajectories of change could be studied over time. This research lays the foundation for future studies, highlighting the necessity of addressing individual responses and adaptations to the same injury, as there is substantial individual variation.

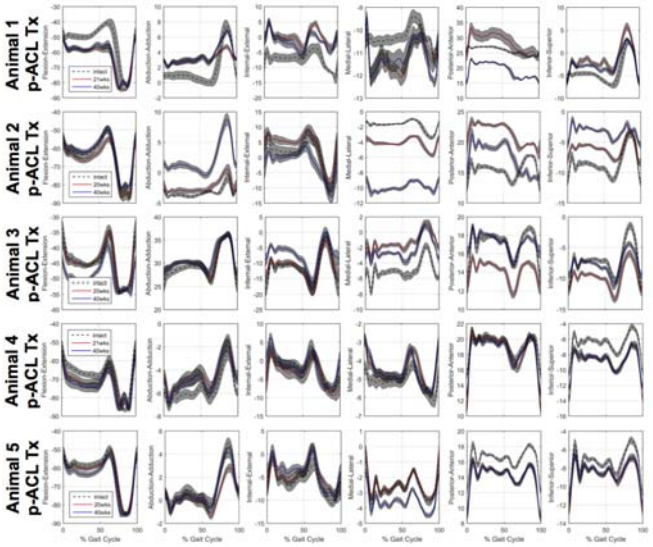

Figure 1: The *in vivo* kinematics of the ovine stifle joint of all animals during gait, before (black hashed line), at 20-21 weeks post p-ACL Tx (red line), and 40 weeks post p-ACL Tx (blue line); rotations in degrees and translations in mm.

CONCLUSIONS

There was considerable inter-subject variability in the kinematic patterns following p-ACL knee injury within animals, which is clinically similar to humans after knee injury. The p-ACL Tx ovine model creates significant progressive post-traumatic OA-like damage by 40 weeks. There were consistent changes in medial-lateral, posterior-anterior, and inferior-superior translations at 40 weeks from intact to after p-ACL Tx.

P339 - OVERGROUND WHEELCHAIR PROPULSION INDUCED FATIGUE CHANGES PROPULSION BIOMECHANICS

INTRODUCTION

Wheelchair propulsion has a poor mechanical efficiency and induces a high physical strain on the shoulder. The high prevalence of shoulder pain (69%) in wheelchair users demonstrates the need to look for means to prevent injury [1]. Certain propulsion biomechanics such as propelling with greater applied forces and reduced contact time during steady state propulsion, have been related to pathology [2].

Muscles stabilizing the shoulder joint are prone to fatigue induced by wheelchair propulsion [3]. Also, fatigue induced by repetitive overhead activities induced superior humeral head migration which can cause shoulder impingement [4]. It is not clear how fatigue induced by overground propulsion alters propulsion biomechanics. Therefore, this project aims to determine how wheelchair users change their propulsion biomechanics after an overground fatigue protocol. It was hypothesized that fatigue would induce a reduction in velocity, increased applied forces, and reduced contact time.

METHODS

Twenty-six wheelchair users with a spinal cord injury completed one testing day at the Human Engineering Research Laboratories (VA Pittsburgh HealthCare System, Pittsburgh, PA, USA). Participants were on average 35.5 ± 9.8 years old and 12.0 ± 8.2 years since injury. 71.3% of participants had paraplegia and 71.3% were male. All participants completed a figure 8 fatigue protocol [5] (Figure 1); participants were required to propel as many laps as possible including right-and left turns, full stops, and start-up propulsion for three, four-minute intervals separated by 1:30 minutes of rest.

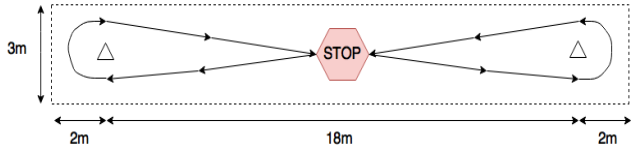

Figure 1: Figure 8 fatigue protocol. Participants came to a complete stop when crossing the stop sign in the middle.

Forces applied on the handrim were assessed with a SmartWheel (Three Rivers Holdings, Inc., Mesa, AZ) attached to the non-dominant side of the participant's personal wheelchair, opposite an identical wheel that did not measure kinetics. Propulsion kinetics of the first and last minute of the protocol were selected. Representing the fresh state, the first four strokes of each of the first three complete course loops of the protocol were selected. Representing the fatigued state, the first four strokes of the last three complete course loops of the protocol were selected. A two-way repeated measures ANOVA was used to address the research question. The main effect of state (2 levels: fresh vs fatigue) and the interaction effect of state with number of strokes (1, 2, 3, and 4) were assessed on the following outcome measures: maximum resultant force, tangential force, radial force, rate of rise of applied force, fraction of effective force, velocity, and average contact time.

RESULTS AND DISCUSSION

Fatigue induced a significant reduction (8%) in propulsion velocity ($p=0.024$) and maximum resultant force (7%, $p<0.001$). There was a significant interaction effect of state and strokes for contact time demonstrating a reduced contact time in the first stroke of start-up propulsion with the occurrence of fatigue ($p<0.001$). For the 2nd, 3rd, and 4th strokes, a similar amount of time was spent on the handrim with fatigue but less force was produced at a slower velocity, suggesting a reduction in propulsion efficiency. Future research is needed to investigate other variables as muscular activation patterns, scapular kinematics, etc. that could be altered with the occurrence of fatigue.

CONCLUSIONS

This study identified reduced applied forces after an overground propulsion fatigue protocol suggesting a load saving mechanism. However, reduced forces were accompanied by shorter contact time and lower velocity. Improved understanding of changes in propulsion biomechanics with fatigue could give further insights into the development of interventions that prevent injury (e.g. wheelchair setup, propulsion techniques, or strength training).

P340 - A NOVEL INSTRUMENT FOR SYSTEMATIC ASSESSMENTS OF UPPER LIMB MOTOR FUNCTION

INTRODUCTION

Muscle spasticity is a common symptom seen in patients with cerebrovascular accidents and spinal cord injuries. Modified Ashworth Scale (MAS) [1] is the most popular method to assess muscle spasticity clinically. During the test, the examiner would move the joint manually and feel the resistance occurring at one specific location through the joint excursion. Although MAS can quickly grade the severity of muscle spasticity, there are no definite standards to quantify the assessment of muscle spasticity.

In this study, human upper limb has been hypothesized to be a black-box dynamic system including components of hand, forearm, and upper arm. Those components are connected with joints of wrist, elbow and shoulder. When we apply some excitation to the dynamic system, the response of the system would be observed. To prevent the loading effect, Simultaneous Sensing cum Actuating method (SSA) is used to measure the impedance of the system. Based on the hypothesis of dynamic system and SSA method, an upper limb assessment instrument without using any mechanical transducer has been designed in this study.

METHODS

This study used a DC motor and a reducer to drive a disk with a handle. The handle can guide subject's limb or other test samples in a circular trajectory.

Simultaneous Sensing cum Actuating method uses transduction matrix to convert the input electrical impedance (voltage/current) to mechanical impedance (torque/angular velocity). The transduction matrix can be got from theoretical derivation or experiments [2]. To prove the practicality of the method, this study used a torque transducer and an encoder to measure the output mechanical impedance. A hall sensor was used to measure the input current, and the voltage was supplied by a power supply. All the signals were acquired by a signal acquisition card and analyzed by a customized Labview program.

In order to determine the accuracy of the mechanical impedance obtained by the SSA method, this study uses a spring with known spring constant (k) as a sample. The relationship between the spring mechanical impedance and the disk angle is $Z_m = rkd\frac{(l'-l)}{\omega l'}\sin(\theta)$.

Elastic bandages were used to simulate different impedance of human upper limbs. Eleven subjects were asked to sit on a height adjustable chair with a seat belt stabilizing the trunk. The subject's right hand was attached to the handle with a bandage with shoulder abduction 90°. The subject was then asked to relax when the instrument guides their hand. After the test, wrapping different width (2 inches and 4 inches) of bandage around elbow joint was used to simulate different resistance to movements when joint extended passively.

RESULTS AND DISCUSSION

This study recorded the input electrical impedance and output mechanical impedance when attached different loads to the disk. We got the transduction matrix of the instrument by using least square approximation. The transduction matrix is $\begin{bmatrix} 0.21 & 6.98 \\ 0.18 & 0.35 \end{bmatrix}$.

While using the spring as a sample, the results getting from direct measured mechanical impedance or transduction matrix are very similar. When comparing the black curve (without bandage) to the red and blue curves (with bandages) in Figure 1, we can see a big increase at 110° and 330°. These two angles mean the joint's maximum extension and maximum flexion. The result shows that the instrument can detect the increasing impedance efficiently.

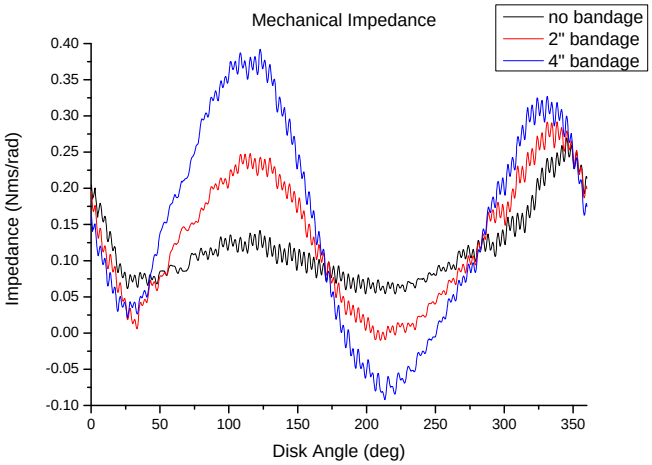

Figure 1: mechanical impedance in different bandage conditions.

CONCLUSIONS

This study designs a novel instrument which can be used to measure mechanical impedance without using mechanical transducer. The experimental result shows it can measure the impedance with validity. This instrument can be used to assess the muscle spasticity in the future.

P341 - VERTICAL JUMP AND STANDING LONG JUMP POWER TO DETERMINE LOWER EXTREMITY IMBALANCE AND INJURY RISK

[1]Suzanne M. Konz
[1]Marshall University, Huntington WV
Corresponding author email: konz@marshall.edu

INTRODUCTION

Movement tests, such as the VJ and SLJ, are used to determine power, athlete development, and quantify training protocol effectiveness. An idea exists to compare the power outputs from a VJ and a SLJ to give a picture of lower extremity injury risk [1,2]. The ability to use easy and cost-efficient common movement tests, such as the VJ and SLJ, could greatly enhance the capabilities of allied health care professionals. The power outputs from both VJ and SLJ should be in agreement. For example, an individual with higher power output for the VJ, when compared to SLJ power, is at risk for hamstring and knee injury [2]. The information gained could assist sports medicine and strength staffs in protocols to minimize injury risk in athletes. The purpose of this study was to examine the ability to predict the previous knee and thigh injuries of athletes using ROC curves to assess allometrically scaled ratios of average power and peak power from VJ and SLJ testing.

METHODS

Participants included 26 female NCAA-I athletes from soccer and volleyball teams. The study examined strength and conditioning testing data from the athletes conducted before an off-season training cycle. All measurements were allometrically scaled [3]. Athlete injury history was accessed to determine the existence of knee, quad, and hamstring injuries. The injuries were coded and used to assess sensitivity and specificity of allometrically scaled VJ and SLJ power outputs [1]. Previous thigh or knee injury was compared to scaled average power ratio, peak power ratio, and calculated z-scores for average power ratio and peak power ratio. Correlation and ROC curves analyzed the relationships between previous injury and power output variable. Data was assessed by the individual team as well as combined. Significance was set at the .01 level for the correlation analysis

RESULTS AND DISCUSSION

There were no correlations between the variables of interest and an athlete's past injury history. The individual team variables also revealed no correlation. A reason for the lack of correlation could be due to the crossover in vertical and horizontal components of VJ and SLJ success. The crossover of the horizontal components in the VJ jump is not as impactful as the vertical pieces of the SLJ. Each sport has different skills involved. A previous ankle injury or compromised mobility can impact the ability to get meaningful information from the VJ/SLJ ratio [2]. An athlete without a history of ankle related issue is hard to come by in soccer or volleyball.

Combined team ROC curves indicated the area under the curve was as follows VJ average power (.631), VJ peak power (.663), SLJ average power (.622), and the VJ/SLJ peak power ratio (.663). The results of the ROC curve analysis poorly indicated previous knee or thigh injury in the teams. ROC curves indicate that the ratio of average power output for VJ and SLJ (.406) does not predict previous injury while the peak power output for VJ and SLJ (.663) poorly predict injury history. The ROC curves do not provide strong specificity or sensitivity for predicting injury risk. The peak power ratio does not provide a solid means to predict injury risk. Ankle mobility issues due to previous injury or otherwise may confound results of any testing.

The original idea behind the VJ vs. SLJ comparison states to use the z-scores [2]. The z-scores of the average power ratio and the peak power ratio failed in sensitivity and specificity to predict a previous injury. Previous ankle injuries by many of the athletes complicated this interpretation.

However, using the individual team outputs of each revealed information. VJ average power, VJ peak power, and SLJ average power provide a degree of injury prediction capability. The data confirms that the two sports are different from each other in power needs. It does give indication that soccer is and volleyball is…..

CONCLUSIONS

Using power output from the performance tests of the VJ and the SLJ to determine injury risk does seem to minimally predict the possibility of a previous knee or a thigh injury, but not with convincing fashion. A question arises. By training athletes to be equal in horizontal and vertical power to maximize protection, will a decrease in the athlete's sport specific capabilities occur?

P342 - DETERMINATION OF THE ONSET OF FALL IN THE ACTIVITIES OF DAILY LIVING

[1]**Youngho Lee**, [1]Jaemin Kim, [1]Soonmoon Jung, [1]Dongwook Yang, [1]Jeongwoo Lee, [1]Beomgeun Jo and [1]Junghwa Hong[#]

INTRODUCTION

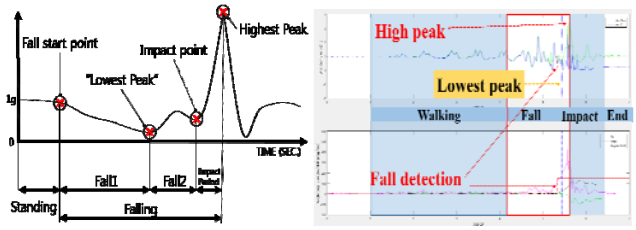
More than 30 % of the elderly over the age of 65 years have experiences at least one fall per year, which significantly deteriorates quality of life. Based on movements, the elderly falls during the level walking (43 %), going in-and-out of a bathroom (30 %), during sitting down and standing up from a seat (13 %), and in ascending and descending stairs (15 %), which are the activities of daily living (ADL) [1]. Many of these falls may be avoided if fall risk assessment and prevention tools where available as an integral part of ADL. However, the fall risk assessment is still not completed at this moment. Currently, active protecting devices for fallers are developing to protect fallers' body from severe injuries as an alternative or for a practical purpose. For these developments, the exact detection of falling is important for active control of the protecting devices. Since the falls involve very complex body movements, a precise detection of the fall events is very challenging task, particularly for industrial applications. In this study, a methodology for detecting the falling events is proposed using an accelerometer and a gyro-sensor for an active protecting device from the falling injuries.

METHODS

21 male subjects participated in the experiment for falling data. The 3D accelerometer (LIS3DSH, ±16 g, 0.73 mg/digit; STMicroelectronics, Switzerland), gyro-sensor (L3G4200D, ± 2000Deg/sec, 70mdps/digit; STMicroelectronics, Switzerland), and compass (HMC5883L, ± 8 Gauss, 5 milli-gauss; Honeywell Solid State Electronics Center, USA) put on the sacrum of the subjects for the falling experiments during the level walking, sitting down, and in ascending and descending stairs. In addition, the 3D kinematics of the lower limbs and upper body during the locomotion or movements were measured using a stereo photogrammetric system (Motion Analysis System, USA). The data from the sensors were wirelessly transmitted by using RF (nRF2401+, 2.4GHz). For applications to an active protecting device, the falling detection must be precisely performed just after the start of falling event, which a faller cannot returned to the balanced posture. For the falling detection, the accelerations, angular velocities, and angle at the sacrum, thus pelvis, were used. Based on the resultant acceleration as depicted in Fig. 1 (a), a falling event could be classified as the Fall 1; the period from the start of fall to the lowest peak, and the Fall 2; the period from the lowest peak to the impact. For the perfect protection of faller's body, the detection should be fulfilled within the Fall 1. At the same time, the detection must be capable of discerning real fall from movements in ADL. In this study, the experimental data collected from ADL such as the level, slope, and stair gait, as well as the sit down and up motions were statistically analyzed to obtain falling criteria. The falling criteria were determined based on the superior-inferior and resultant accelerations, pelvic tilt and obliquity angles, and resultant angular velocity. The signals from the sensors were processed for the reduction of moving artifacts and random noises. Then, the onset of fall using the criteria was detected after applying a triple threshold algorithm [2].

RESULTS

After analyzing the data collected from movements in ADL, the resultant acceleration at the sacrum could detect the falling almost all movements such as in the level, stair, slope, and sit up and down, except those in running. The pelvic tilt, superior-inferior acceleration, and resultant angular velocity could discern real fall from all movements in ADL except in sit up and down, and lay down. For the level walking, the falling onset time was faster than the lowest peak point as much as 0.105 sec. In addition, the falling onset time by the bump trap was earlier than the lowest peak point as much as 0.329 sec (Fig. 1 (b)). In general, the falling onsets by applying all perturbations were detected before the lowest peak points for all movements in ADL situations. The detections were accurate more than 99.9 % in ADL based on the field experiments, which were performed for the elderly in a retirement home.



(a) (b)

Fig. 1 (a) Definition of fall and (b) a fall detection result

CONCLUSIONS

The applied fall detection sensor network and algorithm could detect the onset of fall with an excellent accuracy before the impact in ADL. However, further research is required for the detecting capabilities for the non-ADL situations.

P343 - A PILOT STUDY OF GAIT INTENTION DETECTION FOR TRANSFEMORAL AMPUTEES

[1]**Taekyeong Lee**, [1]Youngho Lee[1], [1]Jaemin Kim, [1]Soonmoon Jung, [1]Dongwook Yang, [1]Jeongwoo Lee, [1]Beomgeun Jo and [1]Junghwa Hong[#]
[1]Department of Control and Instrumentation Engineering, Korea University
Corresponding author email: hongjh32@korea.ac.kr

INTRODUCTION

Recently advent power knee prostheses mainly for assisting transfemoral amputees' gait require capabilities in ascending and descending stairs and slopes. As a result, the power knees could adapt or change powered mechanisms for depending on the level, stair, and slope. For adaptations, the power knees should acknowledge the walking environments. Therefore, the knee prostheses should know gait intentions of transfemoral amputees. Since EMG activities of transfemoral residual muscles such as the rectus and bicep femoris have correlations with the hip moments of the transfemoral amputees [1], it could be closely related to the user's gait intention. Thus, EMG activities of the residual rectus and bicep femoris could be utilized for detecting gait intentions of the above-knee amputees. However, the EMG activities in the thigh stump of transfemoral amputees have strongly different individual characteristics. As a result, a detecting gait intention requires an intelligence for training each individual EMG patterns. The purpose of this study is to develop a detection method using an adaptive filter and a time-delayed neural network (TDNN) to detect gait intentions based on the surface EMG (sEMG) from the residual rectus and bicep femoris of transfemoral amputees' gait.

METHODS

2 male transfemoral amputees were participated in the experiment. Based on the research [1], sEMG signal was acquired on the residual muscles (rectus femoris and biceps femoris) and the same muscles of the sound leg during transfemoral amputees' gaits. 3D motion and sEMG data were measured using a specially designed wireless sEMG instrument with thin fabric electrodes (safely located between the stump skin and inner of socket) and using a stereo photogrammetric system (Motion Analysis System, USA). The consecutive gait test was composed of 3 states, which were a level walking, slope ascending, and descending states. A rate of inclination of slope was 1/12. Tests were performed a total of 4 times for each subject. The collected sEMG signals were digitally filtered to remove noises and motion artifacts. Then, the features of the sEMG were extracted before the classification processes. The classification was divided two distinct phases, the training and prediction phases. The sEMG amplitudes were estimated using an adaptive filter to estimate the coefficients of AR (autoregressive) model for rejecting the noise effects such as motion artifacts and additive noise.[2,3] The estimated sEMG signals were used for the TDNN input data in training part for a prediction of gait state. A classification of a gait state was performed utilizing a nearest-neighbor classifier based on the distance weighting. After the classification, a prediction of gait state was processed using the TDNN. A predictive object for training was the sEMG from the sound leg because the object of the algorithm was to resemble the prosthetic leg motions to the motions of sound leg.

RESULTS AND DISCUSSION

In this study, a gait state was predicted using sEMG signal that was adjusted the adaptive filter, and then applied to TDNN. The estimated sEMG signals using the adaptive filter were fitted well to the real or measured sEMG signals without amplitude losses. Fig. 1 shows the results of filtered sEMG, prosthetic knee angle, sound knee angle, and prediction of gait state. After applying TDNN, the time delay was 24ms. However, the trained sEMG predicted a gait state by the predictive accuracy 92.3%.

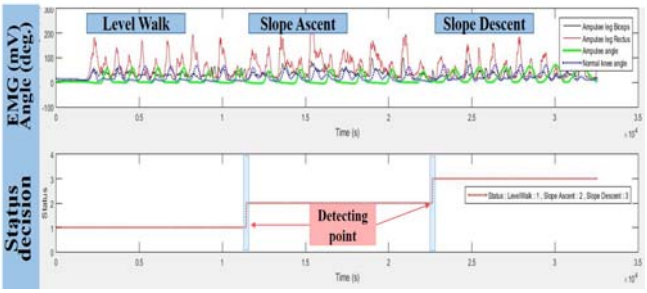

Figure 1: A prediction of transfemoral gait state

CONCLUSIONS

In this study, a method using adaptive filter and TDNN algorithm was applied to predict in a transfemoral gait state from the measured sEMG. The prediction was successful, but more accuracy for the prediction is required for a practical application. To do that, more measured sEMG from the other residual muscle locations would be required for future research.

P344 - USING KINECT SENSORS FOR DETERMINING FUNCTIONAL REACH VOLUME AS AN UPPER-EXTREMITY FUNCTIONAL OUTCOME MEASURE

[1] Kevin J. McQuade, [1]Renshu Gu and [1]Jenq-neng Hwang[3]
[1]University of Washington, Seattle WA. 98195 ,USA
Corresponding author email:kmcquade@uw.edu

INTRODUCTION

The search for low cost markerless motion capture alternatives to multi camera lab based methods has led many researchers to explore the use of Microsoft's kinect sensors technology [1-3]. Because the kinect system does not have the kinematic accuracy of traditional multi-camera motion capture systems [4] it has mainly been employed as a qualitative biofeedback tool for rehabilitation Based on the international classification of impairment, function, and disability (ICF) model however, exact kinematics may not be as important as functional performance metrics. For the upper extremity, the Functional Reach Volume (FRV), or reachable workspace, is a metric that can easily be obtained using a kinect approach and provides a more functional representation of a persons overall functional reaching capacity as an outcome measure for post-surgical or rehabilitative assessments. Such a metric could provide an in-clinic solution so that therapists can quickly and effortlessly obtain an objective examination of upper-extremity functional movement limitations by determining a patient's FRV or reachable workspace.

METHODS

As proof of concept experiment, both a single kinect II sensors and an 8 camera Qualysis system were used to determine the FRV for a subject moving their arms in a space that represented the volume of a cube.

We then simulated upper extremity impairment by asking a physical therapist familiar with movements of patients with shoulder problems, to move his left arm in a manner to mimic movements of a patient with a painful shoulder and decreased motion. A series of movement tasks were performed with the subject attempting to make full circles in the frontal, sagittal, and transverse planes. The subject repeated test movements with their unimpaired "healthy" side with no restrictions. These movements were performed for three trials using no external load and three trials using a hand load of 2 Kg to simulate an additional movement constraint

Kinect data was collected using Kinect 2.0, pairing with Kinect SDK v2.0. Skeletal joints were exported to a Matlab program that calculated the Functional Reach Space (FRV) by calculating the volume of convex hull of the hand movement trace.

RESULTS AND DISCUSSION

In our pilot test, the calculation of the FRV between the two methods showed that the FRV calculated from the kinect 0.0355 m^3 for left arm test movement and 0.1030m^3 for the right arm movement. These values calculated using the Mocap cameras were 0.0372m^3 and 0.1027m^3 respectively. This indicates 95% to 99% agreement and suggests good initial criterion based validity of the method.

The simulated impairment test, comparing both unweighted and weighted arm movement, the impaired arm reaching capacity was only 59% and 73% respectively of the reach capacity of the uninjured arm. The visual difference in the FRV can be seen in figure 1. The pilot test also confirms total reaching volume symmetry when there is no simulated impairment between left and right sides.

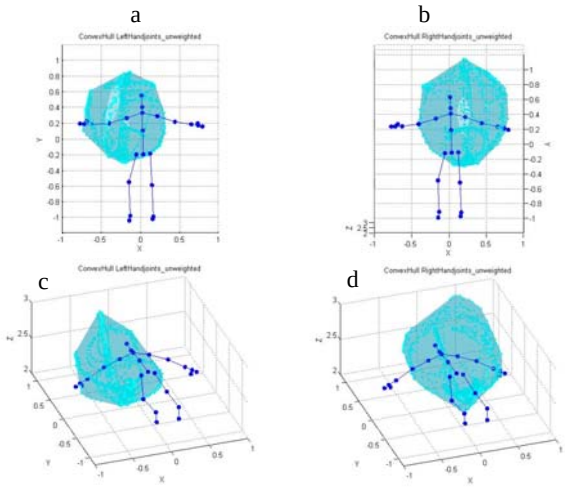

Figure 1 General representation of the FRV calculated using the convex-hull method in Matlab. (a)&(c)=Impaired, two different views. (b)&(d) = unimpaired, two different views. Data : Impaired FRV 0.4866 m^3, Unimpaired FRV =0.8275 m^3

CONCLUSIONS

Our preliminary results demonstrate that the use of a summary movement index such as the FRV may be a quick and easy functional metric for overall arm reaching capacity under different conditions. Future studies will test patients with specific shoulder pathologies and will correlate FRV to self–report functional scales such as the DASH and the SPADI.

P345 - BIOMECHANICAL INVESTIGATION METHODS OF QUAD BIKE FATALITIES

[1,2,3]Andrew S McIntosh and [1]**Declan A Patton**

INTRODUCTION

Deaths arising from quad bike use in Australia reached a critical point in the recent past, which demanded evidence to inform safety policy and practice. The authors were engaged to undertake a study of the mechanisms of injury and death in fatal quad bike cases as part of the larger Quad Bike Performance Project (QBPP). At that time there was knowledge that death by asphyxiation occurred as a result of rollover crashes [1]; however, the circumstances of crashes and potential survivability was unknown. The authors undertook an in-depth review of fatal cases extracted from the Australian National Coronial Information System (NCIS), which was published in 2016 [2].

METHODS

Institutional ethics approval was obtained in addition to approval from the Victorian Department of Justice Human Research Ethics Committee (JHREC) and the Western Australia Coronial Ethics Committee (WACEC). Once NCIS access was obtained, the database was searched using two strategies and a list of unique cases was compiled. The first search strategy involved a Boolean combination of search terms, e.g. 'quad bike', 'quadbike', 'quad-bike', 'ATV', 'all terrain', 'all-terrain', 'off road', 'off-road' and 'vehicle'. The second search strategy involved selecting pre-existing categories and descriptions, e.g. category 1, ‘mobile machinery or special purpose vehicle’; category 2, ‘other mobile machinery or special purpose vehicle’; description, ‘special all-terrain vehicle/off-road vehicle, quad bike’.

For each case, the NCIS included varying combinations of the police report, autopsy report, toxicology report and the coroner’s findings; however, the level of detail in each document varied between cases, e.g. police reports ranged from single sentence summary to a detailed narrative description. Through written requests to the coroners’ courts in all states and territories, the full brief of evidence for each case was viewed and/or as per the prevailing laws.

Table 1: Coded fields from the full brief of evidence.

Topic	Fields
Demographics	Gender; Age; Stature and Body Mass; Recreational or Work-related; Specific activity; Industry (work-related); Helmet
Vehicle	Type (quad bike, side-by-side, other); Make; Model; Engine Capacity; Build Year; Attachments at time of incident; Operator protection device installed
Environment	Terrain; Ground cover; Slope; Collision partner
Crash	Initiator; Rollover; Speed; Roll characteristics; Free text
Injury	Cause of death (region, nature and main mechanism); Pinning of operator; Injuries by body region and anatomical part; MAIS coding of cranium, cervical spine, thorax and abdomen [3]; Asphyxia; Mechanisms of main injuries; Free text

Specifically, the relationships between the operator demographics, vehicle, environment, crash characteristics, injuries and cause of death were investigated by extracting and coding data from the available files (Table 1).

RESULTS AND DISCUSSION

Initially, 141 closed cases were identified; however, 35 cases were excluded from further analysis [2]. The remaining 106 comprised 53 work-related cases and 53 recreational cases. For work-related cases, riders were typically pinned under the quad bike (68%) after a rollover incident (85%) and died by asphyxiation (42%). In many of such cases, the impact trauma sustained by the rider was moderate and survivable, e.g. a small number of fractured ribs; however, the weight of the vehicle pinned and asphyxiated the rider.

In contrast to work-related cases, recreational riders typically suffered complex impact injuries to the head and thorax, which occurred after the rider was travelling at high speed, lost control, was ejected and collided with an object and/or interacted with the moving quad bike.

CONCLUSIONS

The biomechanical investigation was successful in identifying the different characteristics of recreational and work-related cases of quad bike fatalities and unique operational and safety requirements. Through this investigation and work by others on quad bike stability and handling, the QBPP team was able to identify safety interventions.

ACKNOWLEDGEMENTS

The QBPP was funded by the Workcover Authority of New South Wales and the Australian Consumer and Competition Commission (ACCC) and supported by WorkSafe New South Wales and the Heads of Workplace Safety Authorities (HWSA).

The QBPP was directed by Professor Raphael Grzebieta at Transport and Road Safety (TARS) Research, University of New South Wales.

The authors gratefully acknowledge the Victorian Institute of Forensic Medicine (VIFM), NCIS liaison officers, state coroners and court staff members.

P346 - ASSESSMENT OF THE IMPACT OF THE PARACHUTE RESCUE SYSTEM TO REDUCE THE RISK OF INJURY TO THE CREW IN CASE OF EMERGENCY LANDING GYROPLANE

INTRODUCTION

The goal of the study was assessment of dynamic effects of deployment of parachute rescue system (PRS) for a small gyrocopter in emergency situations. Besides the structural response of an aircraft (that is not described in this paper) the special area of interest was pilot/passenger injury risk assessment in a number of different flight and landing scenarios, depending on assumed initial conditions (loads and configurations at the time of deployment the PRS).

METHODS

Computer simulation was the main method used in this study. The numerical simulations were run using both Finite Element (FE) analysis (MSC.Nastran [1]) and Multi-Body (MB) approach (MADYMO [2]). FE model was used mostly for prediction of the transient dynamic response of the aircraft while the biomechanical analyses, both during the period of deployment of the PRS as well as during the period of contact with the ground, were conducted using a multi-body model (Figure 1). Some results of FEM simulations were used as input to MB simulations. The pilot and passenger were represented by the 50-percentile Hybrid III FAA dummies [3].

Figure 1: Multi-body model of the analysed gyrocopter with two occupants (Hybrid III FAA dummies).

RESULTS AND DISCUSSION

In order to test the loads transmitted to the body of the pilot/passenger during collision with the ground, a series of simulations was performed in which the gyroplane collides with the ground. The calculations were performed for many variants of initial conditions, which differ from each other by vertical speed with which the machine hits the ground.

From the point of view of the considered aircraft equipped with the PRS, the most interesting was the variant with vertical speed at impact time v_v=23km/h (6.4m/s), the maximum speed of descent of the aircraft equipped with such system for chosen type and size of a parachute. In this case the loads registered on the structure of the gyroplane do not exceed maximal allowed values, e.g. despite the considerable force impacting the undercarriage, it remains undamaged, cushioning the hit until its very end.

The main quantities characterizing the dummy loads are the acceleration of the centre of gravity of the head (the biggest value of acceleration peak in the duration time of 3ms, a_{h3ms}), HIC_{36} [4], compression force in the lumbar spine (F_s), the acceleration of the chest (a_{ch}), pelvis (a_p) and the compression force in the femur (F_f).

The obtained results allow concluding that for v_v=23km/h (emergency landing with fully deployed PRS), the risk of serious head injuries is minor: a_{h3ms}=35g (tolerance level=75g), HIC_{36}=55 (t.l.=1000). Also the acceleration of the chest (a_{ch}=40g), pelvis (a_p=54g) and the compression force in the femur (F_f=2,8kN) are below tolerance levels (respectively: 60g, 60g and 7.85 to 9.07kN). The maximum compressing axial force at the lumbar spine reaches the value of F_s=9.1 kN that exceeds to some extend the limit considered to be “safe” (tolerance level) equal to 6675 N (1500 lbf) [4] (minor to moderate risk of injury to the spine).

In case of the gyroplane without the PRS emergency landing, loads acting on the crew are much higher. For example, when the aircraft hit the ground with the vertical speed v_v=54 km/h, only the HIC_{36}=330 do not exceed the limit and a_{h3ms}=74,7g is very close to its limit. Analysing other body loads, such as a_{ch}=129g and a_p=128g, it can be concluded that they exceed by twofold the limit values. The maximum axial compressing force at the lumbar spine reaches the value of F_s=19kN (approx. 3 times the tolerance level). This leads to the conclusion that in this case, very serious (probably fatal) damage to the spine is almost certain.

CONCLUSIONS

Results of performed simulation studies and research on scaled hardware models confirms that the proposed rescue system can fulfil its role in accordance with expectations and contribute to a significant reduction in the risk of serious (or fatal) injury of pilots/passengers as well as limit destruction of the gyroplane.

P347 - THE EFFECT OF ANTERIOR CRUCIATE LIGAMENT RECONSTRUCTION IN HIGH-FUNCTIONING PATIENTS DURING DEMANDING DYNAMIC TASKS

[1]**Kenneth B Smale**, [1]Teresa E Flaxman, [2]Tine Alkjaer, [2]Erik B Simonsen, [3]Michael R Krogsgaard, and [1]Daniel L. Benoit

INTRODUCTION

Studies examining anterior cruciate ligament (ACL) injured populations have come to varying conclusions in regards to the muscle activation and biomechanical strategies employed through a variety of tasks. This could be attributed to treating the variables as discrete values and/or cross-sectional designs. The purpose of this study was to evaluate neuromuscular and biomechanical movement strategies implementing by high-functioning ACL injured patients. This purpose was achieved by comparing the patient-related outcome measures (PROMs), muscle activation and biomechanical properties of healthy controls (CON), ACL deficient (ACLd) patients and these patients 10 months post-reconstruction (ACLr) by using a time-sensitive statistical method.

METHODS

The 20 patients who were tested in the ACLd and ACLr state were matched to 20 healthy control participants. Upon arrival, all participants completed PROMs (KOOS, KNEES-ACL, IKDC, Tegner, and Lysholm) and then performed 3-5 successful jump lunge and side cut maneuvers. Whole-body kinematics were collected with a 10-camera system (Vicon, UK), ground reaction forces (GRF) with a force plate (AMTI, USA), and electromyography (EMG) with a ten-channel system (MQAir, Denmark).

Linear envelopes and GRFs were quantified through MATLAB (Mathworks, USA) while scaling, inverse kinematics, and inverse dynamics were performed based on the Rajagopal model [1] using a MATLAB-OpenSim (Simtk, USA) interface.

Differences in PROMs were tested for significance using independent (CON vs ACLd, CON vs ACLr) and dependent (ACLd vs ACLr) T-tests using SPSS (IBM, USA). Differences in linear envelopes; GRFs; hip, knee, and ankle sagittal plane angles and moments were tested for significance using independent (CON vs ACLd, CON vs ACLr) and dependent (ACLd vs ACLr) T-tests using statistical parametric mapping through MATLAB. Alpha was corrected for multiple comparisons, which made significance determined by p-values < 0.025.

RESULTS AND DISCUSSION

All PROMs showed significantly greater functionality scores for CON compared to both the ACLd and ACLr. Compared to the ACLd, ACLr reported higher functionality in all PROMs except the KOOS-Symptoms, KOOS-Pain, and KOOS-Activities of Daily Living.

No differences between all three groups in EMG linear envelopes were observed during the side cut while during the jump lunge, ACLd had a greater medial gastrocnemius activation than CON between 91-103ms (p=0.018) post-contact and ACLr had a greater biceps femoris activation than CON 239-300ms post-contact (p<0.001).

The medial GRF during the side cut indicated CON had a greater medial force mid to late stance compared to both ACLd and ACLr, while ACLr had a greater medial GRF in early stance compared to ACLd.

No differences in sagittal hip, knee, and ankle angles were observed during the side cut (Figure 1) while the knee was observed to be significantly less flexed in the ACLr compared to CON from 84-196ms post-contact in the jump lunge (p=0.007).

The knee extensor moment was significantly greater for the CON group compared to both injured groups in the side cut (Figure 1) and jump lunge.

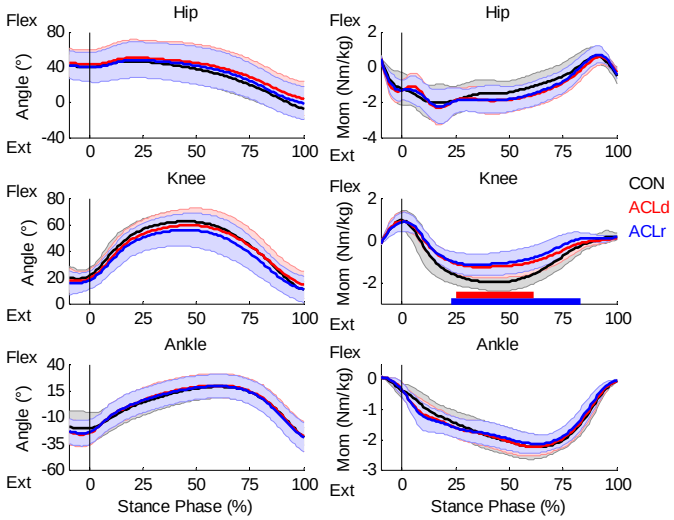

Figure 1: Sagittal plane angles and moments during the side cut movement. Black vertical line represents time at contact; red horizontal bar represents significance between CON and ACLd; and blue horizontal bar represents significance between CON and ACLr.

CONCLUSIONS

With the application of this test-retest design, it was found that ACL injury is associated with lower scores in subjective stability/functionality, changes in muscle activations and movement characteristics. After reconstruction, patients report significantly improved functionality from their ACLd state although these changes were not reflected in their muscle activations and movement profiles. These findings suggest that in high-functioning ACLd patients, ACL reconstruction may improve their self-reported function; however, no changes are observed in their neuromuscular and biomechanical measures. Therefore, rehabilitation programs may be improved by having return to play standards set based on high-functioning patients rather than healthy, uninjured standards that even after reconstruction, high-functioning, self-confident patients fail to achieve.

P348 - PREPARATORY TRUNK ANGULAR MOMENTUM PREDICTS ACL INJURY RISK DURING SIDESTEPPING

[1]Jonathan M D Staynor, [1]Jacqueline A Alderson, [2]Jeffrey A Reinbolt, [1]Marcel Rossi and [1]Cyril J Donnelly
[1]University of Western Australia
[2]University of Tennessee

INTRODUCTION

Simulation research has shown that lateral positioning of the whole-body center of mass is an important factor influencing peak knee valgus moments (PKVM) and associated anterior cruciate ligament (ACL) injury risk, during unplanned sidestepping [1]. The trunk is the heaviest body segment, with the greatest individual-segment impact on whole-body center of mass. Experimental research has observed associations between weight acceptance (WA) trunk kinematics and ACL injury risk [2], which is important given peak injury risk occurs during WA [1]. However, there is at least a 25ms electromechanical delay in muscle force production [3], limiting the opportunity for the neuromuscular system to modulate trunk position within the WA time frame (20-30ms). It is probable that preparatory trunk segment mechanics during the flight phase prior to WA, influences subsequent WA kinematics and ACL injury risk. The aim of the current study was to investigate the influence of preparatory trunk angular momentum ($\mathbf{H}_T$) on PKVM during the WA phase of unplanned sidestepping. It is hypothesized that multi-planar preparatory $\mathbf{H}_T$ will predict PKVM during WA.

METHODS

Eighteen male participants (22±5yrs, 1.85±0.06m, 80±10.0kg) completed an established unplanned sidestepping protocol [1]. Kinematic and kinetic data were collected as part of another study [1], and low pass filtered at 14Hz. A participant specific skeletal model [1] and anthropometric segment inertial parameters [4] were used to estimate 16 body segments and whole-body center of mass position. PKVM during WA were calculated via inverse dynamic procedures [2] and normalized to participant mass and height (kg.m). Segmental angular momentum ($\boldsymbol{H}_{seg}$) was calculated about the whole-body center of mass for the head, thorax, middle torso and lower torso segments during the flight phase (toe-off to one frame before landing) prior to WA:

$$\boldsymbol{H}_{seg} = (\boldsymbol{CM}_{seg} - \boldsymbol{CM}_{WB}) \times m_{seg} (\boldsymbol{V}_{seg} - \boldsymbol{V}_{WB}) + \mathbf{I}_{seg}\boldsymbol{\omega}_{seg} \qquad (1)$$

Where *seg* refers to the segment, *WB* to whole-body, ***CM*** to center of mass, *m* to mass, ***V*** to velocity, **I** to moment of inertia and $\boldsymbol{\omega}$ to angular velocity. $\mathbf{H}_T$ was calculated by summing the angular momentum of the head, thorax, middle torso and lower torso segments and normalized to participant mass, height and approach velocity ($kg.m^2.s$).

Using 80% of the trials (n=49) a linear mixed model was implemented to predict PKVM from three-dimensional preparatory $\mathbf{H}_T$. Participants were modelled as random factors to account for within-subject variability. Independent variables were mean single plane $\mathbf{H}_T$ (frontal, sagittal and transverse), and were removed from the model manually in order of highest *p* value until all remaining independent variables were significant (α=0.05). The regression model was externally validated against the remaining 20% of the trials (n=12) using a paired samples t-test and Cohen's *d* effect size to compare predicted vs measured PKVM.

RESULTS AND DISCUSSION

Sagittal plane $\mathbf{H}_T$ did not significantly correlate with PKVM ($p \geq 0.05$), and was removed from the model. Significant correlations were found between frontal, and transverse plane $\mathbf{H}_T$, and PKVM (Table 1). The regression equation was deemed capable of predicting PKVM as there was no significant difference ($p \geq 0.05$) between predicted (0.63±0.21) and measured (0.65±0.29) moments, with differences shown to be small in effect size (d=0.10). This observation suggests that multi-planar $\mathbf{H}_T$ were capable of predicting PKVM and ACL injury risk during unplanned sidestepping.

Table 1: Parameter coefficients (β) and standard error (SE) for significant H_T predictors of PKVM.

Parameters	β	SE	p
Intercept	0.57	0.07	<.001
Frontal H_T	-177.37	46.38	<.001
Transverse H_T	461.93	137.86	.002

Increases in frontal $\mathbf{H}_T$ (e.g. momentum acting to laterally flex the trunk towards the change of direction) were negatively correlated with PKVM. This is in agreement with experimental research which reported increased PKVM with increased peak lateral trunk flexion away from the change of direction during WA [2]. Increases in transverse $\mathbf{H}_T$ (e.g. momentum acting to rotate the trunk towards the intended change of direction) were positively associated with PKVM. It is possible that preparatory $\mathbf{H}_T$ in the transverse plane requires an athlete to adopt kinematic postures during WA, such as a wide lateral foot placement [2], that are associated with high PKVM. This rationale is currently speculative and is being investigated within a larger sample size (n=40).

CONCLUSIONS

The current study has established a link between preparatory $\mathbf{H}_T$ and PKVM during the WA phase of unplanned sidestepping. These findings provide a rationale to investigate how an athlete's preparatory mechanics influences ACL injury risk during non-contact movement.

P349 - ANKLE TAPING ALTERS HIP AND PELVIS KINEMATICS DURING GAIT IN INDIVIDUALS WITH CHRONIC ANKLE INSTABILITY

Michelle Smith[1], Drew Button[1], Hayden Cook[1], Wolbert van den Hoorn[1], **Kylie Tucker[2]**
[1]The University of Queensland
Corresponding author email: k.tucker1@uq.edu.au

INTRODUCTION

Ankle sprains are a prevalent problem, particular in young individuals who participate in sport [1,2]. Nearly 3/4 of individuals who sprain their ankle, experience recurrent sprains and go onto develop chronic ankle instability [3,4].

Ankle taping is an effective practice used to minimise the incidence and severity of lateral ankle sprain in sport, particularly in individuals who have a history of previous ankle sprain [5]. Application of tape is associated with reduce ankle plantarflexion and inversion range of motion (ROM) [e.g. 6,7]

Consistent with that observed with foot orthotics [8], it is likely that ankle taping may affect kinematics of other lower limb joints. Altered proximal lower limb kinematics has been identified as a risk factor for musculoskeletal injury [9]. The aim of this study was to determine if ankle taping alters knee, hip and pelvic joint kinematics during walking.

METHODS

Twenty individuals (15 females, 5 males; 25.2 (8.7) years; 23.8 (4.0) kg.m^2 BMI) were recruited with mild-moderate chronic ankle instability. Respondents were screened for chronic ankle instability using criteria from the International Ankle Consortium [10].

Participants walked on a treadmill at a speed of 4.5 km/h with and without application of ankle tape [Figure 1].

Figure 1: Closed basketweave tape was applied to the ankle assessed as having (greatest) chronic ankle instability.

A 10-camera Optitrack system was used to collect 3D angular kinematics. Data were extracted from 30 strides that began 60 seconds after the commencement of each trial.

Peak ROM and total ROM for ankle plantarflexion and dorsiflexion, knee flexion and extension, hip flexion and extension, hip abduction and adduction, and hip internal and external rotation were calculated for the affected/taped limb.

Peak and total ROM for pelvic movement in the sagittal plane (anterior and posterior pelvic tilt), transverse plane (left and right rotation), and frontal plane (left and right obliquity) were also calculated.

RESULTS AND DISCUSSION

There was no change in stride time between conditions ($p=0.09$). Ankle taping had a significant effect on kinematics at the ankle, hip and pelvis. Specifically, hip flexion-extension ROM, peak hip extension and transverse pelvic ROM was decreased when walking with tape compared to without tape (all, $p<0.02$). The application of tape was associated with small increases in abduction-adduction and internal-external hip rotation ROM, and an increase in peak hip internal rotation (all, $p<0.04$). As expected, tape significantly reduced peak plantarflexion and dorsiflexion- plantarflexion ankle ROM ($p<0.001$). No changes in knee kinematics were observed with tape ($p>0.37$).

CONCLUSIONS

This is the first study to investigate the effect of ankle taping on kinematics of the entire lower kinetic chain during gait in individuals with CAI. Kinematic changes during ankle taping are not isolated to the ankle, but also occur at the hip and pelvis. Changes in hip extension and transverse pelvic rotation likely occur due to decreased plantarflexion in terminal gait. Other kinematic changes at the hip (increased frontal and transverse plane hip motion) may occur to compensate for a reduction in multi-planar ankle ROM associated with the application of tape.

Whether longer-term consequences are associated with the small changes in proximal lower limb kinematics observed during ankle taping is not known. It is possible that kinematic changes may lead to altered joint loading and increased risk of injury.

ACKNOWLEDGEMENTS

Strapit Sports Elite (Australia) provided the rigid strapping tape for this study. Strapit Sports Elite had no role in the study design; collection, analysis and interpretation of data.

P350 - EFFECT OF LANDING HEIGHT ON ACL LOADING DURING UNILATERAL LANDINGS

Joshua T. Weinhandl, Onyebuchi N. Okereke, and Ashley N. Grillo
University of Tennessee, Knoxville
Corresponding author email: jweinhan@utk.edu

INTRODUCTION

Anterior cruciate ligament (ACL) injury is one of the most debilitating and costly lower extremity injuries experience by athletes [1]. It has been shown that 70% of ACL ruptures occur in a noncontact situation, specifically during rapid decelerations of the body's center of mass [2].

A number of studies have examined the ground reaction forces (GRF), lower extremity kinematics and kinetics during unilateral landings, comparing between genders and between landing heights. Yeow [3] reported an increase in landing height elevated the peak vertical GRF and increased initial contact knee extension. Gender-wise, women have been shown to land with greater peak posterior GRF and peak knee adduction moment compared with men [4]. These combined results indicate that women land stiffer than men and that landing stiffness increases as landing height increases. While landing stiffness is related to ACL loading [5] there is still a lack of understanding on how increases in landing height influences ACL loading in men and women. Therefore, the purpose of this study was to compared ACL loading during unilateral landings from two heights in men and women.

METHODS

Forty-two recreationally active women (60.9 (8.6) kg, 1.64 (0.06) m) and forty-two recreationally active men (81.4 (15.2) kg, 1.79 (0.07) m) volunteered to perform unilateral landings on the right leg from 30 cm (D30) and 50 cm (D50). Prior to data collection, participants were informed of study procedures and provided written informed consent in accordance with institutional guidelines. Three dimensional marker coordinate data were collected at 200 Hz using an eight-camera Vicon motion analysis system. Synchronously, three-dimensional force data was collected at 1000Hz using a Bertec force plate.

A participant-specific musculoskeletal model was then generated in OpenSim [6] consisting of 21 degrees-of-freedom (*dof*). The left leg was actuated by joint torque actuators, while the right leg and back were actuated by 43 Hill-type muscle actuators. Pelvis position and orientation relative to the ground was defined with 6-*dof*. The head, arms and torso were represented as a rigid segment connected with the pelvis by 3-*dof*. Each hip was modeled as a 3-*dof* ball-and-socket joint. The left knee was modeled as a 1-*dof* revolute joint, while the right knee was modeled as a 3-*dof* joint. Both ankles were modeled as 1-*dof* revolute joints. Static optimization was used to calculate the muscle forces required to reproduce the joint moments of each trial. The optimization minimized the sum of muscle activations to distribute muscle forces. Simulated knee joint reaction forces and moments along with hamstrings, quadriceps and gastrocnemius muscle force estimates were input into a three-dimensional knee model to estimate ACL loading [7].

A 2×2 repeated measures ANOVA was used to assess differences in peak ACL force (pACL) between D30 and D50 trials and between men and women. Other variables of interest included timing of peak ACL force (tACL), as well as sagittal ($pACL_s$), frontal ($pACL_f$) and transverse ($pACL_f$) plane ACL loading at pACL. Significance for all tests was set at $p < 0.05$.

RESULTS AND DISCUSSION

There was a 3.9 $N \cdot kg^{-1}$ increase in peak ACL loading as landing height increases. This was due to a significant increase in sagittal plane ACL loading of 3.5 $N \cdot kg^{-1}$. Transverse plane ACL loading also significantly greater during D50 compared to D30 landings; however, this was only a 0.2 $N \cdot kg^{-1}$ increase. Finally, peak ACL loading occurred 15 ms earlier during D50 landings. There were no gender differences observed for any of the variables.

Table 1. Mean (STD) peak ACL loading ($N \cdot kg^{-1}$), timing (ms), and planar components during unilateral.

	D30		D50	
	Men	Women	Men	Women
pACL*	11.5 (4.9)	11.3 (4.0)	15.2 (6.7)	15.4 (4.3)
tACL *	38 (17)	37 (23)	27 (18)	20 (14)
$pACL_s$ *	9.0 (4.2)	9.1 (3.1)	12.2 (5.7)	12.8 (3.9)
$pACL_f$	2.0 (1.2)	1.8 (1.8)	2.4 (1.9)	2.0 (1.3)
$pACL_t$ *	0.5 (0.3)	0.4 (0.2)	0.6 (0.4)	0.5 (0.4)

* Significant main effect for landing height ($p < 0.05$).

CONCLUSIONS

The increase in ACL loading as landing height increased was primarily due to the increase in the sagittal plane. Furthermore, sagittal plane load contributed the most to total ACL load at approximately 80%, while the frontal and transverse planes contributed approximately 16% and 4%, respectively.

Interestingly, there were no gender differences observed in ACL loading, regardless of landing height. As women women experience ACL rupture at a higher rate than men during sport participation [1], future studies should attempt to integrate more sport-relevant factors such as unexpected perturbations within in vivo experimental testing environments. Such an approach may provide further insights into causative factors of non-contact ACL injury, facilitating development of more effective and adaptable prevention methods.

P351 - THE EFFECT OF PROXIMAL TIBIOFIBULAR JOINT ANTEROPOSTERIOR JOINT MOBILIZATION ON INCREASING TIBIAL INTERNAL ROTATION IN INDIVIDUALS WITH PRONATED FOOT: A PRELIMINARY STUDY f

[1] **Yu-Ning Cheng**, [1]Tai-En Li, [2]An-Hua Huang, [3]Mark Comerford, [1] Wen-Yin Chen

INTRODUCTION

Pronated foot, defined as the foot with excessive compensatory pronation of subtalar joint and/or mid-tarsal joint during weight-bearing activities [1], is related to biomechanical changes of the lower limbs as well as musculoskeletal injuries at the proximal joints. Previous studies had shown that abnormal pronation results in excessive tibial internal rotation which increased the valgus knee loading [2]. However, this internal rotation is in fact, tibia external rotation relative to the femur in order to compensate for the instability of the lower extremity, a scenario described by Tiberio in individuals with patellofemoral pain [3]. When the tibia constantly locked in the external rotation position, it would loss the range of internal rotation relative to the femur. In the meanwhile, the tensile force vector of the fibular collateral ligament is oriented anteriorly, causing anterior translation of the head of the fibula with restrictionin posterior glide [4]. Mobilization or manipulation of the proximal tibiofibular joints may offer the ability to restore normal joint arthrokinematics, improve impairments, and restore function in individuals with pronated foot.

This preliminary study purpose aimed to determine whether proximal tibiofibular joint anteroposterior joint mobilization could increase tibial internal rotation relative to the femur in individuals with pronated foot.

METHODS

10 participants with low arch (arch height ratio less than or equal to 0.275) were recruited in this study. Participants were exclude if they reported previous lower extremity surgery or injuries in last 3 months.

To assess the tibial internal rotation relative to the femur, participants were measured with a self-made tibial rotation measuring disc while the subjects sitting with the hip, knee and ankle at 90° of flexion. The thigh of the test leg was stabilized firmly with an adjustable femur fixator to prevent hip abduction or adduction. The foot of the test limb was placed on the rotary platform of the measuring instrument with the axis of vertical rotation passing through the midpoint between the medial and lateral malleoli. The medial side of the foot was aligned parallel to the sagittal plane and the second metatarsal was positioned 10 degrees lateral to the sagittal line. This position was defined as the starting position of the neutral rotation. Then, the maximum tibial internal rotation relative to the femur were measured, stopped when the subject starts to invert his/her foot. A total of 3 measurements were obtained and averaged for each subjects.

After baseline data were gathered, the treatment provider performed the anteroposterior joint mobilization on the superior tibiofibular joint. Then, the assessor collected the outcome measurements again.

RESULTS AND DISCUSSION

There was a significant difference in pretest and posttest tibial rotation range (table 1.). The result indicates that anteroposterior joint mobilization on superior tibiofibular joint can sbstantionally increase the tibial internal rotation range up to 60%.

Because abnormal lower extremity biomechanics changes, especially excessive knee valgus has been implicated as the contributing factor to numerous knee pathology, including ACL injury and patellofemoral joint dysfunction [5], we strongly recommend including the assessment and treatment of the proximal tibiofibular joint in individuals with pronated foot. To help correcting the alignment of the lower extremity and to lower the injury risk.

	mean	N	SD	p-value
Pretest	14.86°	10	4.65	0.01
Posttest	24.15°	10	6.33	

Table 1: outcomes of tibial internal rotation relative to the femur measure

CONCLUSIONS

The anteroposterior joint mobilization on superior tibiofibular joint can increase the tibial internal rotation range.

ACKNOWLEDGEMENTS

Special gratitude to those participated in this study and those who helped with recruitment.

P352 - ALTERATION OF CONCUSSION RISK BY NEW AND USED AMERICAN FOOTBAL HELMETS

[1] **Yuelin Zhang**, [1] Satoru Yoneyama, [2] Hiromichi Nakadate, [3] Takayuki Koyama and [2] Shigeru Aomura

INTRODUCTION

American football is known as a kind of contact sports. The head-to-head impact always caused the traumatic brain injury during the game. To protect player from traumatic brain injury, wearing a helmet is obligatory during the game. However, for student sports such as club activity etc., the player is often used one helmet for 2 or 3 years because the high price of the helmet. Therefore, there is concern about deterioration of protection performance due to a change in shape such as scratches, dents, cracks, deterioration of helmet liner. In 1969, safety standards for helmets were established, but the free fall test only preformed 3-5 impacts in the evaluation [1].

According to above, the aim of this study is to visualize the onset of concussion by analyzing accident cases, and to clear the difference in injury risk when wearing a new or a used helmet.

METHODS

Injury assessment system

The injury assessment system consists of two parts, the motion analysis part by mathematical model of whole body, and the evaluation part of intracranial parameters by FE head model with helmet.

At the first part the motion during the accident is reproduced by the whole body mathematical model and the kinematics of the colliding two players is determined. The motion analysis based on the game video is performed by using human models implemented in MADYMO software. The human models of MADYMO are validated against post-mortem human tests (MADYMO Human Body Models Manual 7.5). The posture, acceleration and velocity of the two heads just before collision can be calculated.

At the second part the intracranial mechanical parameters causing the head injury are calculated by FE analysis (LS-DYNA ver.8.0). In the FE simulation, the relative velocities and position of the heads obtained by whole body simulation are input to the helmeted FE human head models as initial condition. Next the head injury risk is evaluated by some indexes previously proposed by other researchers, where these indexes are calculated based on mechanical parameters obtained by FE analysis.

Head-to-head impact accident cases

In this paper, 5 accident cases were analyzed using the above system. As an example of the cases the detail of the case 1 was shown in this report. In the case 1, the injured player is a defensive back player and struck the left side of his head. The athletic trainer of the team promptly removed the player from the game because of a suspected concussion. Due to concerns for an emergent injury, the player was taken to the emergency room, where an appropriate trauma evaluation based on the guideline of American Academy of Neurology 2013 was performed including a head CT, and no remarkable symptom was observed. The player was then diagnosed as a concussion by the medical team doctor.

The injury risks were evaluated by wearing a new or used helmet model of the FE simulation. The impact properties of the new and used helmet were identified by using the free-fall experiment of the helmets, and the used helmet was used for one and a half years. The human head FE model was constructed using MRI data of a man and validated against the experiments of post-mortem human [2].

RESULTS AND DISCUSSION

The injury risks[2] based on accelerations of the head caused by the impact, a maximum linear acceleration (A_{max}) or rotational acceleration (α_{max}), SI, HIC, RIC and GAMBIT, and the maximum value of strain, strain rate and von Mises stress inside skull were calculated (Figure 1). The results of all cases shown that the risks when wearing a new helmet were lower than wearing a used one. From the results of the impact FE analysis, the new helmet was deformed more and absorbed the impact energy than the used one.

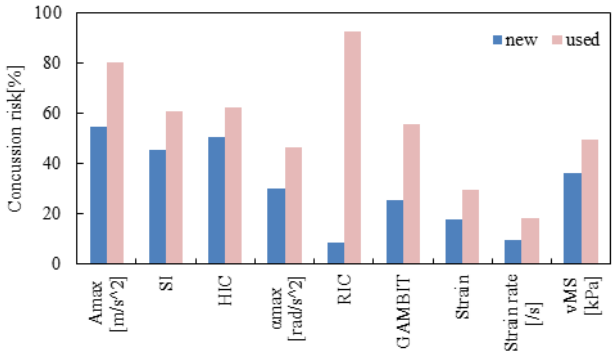

Figure 1: Concussion risk estimation results of the accident case 1.

CONCLUSIONS

In order to clear the alteration of concussion risk by new and used American football helmets, 5 accident cases of the head-to-head impact during the game was replicated using the proposed brain injury assessment system. The results shown that the new helmet has better protection capability to the head impact than the used one. As the future works, it is necessary to verify this trend by analyzing more cases and other types of helmets.

P353 - ATLANTO-AXIAL FACET JOINTS DISPLACEMENT DURING REGIONAL MOBILISATION INTO ROTATION: IN VITRO 3D KINEMATIC ANALYSIS.

Luca Buzzatti, Erik Cattrysse
Vrije Universiteit Brussel, Belgium, KIMA-Department, Experimental Anatomy Research Group
Corresponding author email: Luca.Buzzatti@vub.ac.be

INTRODUCTION

Extensive literature has been published on upper cervical spine and in particular on atlanto-axial joint kinematics. However the majority of the studies have just investigated the amount of rotation around the three axes of movement (XYZ). For this reason very little information is available about facet joints displacement during active or passive movements. C1-C2 facet joint surfaces lose more than 70% of contact area in healthy subjects [3,4]. Duan et al. (2007) [2] reported an absolute facet displacement approximating 7.7 mm during active head rotation in supine position of healthy in vivo subjects. Buzzatti et al. (2015) [1] showed a mean 3D atlanto-axial facet joints displacement of 6 mm during the execution of a High-Velocity Low-Amplitude manipulation.
The aim of this study was to analyze the displacement of C1 facet relative to C2 facet joint during axial rotation mobilization in in vitro specimens both to quantify the amount of displacement and to study the trajectory of the facet joints as no data is currently available in literature.

METHODS

The complex multidimensional kinematics of 10 fresh human cervical specimens was analyzed using a Zebris CMS20 ultrasound-based motion tracking system (Zebris Medical GmbH e Germany). The skin, the subcutaneous tissue and the muscles were accurately dissected before the registration. Two investigators, with more than 10 years of experience in orthopedic manual therapy, performed the regional axial rotation in both right and left direction in a test-retest setting. After completing the registrations the specimens were fully dissected. Then, the centers of the facet joints and other specific landmarks were digitized (3D-microscribe®). Entering these 3D digitized coordinates in the Zebris software, it was possible to calculate the kinematics of the center of C1 facet joint relative to the center of C2. Following the International Society of Biomechanics (ISB) guidelines [5] an embedded XYZ reference frame was defined to describe movement directions.

RESULTS AND DISCUSSION

The left facet of the atlas showed a mean displacement along the X,Y,Z axes during a right rotation mobilization respectively of 3.2 ±1.5 mm, 4.6±2.3 mm and 5.3±2.5 mm. The right facet showed a mean displacement of 2.3±1.7 mm, 3.3±1.7 mm and 5.5±3.0 mm. The absolute displacement for the left facet was 8.1±2.7 mm during left rotation and 8.3±3.2 mm during right rotation. The right facet showed an overall displacement of 7.0±3.1 mm during a left rotation and 7.3±3.2 mm during right rotation. The movement through the three planes was represented in Figure 1. On the sagittal plane (YZ) the left facet joint seems moving

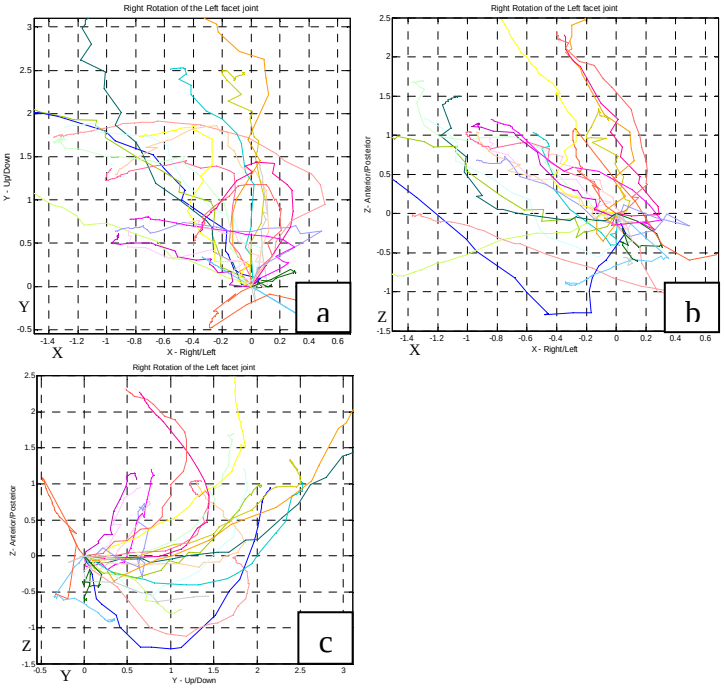

Figure 1: Displacement of the center of the left facet joint during a right rotation express in mm. Representation of 6 datasets. a = XY; b = XZ; c = YZ. X+ = leftward; Y+ = upward; Z+ = forward.

upward, with a gradual anterior displacement. On the frontal plane (XY) the facet tends to move upward and to the right. On the horizontal plane (XZ) the facet displaces forward and to the right. An overall displacement of 8 mm is in line with Duan et al. (2007) [2] findings in vivo subjects and highlights the reliability of our results as a very similar setting with the specimen supine was used. Experienced manual therapists seem able to induce a very similar amount of facets displacement compare to an active rotation.
A proper methodology is also imperative to describe such patterns of movement.

CONCLUSIONS

Our study is the first that has shown real time movement of the atlanto-axial facet joints during the performance of a manual technique. Further in vivo studies through the use of a 4D-CT device will allow to describe with higher accuracy cervical spine facet joint movements in vivo subjects and improve our insight of facet joints dysfunctions and effect of manual techniques.

P354 - THE EFFECTIVENESS OF ANTI-PRONATION TAPING IN LOWER EXTREMITIES TO LOW MEDIAL LONGITUDINAL ARCHPEOPLE DURING LANDING PHASE

Chun-Wei Chiou, Cheng-Feng Lin
Department of Physical Therapy, College of Medicine, National Cheng Kung University, Tainan, Taiwan
Corresponding author email: connie@mail.ncku.edu.tw

INTRODUCTION

Flat foot is one of the most common foot deformities in the world. This deformity will cause a fallen medial longitudinal arch. Possible risks factors for the development of flat foot include obesity, muscle unbalance or foot structure deformity. McKeon, Hertel, Bramble, Davis (2015)[1] point that the foot core system consisted of neural subsystem, passive subsystem and active subsystem. These subsystems would infect one another. This study aims at improving landing performance by changing foot passive subsystem. The treatments for flat foot include local injection of steroid, surgery, foot orthoses, and stretching exercises. The low-dye taping was first used to help athletes with flat foot improving their performance. Furthermore, some studies used it on flat foot patients and showed improvement in pain and walking ability. However these studies[1] showed the short term effect in ankle joint with LDT. And there aren't studies points out the effect on proximal joint. Furthermore, according to the kinematic chain, the flat foot may also affect upper joint by rotating the tibia & hip. Those changes will lead hip and knee joint suffer more stress. Therefore, we want to find if there is kinematic and kinetic changes in the knee joint after LDT taping.

METHODS

Six participants between 20 to 30 years old were recruited from Tainan area. Low longitudinal arch (low arch) subjects were randomly assigned to 2 groups, intervention group or placebo group. All participants met the inclusion criteria of having a low foot arch- the Navicular drop test over 8mm, Visual Analog Scale below 6. Participants are free of substantial lower limbs injury in the 6 months before the study, such as a sprain and other symptoms that would affect landing tasks.

Navicular drop test (NDT) was using the navicular drop height to evaluate the severity of flat foot. First, let subjects sit in 90-90 degree of hip/knee joints, and then check the subtalar joint in a neutral position. In that position, the distance between navicular bond & ground surface was recorded. Second, subjects stood up and then ensure they were standing with neutral subtalar joint position and recorded the distance between navicular bond & ground surface. The difference between two distances is the navicular drop height.

A certified physical therapist recorded subjects' basic data including leg/ foot length and navicular drop height. The 3D motion data collection was conducted before and after intervention using 8 infrared cameras (Eagle camera system, Motion Analysis Corporation, USA) and two kistler force plates. The marker set were top of head, bilateral tragus of ear, 7th cervical spinal process, sternum, bilateral acromion process, bilateral lateral epicondyle of humerus, hand, sacrum, anterior superior iliac spines, greater trochanter, lateral and medial epicondylitis of knee, midpoint of lateral thigh and shank, lateral and medial malleoli of ankle, 3rd metatarsal head and heel. There were 3 different jump tasks that including double legs forward landing (DLL), single leg forward landing (FL), and single leg side landing (SL). Those single leg landing tasks mentioned above concluded both right and left jump landing tasks. These tasks were performed in a random order.

The outcome measure included joint angle at knee and ankle joint, trajectory of resultant ground reaction force. First, variables of lower limb kinematic data including knee joint and ankle joint during landing trial were calculated by rotation matrix between lower limb segments. Second, trajectory of reluctant ground reaction force was calculated by force vector during the landing.

RESULTS AND DISCUSSION

There was no significant difference in the joint angle variables before and after LDT intervention. The trajectory of reluctant ground reaction force in intervention group showed a decreasing trend. (DL-L means double leg landing left leg. DL-L in pre-taping: 24.76, DL in post- taping: 8.45; DL-R in pre- taping: 43.11, DL-R in post- taping: 14.79; FL-L in pre- taping: 17.11, FL-L in post- taping: 9.97; FL-R in pre- taping: 32.27, FL-R in post- taping: 13.08; SL-L in pre- taping: 30.47, SL-L in post- taping: 11.16; SL-R in pre- taping: 34.00, SL-R in post- taping: 13.31)

The decreased trajectory of GRF may show that the anti-pronation taping skill could improve the landing stability in flat foot population.

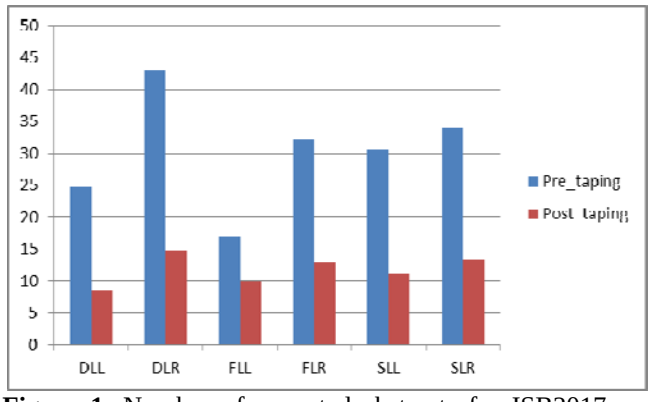

Figure 1: Number of expected abstracts for ISB2017 per week in January 2017.

CONCLUSIONS

The changes in trajectory of GRF showed there must be some mechanism differences behind the landing tasks. However, the kinematic data in this study cannot explain how anti-pronation taping changes the kinetic data. The further study could focus on different variables to explain the mechanism behind.

P355 - A PERSONALIZED SPATIAL MODEL OF THE ANKLE MOTION FROM MEDICAL IMAGES

[1]**Nicola Sancisi**, [1]Michele Conconi and [1]Vincenzo Parenti-Castelli
[1]University of Bologna
Corresponding author email: nicola.sancisi@unibo.it

INTRODUCTION

The capability to model human joint motion is a fundamental step towards the definition of effective treatments and medical devices, with an increasing request to adapt the devised models to the specificity of each subject. Joint models are also important for gait analysis, where they can be used to reduce the effect of skin artefact on the motion estimation accuracy [1]. Among the different models proposed for the ankle, spatial parallel mechanisms proved to replicate the natural tibiotalar motion with a high accuracy [2, 3] and were used to define models with both rigid and deformable ligaments [1]. These models start from the consideration, supported by relevant experimental analyses [2], that the natural tibiotalar motion has a single degree of freedom (1DOF), guided by the passive structures of the joint. They feature the main articular structures that guide the joint motion, namely articular contacts and isometric fibres of the tibiocalcaneal (TiCaL) and calcaneofibular (CaFiL) ligaments. The main limitation of these models is that they require a motion estimate of the subject to adjust the model parameters. An accurate estimation of the joint motion is difficult to obtain in vivo: non-invasive techniques can be inaccurate (skin-markers) or too complicated (fluoroscopy) for standard practice, while more invasive techniques (bone-pins) are not acceptable in several applications.

A new technique was proposed recently that obtains the ankle natural motion by maximizing the joint congruence at all flexion angles [4]: it only requires the 3D model of articular surfaces, which can be obtained by medical images. In the present study, a procedure is developed that combines this technique and parallel mechanisms, in order to define spatial models that include the joint constraints and predict the tibiotalar natural motion of a specific subject from standard medical images. To validate the procedure, which is general and can be applied in vivo without the need to measure the patient articular motion, five ankles have been analyzed in vitro, experimentally measuring their natural motion by bone pins.

METHODS

Data measured on five ankle specimens were used in the present study [3]. A stereophotogrammetric system (Stryker Navigation System; nominal accuracy: ±0.5°, ±0.5 mm) was used to obtain the tibiotalar natural motion of each specimen in unloaded conditions by bone pins. Anatomical reference frames were defined according to standard conventions and the relative motion was represented as 6 motion components (i.e., 3 displacements and 3 rotations). This experimental motion was used only to validate the procedure and was never used for the model definition. Articular surfaces at the tibia and talus, and TiCaL and CaFiL insertion areas were also digitized by the same stereophotogrammetric system. Since the joints could not be disarticulated, articular surfaces could be digitized only partially. The missing portions were reconstructed by scaling and adapting the data of one complete specimen. Triangular mesh bone models were obtained from the digitized surfaces. Flexion angle was imposed and the other 5 motion components were obtained by maximizing joint congruence between these bone models. The procedure was repeated over the full flexion arc and a tibiotalar reference motion was obtained for each specimen [4]. This motion was used to define each specific ankle model geometry. Preliminary mechanism parameters were obtained from the surface and ligament data: articular contacts at the medial, lateral and fibular compartments were approximated by three sphere-on-sphere pairs; TiCaL and CaFiL isometric fibres were substituted by rigid links. These parameters were then adjusted (maximum difference of 2 mm for all parameters) to best fit the estimated motion [2, 3]. The motion of each final mechanism (one for each specimen) was then compared to the motion originally measured during the experiment. Mean absolute errors (MAE) were computed for each specimen and each motion component.

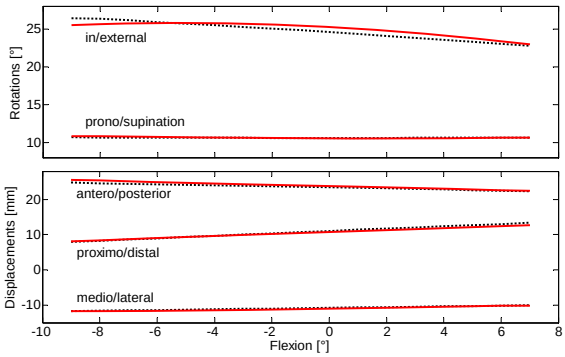

Figure 1: Model (solid) vs experimental (dash) motion.

RESULTS AND DISCUSSION

Results show that the proposed procedure successfully predicts the specific tibiotalar natural motion of each specimen. Motion components of the final personalized model are reported for a representative specimen in Figure 1. The average MAE over all specimen was below 0.9° for rotations and 0.4 mm for displacements; maximum MAE was 1.8° for rotations and 0.7 mm for displacements.

CONCLUSIONS

A procedure was proposed for the definition of a personalized ankle model, which can predict the natural tibiotalar motion based on non-invasive medical images taken on the specific subject. The proposed procedure was tested on data obtained on 5 ankle specimens and proved to be accurate. The final result is a model that reproduces the natural tibiotalar motion and, at the same time, replicates the main anatomical constraints, such as articular contacts and ligaments, of the specific joint under investigation.

P356 - REGIONAL MECHANICAL PROPERTIES OF THE HUMAN PATELLAR TENDON AND QUADRICEPS MUSCLES *IN-VIVO*

[1] **Brooke K Coombes**, [1]Brandon Ziegenfuss, [1]Rohitha Badya and [1]Kylie Tucker
Corresponding author email: b.coombes@uq.edu.au

INTRODUCTION

Patellar tendinopathy is a common painful musculoskeletal disorder affecting up to half of athletes in jumping sports[1]. Histological changes frequently affect the proximal deep (posterior) region of the tendon[2]. Stress-shielding of these posterior fibres has been proposed to explain the focal development of pathology[3], however *in-vivo* research is lacking.

Shear wave elastography is an ultrasound-based technology that involves measuring the speed of propogation of shear waves generated within soft tissues by focused acoustic beams. Increased shear wave velocity (SWV) is found in tissues with greater material stiffness or in tissues under greater passive tension. Using shear wave elastography we aimed to investigate the *in-vivo* region-specific mechanical properties of the patellar tendon in healthy individuals.

Aims

1. To determine whether there is a difference in SWV between the anterior and posterior parts of the proximal patellar tendon.
2. To determine whether these differences vary for different degrees of knee flexion.
3. To determine whether SWV of the patellar tendon is correlated with SWV of three of the four quadriceps muscles.

METHODS

Nineteen healthy participants aged 19 to 24 years (10 males, 9 females, 21.8±1.4 years, 171.5±9.4cm and 66.1±10.3kg) with no history of lower limb injury were recruited. An isokinetic dynamometer held the non-dominant leg at 25, 40,55,70 and 85° of knee flexion. Surface electromyography (EMG) was used to ensure participants were fully relaxed during testing. Elastography videos (10s duration) of the patellar tendon (PT), vastus medialis (VM), rectus femoris (RF) and vastus lateralis (VL) were captured at each successive knee angle. Testing was completed twice, with ten passive cycles (0-°85, 30°/s) performed prior to each set.

Customised MATLAB scripts were used to extract the mean SWV for the anterior and posterior regions of the proximal patellar tendon and VM, RF, VL muscles. Regions of interest were manually traced on overlaid B-mode images. Repeated measures analysis of variance was used to compare SWV between tendon regions and knee angles using Statistica version 13.1.

Intra-tester and inter-tester reliability was examined in five participants by performing the complete protocol on two occasions (separated by 90mins) and by extracting SWV values for each tendon region by two examiners.

RESULTS AND DISCUSSION

Intra-tester and inter-tester reliability for anterior and posterior tendon regions were good to excellent for all angles (Intraclass coefficients 0.63 to 0.96), except 85°, where they were moderate to good (0.37 to 0.66).

A significant effect of joint angle and a significant interaction between tendon region and joint angle were found ($p<0.05$). SWV increased at each successively greater knee flexion angle. No significant difference was found between anterior and posterior regions at 25, 40, or 55°. However, at 70 and 85°, anterior fibres displayed greater SWV than posterior fibres ($p<0.05$).

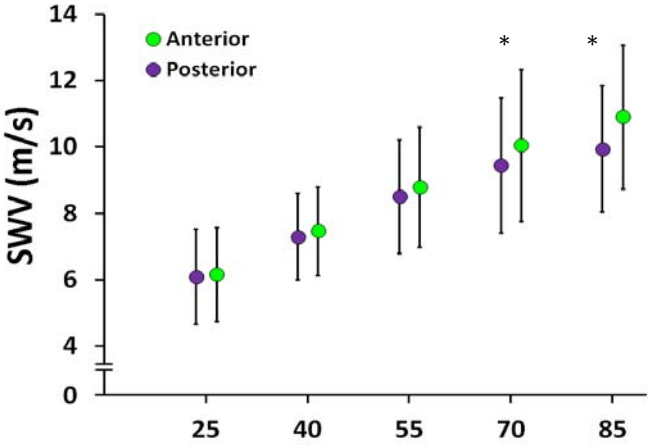

Figure 1: SWV comparison between tendon regions. Data displayed as mean ± SD.

Proximal patellar tendon SWV was positively correlated with the SWV for each of the measured quadriceps muscles ($p<0.05$). VL displayed the strongest correlation ($R^2=0.51$), followed by VM ($R^2=0.34$), and finally RF ($R^2=0.18$), which may reflect different musculotendinous architecture.

CONCLUSIONS

The distribution of stiffness across the anterior and posterior parts of the proximal patellar tendon was affected by passive knee joint angle. At large knee flexion angles, lower stiffness was evident in the posterior than anterior fibres, suggesting stress-shielding. Further research in jumping athletes with and without symptoms is needed for a better understanding of the role of stress-shielding in the development of patellar tendinopathy.

P357 - THREE DIMENSIONAL HUMAN LUMBAR INTERVERTEBRAL DISC INTERNAL STRAINS DURING COMBINED REPETITIVE LOADING

[1]Dhara B Amin, [1]Christina Moawad, [1]Richard Stanley, [2]Boyin Ding and [1]John J Costi
[1]Biomechanics & Implants Research Group, The Medical Device Research Institute, School of Computer Science, Engineering & Mathematics, Flinders University, SA
[2]School of Mechanical Engineering, The University of Adelaide, SA

INTRODUCTION

Repetitive manual handling is the most common mechanism for disc injury and disease among people aged 25-64 years [1], resulting in a direct and indirect health expenditure in Australia of over $3 billion [1], and over $50 billion in USA [2].

Despite its high resilience, epidemiological and in-vitro studies have shown that the disc can be damaged during excessive sudden compression in combination with flexion or lateral bending, leading to posterior or posterolateral herniation [3]. In addition, repetitive loading at lower, more physiological motions can also cumulatively damage the disc [4]. Disc strains have been measured in-vitro under isolated six degree of freedom (6DOF) motions [5], however no studies have measured internal disc strains during repetitive combined bending loading. An understanding of the internal disc strains during such motions is important for developing new therapies to treat disc injury and for identifying failure criteria for computational modelling of disc injury.

The aim of this project was to examine associations between the magnitude of 3D internal strains, tissue damage and macroscopic evidence of disc herniation after repetitive lumbar motion in normal lumbar discs.

METHODS

Sixteen cadaver lumbar functional spinal units (FSUs) were subjected to pre-test MRI scans to identify normal discs (Pfirrmann grades I-III) [6], and to establish the initial disc tissue appearance. Eight FSUs underwent 20,000 cycles of loading under compression (2.5 MPa) + flexion (13˚) + right axial rotation (2˚) using a novel 6DOF Hexapod Robot [7]. These motion combinations were chosen because flexion and axial rotation have been clinically linked to herniation. The remaining eight FSUs had a grid of tantalum wires inserted into the disc, and stereo-radiographs were taken to track internal 3D displacements [5] at increasing intervals of repetitive lumbar motion (initial neutral position, 1, 500, 1000, 5000, 10000, 15000, 20000 cycles) under the same loading conditions. Internal 3D displacements and maximum shear strains (MSS) (relative to neutral) were calculated from digitised stereo-radiographs using Matlab (R2011b, Mathworks, USA). FSUs without insertion of tantalum wires were used as a control group to compare the effect of wire insertion within the disc. Post-test MRI was conducted on all FSUs after testing. Discs were assessed via MRI and macroscopically examined to determine the extent of tissue damage and correlated with regions of highest internal disc tissue strains.

RESULTS AND DISCUSSION

This study is currently underway and the preliminary results of three FSUs (2 x L2-3, 1 x L4-5) revealed substantial tissue disorganisation after 20,000 cycles. Large increases in disc tissue deformations were observed in the anterior and posterior regions of the disc after 20,000 cycles. Under these loading conditions, the largest mean (95% CI) MSS of 58.14 (5.43) %/˚ after 20,000 cycles was found in the anterior region, with high MSS also seen in the right anterior lateral region (50.55 (4.57) %/˚) and left posterior lateral region (51.34 (5.76) %/˚).

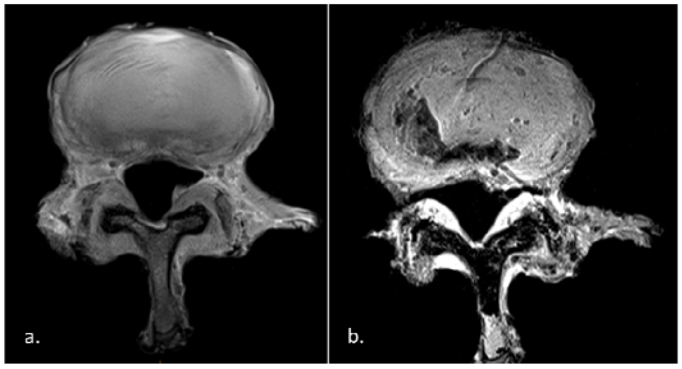

Figure 1: a.) Pre-test MRI (T1) axial image of sample FSU. b.) Post-test MRI (T1) axial image of the same FSU.

Pre and post-test MRI analysis revealed that two out of the three specimens presented with injury and apparent disorganisation in the nucleus (Figure 1). No herniation was observed, however both FSUs had evidence of endplate fracture and one FSU showed evidence of annular tears within the left posterior lateral region.

CONCLUSIONS

This study has the potential to understand the mechanical loading conditions and mechanisms that may lead to lumbar disc herniation in human discs. The manner in which one loads the spine is perhaps one of very few modifiable risk factors that can be addressed to prevent such injury occurring.

P358 - ELBOW FLEXORS RESIDUAL FORCE ENHANCEMENT IN-VIVO

Daiani de Campos [1] **Heiliane de Brito Fontana**[1]
[1]Federal University of Santa Catarina,
Corresponding author email: heiliane.fontana@ufsc.br

INTRODUCTION

An increase in force production is observed when a contraction is preceded by an active lengthening compared to a purely isometric contraction at the same length and activation level. This phenomena, known as residual force enhancement (RFE), is observed in isolated preparations from the sarcomere to the muscle level, with generally bigger stretches leading to greater increases in force [1].

The role of RFE in human movement is still a matter of debate. A major problem when analyzing RFE in vivo can be the difficulty in controlling for similar levels of activation between the enhanced and reference contractions. Muscle inhibition is often observed after active stretches in-vivo and it can prevent RFE from being verified through an increase in torque. In that sense, neuromuscular efficiency (NME), based on the torque to EMG ratio, is probably a more sensitive parameter to infer the role of active stretch in enhancing performance in-vivo [2].

NME increases after stretch can be achieved by: i) a lower level of activation for a given level of torque or ii) a higher torque output for a given activation, and these strategies, for in vivo contraction, may depend on the force generating potential of the muscle at a given joint angle [3].

In this study, we analyzed the potential effect of RFE on the NME-joint angle relationship during human in-vivo contractions. We hypothesized that NME increases after active stretch and that this increase might be based on different factors (EMG decrease or force increase) depending on where in the force-length relationship (FxL) the muscle is working.

METHODS

Five subjects (25 ± 6 years, 56.4 ± 6.5 kg) took part in the study. Joint torque and angle (Biodex) and biceps brachialis EMG (Miotec) were measured during maximal elbow flexor contractions. Two purely isometric contractions (REF) and two isometric contractions preceded by a 20° (RFEshort) and a 40° active stretch (RFElong) were performed at the plateau of the FxL (joint angle θ), at the ascending limb (θ+ 40° flexion) and at the descending limb (θ-50° extension). θ was determined for each subject based on torque and on estimated values of elbow moment arms at each angle [4]. Torque was normalized to the maximal torque at optimal length and EMG was normalized to the maximal EMG at each joint angle. The percent EMG and torque enhancement between REF and RFEshort and RFElong, and the NME (torque/EMG) of each contraction was calculated for the different regions of FxL. RFE occurrence was tested based on a binomial chi-square statistics (α=0.05).

RESULTS AND DISCUSSION

Increase in NME was observed in 18 out of the 25 contractions preceded by an active stretch (p = 0.02). Three of the seven contractions that did not show enhancement were on the descending limb, preceded by a short stretch. NME was typically greater after long compared to short stretches and at the plateau of the FxL relationship (Fig. 1).

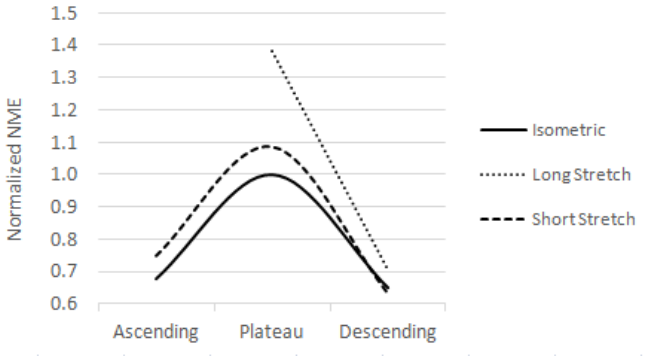

Figure 1: Neuromuscular efficiency (NME)-joint angle relationship for purely isometric contractions and for contractions preceded by a short and long active stretch. Mean elbow angle for the ascending, plateau and descending limb were 130°, 90°, and 40° respectively (0° = full elbow extension). * Long stretches were not possible for most subjects on the ascending limb because of limits in ROM.

With regards to the different strategies to reach an increase in NME; in the plateau of the FxL, all contractions showed a decrease in torque (-8%) and an even bigger decrease in activation (-26%). In contrast, on the ascending and descending limb, all contractions (except for one subject) showed an increase in torque (13% and 8% on the ascending and descending limb respectively) accompanied by a small decrease (-5% on the ascending limb) or a small increase (+4% on the descending limb) in EMG. The values reported are median values for the short and long stretch conditions.

CONCLUSIONS

Enhancement in the NME was observed for all regions of the FxL relationship for contractions preceded by an active stretch, suggesting a role for RFE in human elbow flexor function in-vivo. In addition, the factors that contribute to the NME enhancement differ depending on where on the FxL relationship the muscle is working. The increase in NME despite the big decrease in torque for contractions performed at the plateau of FxL suggests a potential role of RFE in delaying fatigue, but this hypothesis should be tested in future studies.

P359 - MUSCLES STRATEGIES DURING DIFFERENCE STAGES OF OA

[1,2] **Aseel Ghazwan**, [2,3] **Chris Wilson** , [1,2] **Gemma M. Whatling** and [1,2] **Cathy A. Holt**

INTRODUCTION

The primary role of muscles is to move joints, and, while doing so subjects adopt individual strategies to muscle coordination and loading of the joint. The question now arises: what is the exact role of muscles in the mechanical loading of joints? The ideal strategy to understand this scenario is to explore how the muscle forces are affected at different stages of Osteoarthritis (OA).

METHODS

Three-dimensional kinematic and kinetic data were collected from twenty six, fully consented subjects and divided into three groups: ten healthy subjects, eight with medial OA awaiting high tibial osteotomy (pre-HTO), and eight with late stage OA awaiting total knee replacement (pre-TKR). The mean and SD of weight and height for healthy, pre-HTO and pre_TKR cohorts were (79.5±12.6 kg, 88±15 kg, 86.3±20.3 kg), (175.5±3.7cm, 173±9 cm, 169.5±8.3 cm), respectively.

Recorded raw EMG data were band-pass filtered, rectified, low-pass-filtered and normalized to peak values obtained through the activities of daily living. The co-contraction index (CCI) was calculated for the following muscle sets: Vastus Lateralis-Gastrocnemius Lateralis (VLLG), Vastus Lateralis-Lateral Hamstring (VLLH), Vastus Medialis-Gastrocnemius Medialis (VMMG), and Vastus Lateralis-Medial Hamstring (VMMH)

Gait biomechanics were determined using OpenSim v3.3 [1]. For each participant, the customized generic anatomic model was scaled to the participant's anthropometry. The final anatomic model was then used to calculate joint angles, moments and MTU kinematics (lengths and moment arms) for walking trials using OpenSim inverse kinematics (IK), inverse dynamics (ID) and muscle analysis tools, respectively. Gait biomechanics and processed EMGs were then used to calibrate and execute an EMG-driven model that estimated muscle forces using CEINMS [2].

RESULTS AND DISCUSSION

The key finding for the gastrocnemius muscles was that subjects with OA had reduced muscle forces compared to the control. Our finding of increased forces of the quadriceps and hamstrings muscles is supported by an earlier research[3], they found that these muscle groups appear capable of supporting up to 100% of the applied abduction adduction moment, because of their abduction and /or adduction moment arm.

For OA, a decreased plantar flexion moment and less gastrocnemius co-contraction suggest that gastrocnemius overload may not be the primary cause of joint degeneration. The results bring into question the counterbalancing role of the quadriceps and hamstrings during dynamic movements to stabilize the knee.

In agreement with literature, Patients with OA have significantly ($p<0.05$) higher CCI compared to NP subjects. Lateral indices are increased significantly almost two-fold for the pre-HTO group compared to NP subjects. Whereas, no significant differences were found for the lateral indices between the pre-HTO group and pre-TKR group.

Some evidence of co-contraction between quadriceps and hamstring muscles was found, i.e., hamstring CCI are 250% greater laterally and 170% greater medially, for the pre-TKR group compared to NP controls. In the case of VLLH, a significant increase ($p<0.05$) was found for the pre-TKR group compared to NP subjects may contribute to a reduction in medial knee contact force.

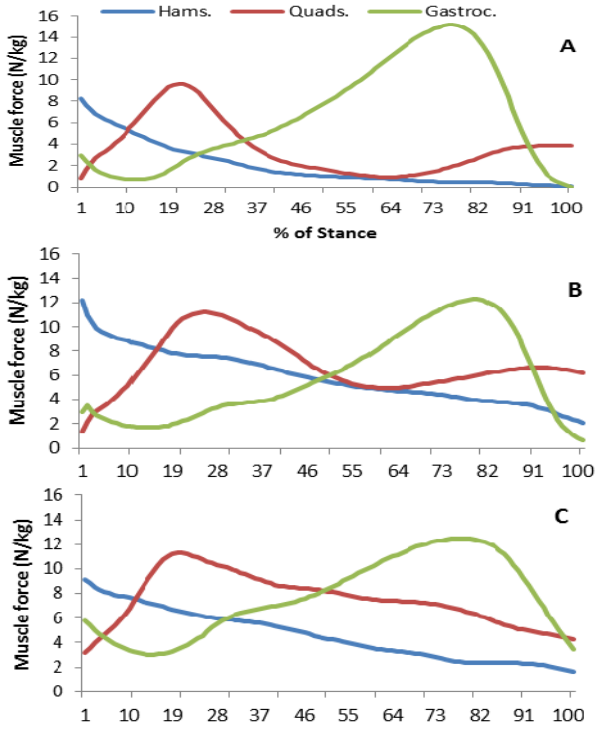

Figure 1: Muscle Forces during stance-phase for healthy subjects - **A**, pre-HTO subjects – **B**, pre-TKR subjects - **C**. Values represent mean.

CONCLUSIONS

In conclusion, a reduction in gastrocnemius muscle force is correlated to OA severity whereas quadriceps and hamstring muscles play a significant role in stabilizing the knee joint, altering their coordination and increasing their forces through different stages of OA severity.

P360 - THE EFFECT OF HUMERAL TRAY PLACEMENT ON REVERSE SHOULDER ARTHROPLASTY IMPINGEMENT

[1,2]**Jonathan Glenday**, [1]Sudesh Sivarasu, [2]Lawrence Gulotta, [1]Stephen Roche and [2]Andreas Kontaxis

INTRODUCTION

Reverse shoulder arthroplasty (RSA) has become an established means of alleviating pain and restoring shoulder functionality to patients who suffer from a massive rotator cuff tear or rotator cuff arthropathies. Despite these initial positive outcomes, concerns regarding the long term success of RSA are present. While the problem of intra-articular impingement and scapular notching is well documented and investigated, the effect of extra-articular impingement (contact of the humerus with the acromion or coracoid process) is often overlooked [1]. The aim of this study was to enhance our knowledge of how the onlay humeral tray positioning can affect impingement in RSA by using a large cohort of specimens and tray positional setups.

METHODS

The Newcastle Shoulder Model (NSM), a virtual biomechanical shoulder model [2], was used to investigate the effect of the onlay humeral tray position on RSA impingement. The CT scans of 10 shoulders were 3D reconstructed using MIMICS (Materialise NV, Belgium). The reconstructions of the scapula and humerus from each scan were used to customize the glenohumeral joint of the NSM, thereby creating a total of 10 subject-specific models. Each model underwent a virtual RSA surgery using the Biomet Comprehensive Reverse Shoulder System (Biomet, USA). The glenoid baseplate was implanted 12 mm superior to the inferior glenoid rim [3] with neutral version and tilt, and the humeral stem was placed at 20° of retroversion [4]. Seventeen onlay humeral tray positions were tested: the default location with no offset and 16 offset locations that placed the tray at 2.5 and 5 mm radial offsets over 45° circumferential intervals. Impingement-free range of motion (ROM) was measured for abduction, forward flexion, internal-external rotation with 90° humeral abduction and one activity of daily living (ADL) that simulates lifting an object to head height. Repeated measures analysis of variance (ANOVA) tests were carried out on the offset positions and offset distances independently for each motion. Post-hoc analysis with Bonferroni pairwise comparison was used to determine significant difference.

RESULTS AND DISCUSSION

Intra-articular impingement did not change for any of the humeral tray offsets during any of the assessed motions. However, extra-articular impingement was significantly affected ($p < 0.05$) by the onlay tray position for all motions (Figure 1). For example, during abduction, impingement free ROM increased from the default 69.5°±26.7° to 74.3°±26.6°, and then to 78.4°±24.7° when using 2.5 and 5 mm lateral tray offset locations respectively. The change in impingement free ROM due to the increase in offset distance was found to not be significant ($p > 0.05$) for all motions expect the ADL ($p = 0.016$). Post-hoc analysis found that the offset positions that significantly affected impingement-free ROM were motion dependent.

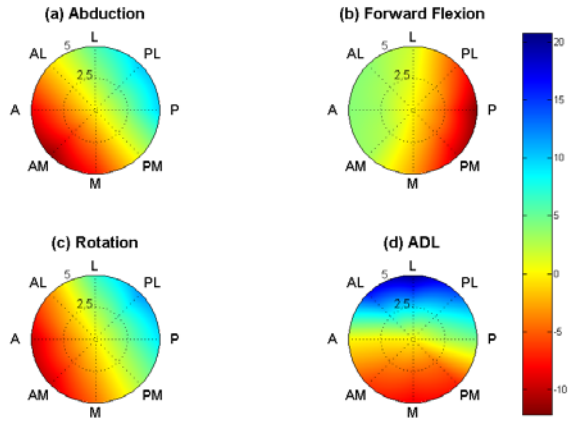

Figure 1: Change in impingement free ROM based on offset position for each motion relative to its default location within the 5 mm radius. Blue represents the relative increase in ROM; red represents a relative decrease in ROM.

The results of this study show that onlay humeral tray offset positioning has a significant effect on extra-articular impingement and does not change intra-articular impingement (humeral tray offsets do not change the location of the humeral cup in relation to the scapula). The lateral offset was found to be the only offset position that significantly increased impingement-free ROM during all of the assessed motions. It was also noted that overall there was no significant difference in extra-articular impingement between the 2.5 and 5 mm offset distances. This is advantageous as 2.5 mm offsets minimize the risk of humeral tray overhang. From these observations it is evident that a 2.5 mm humeral tray offset in the lateral direction would be the optimal location to increase impingement-free ROM. However, this study did not investigate the effect of these changes on the shoulder muscles. Tray lateralization medializes the humerus, potentially resulting in a reduction in deltoid moment arms. This trade-off could necessitate the usage of an intermediate humeral tray offset position that could provide a biomechanical compromise.

CONCLUSIONS

The functional outcomes of RSA can be improved through the use of onlay humeral tray offset. However, investigation into the biomechanical changes of the deltoid muscles is required to understand the implications of tray offsets.

P361 - HISTORY DEPENDENT MUSCLE PROPERTIES CONTRIBUTE TO INCREASED PERFORMANCE DURING STRETCH-SHORTENING CYCLES

[1,2] **Daniel Hahn** and [1]Timotheus N Riedel
[1]Ruhr-University Bochum, [2]University of Queensland
Corresponding author email: daniel.hahn@rub.de

INTRODUCTION

It is well known that muscular force production is history dependent resulting in enhanced and depressed steady states after stretch and shortening, respectively. However, in many cases, muscle contractions during natural human movements are characterized by a combination of stretch and shortening called stretch-shortening cycle (SSC). During the shortening of such a SSC an increased performance has been observed compared to shortening without preceding stretch.

The primary mechanisms associated with enhanced power output of muscles in the shortening phase of SSCs are the activation dynamics, contributions of stretch reflex, and the storage and release of elastic energy [2]. However, already Cavagna et al. [1] proposed a forth mechanism located within the sarcomere, which is related to the residual force enhancement (RFE) observed during steady-state isometric contractions following active muscle stretch. In this context it was recently shown for the human adductor pollicis that either RFE persisted or that residual force depression (RFD) was abolished after SSCs [3]. From these results it was concluded that the intrinsic muscle properties associated with the history dependent RFE also contribute to the enhanced performance during SSC contractions.

Accordingly, the aim of this study was to reproduce the findings of [3] for a muscle that is more relevant for human locomotion and especially for SSC.

METHODS

The triceps surae of 14 healthy subjects (four females, ten males) was electrically stimulated over the muscle belly for 8 seconds (Digitimer DS7AH, UK; 1ms square-wave pulses at 20 Hz) to reach 30% of maximum voluntary contraction torque (MVC) in a 5° plantar flexion position (0° refers to the sole of the foot perpendicular to the shank). The anode (7.5x13cm) was placed over the lateral and medial gastrocnemius muscles at the largest circumference, the cathode (5x5cm) was placed over the soleus muscle.

Testing consisted of five different contraction conditions performed in a randomized order: isometric contractions at 5° plantar flexion (PF) and 10° dorsiflexion (DF), a pure stretch contraction from 5°PF to 10°DF, a pure shortening contraction from 10°DF to 5°PF and a stretch-shortening cycle over the 15° range of motion described above starting from 5°PF, all followed by an isometric hold phase after displacement. Dynamic contractions started with isometric pre-activation and were performed at $120°s^{-1}$ and an angular acceleration of $200°s^{-2}$. Each condition was repeated twice.

Contractions were performed in an isokinetic dynamometer (IsoMed2000, D&R Ferstl, GmbH, GER) with the subjects lying prone on the bench of the dynamometer with the knee slightly bend and the foot tightly strapped to a foot plate to avoid heel lift during contractions. The lateral malleolus was aligned with the axis of rotation and torque and joint angle were sampled at 1000 Hz using an AD-converter (Power1401, CED, UK) and Spike 2.0 software (CED, UK). Torque and angle data were zero-lag low-pass filtered (20 Hz) and torque was corrected for gravity.

Peak torque during stretch, minimum torque at the end of shortening, concentric work during shortening, and steady-state torque during a 1s time window (3-4s after displacement) were statistically analyzed (repeated measures ANOVA and Bonferroni post-hoc comparisons; $\alpha<.05$).

RESULTS AND DISCUSSION

Peak torques during the stretch of pure stretching and SSC contractions did not differ (92.5±17.6Nm and 92.6±17.9Nm) and exceeded the isometric reference torque by 25% ($p<.001$). Work during the shortening phase of the SSC was significantly increased by 12% ($p<.01$) compared to work performed during pure shortening. In addition, torques were significantly lower ($p<.01$) at the end of the shortening phase for the pure shortening compared to the SSC.

During the steady-state after pure stretching, torques were significantly increased (77.4±18.7Nm) compared to the isometric torque at 10°DF (74.3±19.3Nm), i.e. there was a RFE of 4.8% ($p<.05$). After pure shortening the steady-state torque was significantly depressed to 40.9±9.3Nm compared to 46.3±9.1Nm for the isometric contraction at 5°PF ($p<.05$), which corresponds to a RFD of 12%. After SSC the steady-state torque was depressed to 42.3±8.7Nm ($p<.05$) and was further significantly different to the steady-state torque after pure shortening ($p<.05$). This means that there was a reduced RFD of only 8.6% after SSC.

Although we could not exactly reproduce the findings from [3], our results proved the hypothesis of reduced RFD after SSC correct. Usually, the amount of RFD increases with the work done during shortening, however, with reduced RFD after increased work during shortening of the SSC our results showed the opposite. Therefore, we speculate that the increased work during shortening of the SSC is partly due to a stretch-triggered semi-active non-cross bridge mechanism.

CONCLUSIONS

From our findings it is concluded that a force enhancing mechanism triggered by stretch persists during the following shortening and steady-state phases of the SSC. Thus, we suggest that the history dependent muscle properties responsible for RFE also contribute to the enhanced performance during SSC contractions.

P362 - PELVIC RING DEFORMATION UNDER PHYSIOLOGIC AND TRAUMATIC CONDITIONS - A CADAVERIC STUDY ELUCIDATING OUT THE INFLUENCE OF THE INNOMINATE BONE

[1] **Niels Hammer**, [2]Robert Möbius, [2]Stefan Schleifenbaum, [2]Toni Wendler, [3]Michael Werner and [2,3]Ronny Grunert

INTRODUCTION

The sacroiliac joint (SIJ) has evolved from a largely neglected anatomical region to a major target of clinical intervention given its contribution to low back and pelvic ring pain. In contrast to this increased clinical attention, the joint lacks adequate description from a biomechanical perspective. *In-vivo, in-vitro and in-silico* studies vary widely regarding their findings on the SIJ nutation motion and the effects of therapeutic interventions using pelvic support belts, sacroiliac fusion or the consequences of lumbar spine surgery [1,2]. The given study aimed at establishing a novel biomechanical setup using cadaveric pelvises to evaluate SIJ motion under axial loading, allowing for three-dimensional motion at the SIJ and the lumbosacral transition, free rotation at the hip joints in an upright posture. A second aim was to evaluate three-dimensional motion at the lumbosacral transition and pelvis under physiologic loading and following SIJ ligament injury to determine the impact on motion patterns.

METHODS

A testing rig was developed, allowing for a double-stance scenario with loads applied via the fifth lumbar vertebra (L5) via free-rotating ball bearings. Steel wires mounted to the iliac crest served to simulate muscle traction of the erector spinae and abdominal wall muscles. Six human cadaveric osteoligamentous pelvises with adjacent L5 were tested under physiologic conditions, ranging from 0 to 100% of the total individual body weight of the respective cadavers with a biaxial testing device (DYNA-MESS, Aachen, Germany). Cyclic axial deformations were co-registered using three-dimensional digital image correlation (Limess, Krefeld, Germany). Speckle patters attached onto L5, the sacrum and the innominate bones served as reference markers. The following motions were examined: (1) Sacroiliac joint; sacral vs. iliac ala; (2) Lumbosacral transition; L5 vs. sacral promontory; (3) Innominate bone; superior pubic ramus vs. iliac ala; (4) Pubic symphysis; left vs. right superior pubic rami. The tests were repeated following unilateral transection of the SIJ ligaments, prior to yield strength testing. Minimum thresholds for motions to be recognized were 0.1-mm translation or 0.2° rotation between 0 and 100% of the body weight *and* if a given correlation coefficient for load-deformation was >0.8 for the subsequent deformation steps, indicating consistent movement. Translations (T) and rotations (R) were given for the x-, y-, and z-axes as absolute values.

RESULTS AND DISCUSSION

All pelvises completed the loading scenarios with intact and transected ligaments. Mean failure load was 2496±1310 N (range 1045–5167 N). In the intact condition, mean translations at the lumbosacral transition were 0.61 mm (Ty), 0.31 mm (Tz) and rotations 1.20° (Rx), and at the SIJ 0.49 mm (Ty), 0.16 mm (Tz) and 0.57° (Rx; Fig. 1). The largest translations were found for the innominate bone,

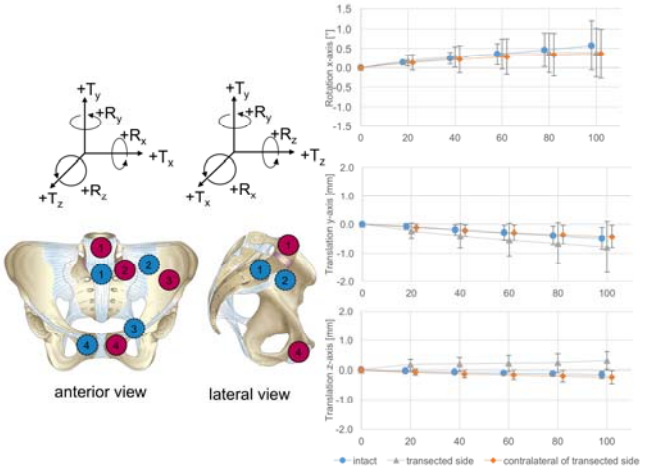

Figure 1: Sacroiliac joint motion in the intact condition. The x-axis shows the body weight in [%], whiskers indicate the standard deviations. Numbers indicate the measurement regions given in the methods section. Paired numbers reflect the measurement sites. T = translation, R = rotation

with 1.46 mm (Ty), 1.80 mm (Tz), and rotations of 0.36° (Rx), 0.37° (Ry) and 0.33° (Rz). Translations at the pubic symphysis were 0.14 mm (Tx), 0.20 mm (Ty) and 0.10 mm (Tz), rotations 0.64° (Rx), 1.20° (Ry) and 0.26° (Rz). Transection of the SIJ ligaments changed motion patterns at the lumbosacral transition, SIJ, innominate bone and pubic symphysis both qualitatively and quantitatively. At the transected SIJ, increased translations were observed (Ty 0.42 mm, Tz 0.31 mm) and a new axis of rotation was introduced (Ry 0.7°). Unilateral SIJ transection increased innominate bone translation (Ty 1.57 mm, Tz 3.00 mm), while innominate bone rotations remained unchanged. Moreover, SIJ ligament transection caused an overall change of translations and rotations at the pubic symphysis (Tx 0.06 mm, Ty 0.23 mm, Tz 0.49 mm; Rx 0.87°, Ry 0.43°, Rz 0.45°).

CONCLUSIONS

While physiologic SIJ motion can be well-described by nutation consisting of y- and z-translation and x-rotation, the overall movements were consistently present and in the sub-mm and sub-degree range. Comparison to the adjacent regions under loading revealed that innominate bone translation outweighs all other motions at the lumbosacral transition and pelvis, indicating that the innominate bone is an additional segment with high importance in pelvic region kinematics with vast influence on overall motion. Moreover, SIJ ligament transection caused altered motion patterns, in particular at the affected SIJ and the pubic symphysis, revealing that ligament disruption cannot solely be considered as an increase of given rotations and translations.

P363 - FIREFIGHTER GEAR AND THEIR IMPACT ON SAFE NECK AND TRUNK MOBILITY

[1] **Rumit Singh Kakar**, [2]Huiju Park, [2]Jie Pei, [2]Manwen Li, and [2]Mengyun Shi
[1]Department of Physical Therapy, Ithaca College
[2] Department of Fiber Science & Apparel Design, Cornell University
Corresponding author email: rkakar@ithaca.edu

INTRODUCTION

Large and heavy air tanks commonly used by firefighters have been known to increase risk of slips and fall. They have also been linked to poor gait characteristics that can negatively influence balance. [1] Movement restrictions due to the protective equipment can further increase the risk of falls. The purpose of this study was to understand the impact of firefighter air tanks on neck and trunk mobility and evaluate trunk anthropometric data to support for personalized protective equipment thus reducing risk of falls.

METHODS

Twenty-one healthy firefighters (16 males; 5 females) were recruited from the local fire department (age: 29.9±11.7 yrs, firefighting experience with standard protective equipment: 5.4±6.5yrs, height: 176.7±8.0, weight: 79.1±11.8, BMI: 25.4±3.6). Participants were asked to perform the following movements 1) maximal neck extension, and 2) forward trunk flexion, with and without airtanks and helmets. They wore biking shorts and tank tops (for females) only to ensure complete capture of the participants' posture. To simulate the thickness of garments that the air tank lies on when firefighters wear the air tank with base layers and firefighters' uniform, parts of the garments were cut and sewn on to the air tank's straps. 3D body scans were done at extremes of ranges of motion (ROM) for each condition. Neck extension ROM, lumbopelvic ROM and standing trunk positions were calculated from the body scans and compared between with and without airtank and helmet conditions using paired t-tests (p <05). Anthropometric measurements of 3647 males were analyzed from SizeUSA, a national dataset, to understand relationship between ranges of torso lengths and air tank dimension, and its impact on mobility of firefighters.

RESULTS AND DISCUSSION

Both neck extension (mean difference= 20.3°; p<.0001) and lumbopelvic flexion ROM (mean difference= 7.5°; p< .0001) were significantly reduced with helmets and airtank and there was a tendency for significant trunk hyperextension in standing position with air tanks (p = 0.083). These results support previous literature suggesting decreased mobility with firegear. [2] Firefighters constantly work in areas with narrow spaces and decreased head and/or foot clearance due to fallen over beams or collapsed ceilings. Therefore, restricted neck extension and trunk mobility limit firefighters' vision and ability to work in a confined space. These can pose serious life threatening risks in such a work environment. Also, standing or walking for long periods of time with increased trunk hyperextension and thus higher and more posterior center of mass, can increase spinal loading by creating a larger extension torque on the back due to an increased moment arm to the load and thus have long-term detrimental effects on low back. Analysis of SizeUSA data shows that length of upper body, where air tank is mounted, ranges between 16.96" and 22.83" (95% of the data). Considering the length of air tank (20.9" on average) for firefighting, the coverage of air tank on the upper back ranges 85% to 127%, which means air tanks height is usually comparable or in most cases greater than torso length for most firefighters. In fact, the rigid metal structure of harness to mount air tank is longer than air tank, which causes mechanical binding while firefighters move upper body and arms, restricting mobility. Firefighters with shorter upper body length may have air tank extended even below the waist, which can create significant mobility restriction not only in trunk bending but also in neck hyperextension because the top portion of air tank hits the back brim of the helmet during the neck hyperextension. On the other hand, it is possible that firefighters with longer upper body length can have less mobility restriction due to more flexibility in adjusting the mounting height of air tank.

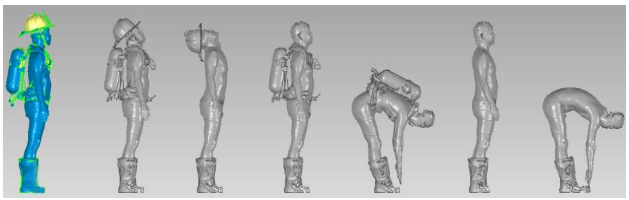

Figure 1: 3D body scan images in different test positions.

CONCLUSIONS

Findings of this study show that wearing air tank can impose significant mobility restriction to firefighters, alter the static and dynamic movement mechanics and even cause musculoskeletal pain or disorder. SizeUSA data implies that shorter firefighters will be more vulnerable to these detrimental effects compared to taller ones. The size of air tank is determined by required duration of oxygen supply (minimum rated service life of 30 minutes) regulated by NFPA1981 (*Standard on Open-Circuit Self-Contained Breathing Apparatus for Fire and Emergency Services*). It is suggested that future research and development of self-contained breathing apparatus should be focused on reducing length of air tank or providing flexible/bendable structure of air tank and harness for improved mobility and safety.

P364 - FRAMEWORK TO CUSTOMIZE MUSCLE PATHS INFORMED FROM MRI

[1,2]**Bryce A Killen**, [1,2]David J Saxby, [1,2]Jason M Konrath and [1,2]David G Lloyd

INTRODUCTION

Within the field of neuromusculoskeletal (NMS) biomechanics, subject-specific anatomic models are becoming increasingly popular. Studies have consistently shown better predictive accuracy of subject-specific models compared to generic models [1,2], showing the incorporation of subject-specific boney geometries, muscle activation patterns, articular mechanisms and muscle tendon unit (MTU) paths are important. MTU paths influence MTU lengths, subsequently affecting muscle operating range and force predictions, and moment arms, which effect MTU moment predictions.

Linear scaling of generic anatomic models alter MTU paths in linear proportion to scale factors. When subject-specific boney geometries are employed linear scaled MTU paths are incorrect therefore, subject-specific MTU paths must be defined. Therefore, if subject-specific anatomic models are to become standard within NMS modelling frameworks, MTU path must be robustly defined. While customized MTU paths may produce visually acceptably results, the resulting MTU lengths and moment arms must also be within physiologic range

We present a novel framework to develop subject-specific MTU paths based on MRI. The aim of this study was to evaluate the validity of MRI-informed MTU paths, and second, to compare MTU origins and insertions with those generated through the musculoskeletal atlas project (MAP) client [3].

METHODS

Subjects (n=14) underwent full lower-limb MRI from iliac crest to toes, using a 3T unit (Ingenia, Phillips Healthcare, Netherlands) with axial T1-weighted 3D fast field echo sequence with 1 mm slices. Subject-specific models were created using MAP-client [3] and customized by adding a subject-specific patella and patellofemoral joint [4]. Tibiofemoral (5-bar rigid link) [5] and patellofemoral (hinge) [5] articular mechanisms were then determined. Muscle segmentations were done using a novel “Muscle Segmentation” tool (Materialise, Belgium). Muscle segmentations and MAP-generated bones were then imported into 3-matic (Materialise, Belgium) to identify relevant anatomic points and surfaces.

For each subject, we developed three different models: a linear-scaled (LS), MAP-generated (MAP), and customized MAP (CUST) (Figure 1A). The framework starts by updating each MTU’s fixed origin and insertion using an attachment area defined as the centroid of the region of attachment on the relevant bone. The model template the MAP client uses is OpenSim Gait2392 [6]. The Gait2392 model has conditional path points which mimic MTU wrapping around bones. We replaced these conditional path points with wrapping surfaces based on the MAP-generated bones to 1) prevent muscle-bone interpenetration 2) maintain MTU shape, and 3) produce more physiologic MTU lengths and moment arms.

MTU length and moment arm relative to knee joint centre will be determined throughout 10º extension to 120º flexion, in 1º increments, with knee adduction/abduction and internal/external rotation defined by subject-specific splines [5]. Correlation between MTU length and moment arms from each model will be calculated. In addition, correlations to previously published data [7, 8] will be presented for MTU moment arms. Differences between MAP-generated and direct MRI muscle origins/insertions will also be calculated, with MRI data serving as criteria.

RESULTS AND DISCUSSION

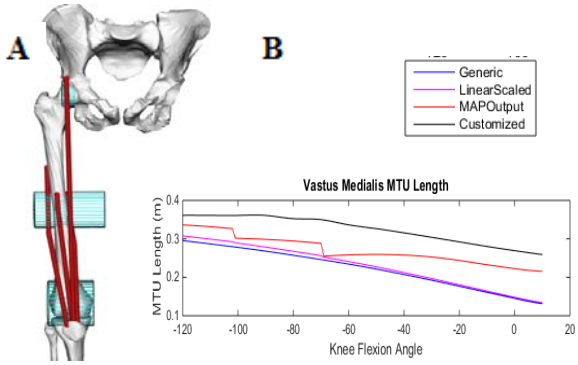

Figure 1. (A**)** OpenSim model with customized boney and MTU geometries (B) Vastus medialis MTU length in various OpenSim models.

Customizing MTU paths and adding wrapping surfaces produced MTU lengths and moment arms which were physiologic, while simultaneously preventing interpenetration of MTU and bone.

CONCLUSIONS

This framework utilizes a novel Muscle Segmentation tool and MAP-client to create subject-specific models with customized MTU path points and wrapping surfaces. We believe MTU geometry must be customized in subject-specific NMS models. Replacing conditional path points with wrapping surfaces results in patterns of MTU lengths closer to the generic template model. Using direct MRI measures resulted in longer MTUs across a physiologic knee’s range of motion compared to generic, linear scaled and MAP generate models.

P365 - MOVEMENT SPEED, LOAD AND LOAD-DISTRIBUTION ALTER LOWER-LIMB JOINT MOMENTS DURING WALKING IN SOLDIERS

[1]**Gavin K Lenton**, [2]Tim L A Doyle, [1]David J Saxby, [1]Jeremy Higgs, [3]Dan Billing, and [1]David G Lloyd
[1]Griffith University; [2]Macquarie University; [3]Defence Science and Technology Group

INTRODUCTION

Carrying heavy loads in the military can cause musculoskeletal injury, with significant costs for rehabilitation of injured soldiers to ensure military readiness [1]. Thus, reducing injury risk due to load carriage is a priority for Defence organisations throughout the world.

It is understood that increasing carried load alters gait biomechanics [2]. Recently, biomechanical modeling methods have been used to examine the effects of carried load on internal joint loading [3]. To date, no study has examined if changing the distribution of carried load affects internal loading at commonly injured sites (e.g. the knee). If a particular load carriage configuration reduces or re-distribute joint moments, this could inform future load carriage design aiming to reduce injury risk, not only in the military, but in recreational carriage (e.g., hikers).

This study aimed to determine the effects of changing movement speed, carried load, and the distribution of body-borne load on lower-limb joint moments during walking.

METHODS

Twenty Australian Army Reserve soldiers (29.5±7.1 yrs) participated. Twelve body armour variations were tested: six armour types (one standard-issue body armour, TBAS, and five prototype designs, ARM) and two carried load magnitudes (15 and 30 kg). Prototype designs incorporated a hip belt that offloaded the shoulders, whereas TBAS did not. Participants completed testing over four sessions, with each session separated by at least two days.

Wearing body armour, participants walked on a force-plate instrumented treadmill (AMTI, Watertown, US) at both moderate (1.53 $m \cdot s^{-1}$) and fast (1.81 $m \cdot s^{-1}$) speeds for 10 minutes at each speed. An 11-camera motion capture system (Vicon, Oxford, UK) collected whole-body three-dimensional marker kinematics. A modified full-body OpenSim [4] anatomic model was scaled from static trial markers. OpenSim inverse kinematics and inverse dynamics analyses were used to determine lower-limb joint angles and net joint moments, respectively. Peak hip flexion and extension moments, knee flexion moment, ankle plantar flexion moment in late stance, and knee adduction moment were determined from ensemble-averaged joint moment curves. Repeated measures ANOVAs were used to compare peak joint moments between movement speeds and armour-load configurations. Significance was set at $p<0.05$.

RESULTS AND DISCUSSION

Peak joint moments, except for knee extension, increased for fast walking compared to slow walking ($p<0.001$) (Table 1). All joint moments were higher with 30 kg of carried load compared to 15 kg ($p<0.001$). We found no significant differences between armour types for peak joint moments.
Concomitant with previous studies, results suggest the magnitude of joint moments is dictated by task demands, rather than armour design [2, 3]. Importantly, prototype designs incorporating a hip belt did not negatively alter joint kinetics. External knee flexion moment in early stance was particularly sensitive to carried load, and is counteracted by increased knee extension moment, probably generated by the increased action of the quadriceps.

Table 1. Peak external joint moments for four conditions. All values are reported in Nm kg^{-1}. *indicates fast walking values were significantly higher than slow walking. ^indicates that 30 kg values were significantly higher than 15 kg ($p<0.05$).

	TBAS		ARM1		ARM2		ARM3

Knee adduction*^	0.74±0.20	0.93±0.14	0.74±0.26	0.91±0.29	0.67±0.25	0.84±0.31	0.76±0.24	0.90±0.24
Hip flexion*^	1.22±0.33	1.29±0.32	1.34±0.40	1.37±0.47	1.28±0.42	1.32±0.43	1.31±0.32	1.28±0.39
Hip extension*^	1.94±0.27	2.83±0.42	2.14±0.48	3.15±0.63	2.10±0.56	2.88±0.59	2.03±0.46	3.00±0.50

Further analyses are underway to determine if these increases result in increased knee contact forces.

CONCLUSIONS

This study suggests soldiers, in carrying heavy loads for many hours in a day and over consecutive weeks, would experience joint loading that may put them at high risk for developing overuse injuries. Additionally, the study showed for the first time that load distribution from the shoulders does not adversely affect joint loading. Future armour design may optimise lower-limb joint loading, however further studies are required to assess novel armour designs.

P366 - PENNATION ANGLE OF GASTROCNEMIUS LATERAL AND MEDIAL HEADS CAN BE MEASURED RELIABLY IN PRONE AND ALSO STANDING POSITIONS

Li Li, Molly Mclaughlin, Diana Tyler, and Dan Czech
Georgia Southern University
Corresponding author email: lili@georgiasouthern.edu

INTRODUCTION

Pennation angle of gastrocnemius muscle is important for muscle force production. This angle is often measured in laying position (e.g., Zhou et al. 2012 [1]). Many human movement we study occurs in standing position. Can this angle be measured reliably in standing position? The purpose of this investigation is to examine the test-retest reliability of both lateral and medial heads pennation angles of gastrocnemius during standing position.

METHODS

Sixteen female college students were recruited for this study. The study was approved by local ethic board and informed consent form was signed by the participant after necessary discussion. Terason t3000^{TM} Ultrasound System (Terason t3000^{TM}, Chicago, Illinois, USA) was used to get the image of gastrocnemius lateral and medial head pennation angles. ImageJ software (U.S. National Institutes of Health, Bethesda, Maryland) was used to measure pennaiton angles from the stored images. Ultrasound images of gastrocnemius muscle were taken while participants laying in the prone, and standing, with ankle joint at neutral position, at 30% distance between the popliteal line and lateral malleolus towards the knee. The gastrocnemius muscle was palpated to find the muscle belly, which is where the clearest muscle pennation angle can be observed. Three ultrasound images were then taken either medially or laterally.

Reliability was assessed using Intraclass Correlation Coefficient (ICC):

$$ICC = \frac{1}{Ns^2}\sum_{n=1}^{N}(x_{n,1} - \bar{x})(x_{n,2} - \bar{x});$$

Where

$$\bar{x} = \frac{1}{2N}\sum_{n=1}^{N}(x_{n,1} + x_{n,2}),$$

$$s^2 = \frac{1}{2N}\left\{\sum_{n=1}^{N}(x_{n,1} - \bar{x})^2 + \sum_{n=1}^{N}(x_{n,2} - \bar{x})^2\right\}.$$

ICC was evaluated based on Cicchetti (1994) [2]: Poor: ICC < 0.40—; Fair: 0.40 <=ICC<= 0.59; Good: 0.60 <= ICC<= 0.74; and excellent: 0.75 <= ICC <= 1.00.

RESULTS AND DISCUSSION

Results are presented in **Table 1**. Pennation angle can be tested with excellent reliability for both between day comparison (ICC = 0.91 and 0.95 for reader 1 and 2, respectively), and between reader comparison (ICC = 0.98 and 0.96 for day 1 and 2, respectively). As for the different heads of the gastrocnemius muscle, pennation angle of the lateral head can be tested with excellent reliability for both positions (ICC = 0.80 and 0.87, for prone and standing position respectively). However, pennation angle of the medial head of the gastrocnemius muscle were only tested with good reliability when tested with the two different testing positons (ICC = 0.68 and 0.71, for prone and standing position respectively).

Differences between testing positions and differences between different heads of the tested muscle were not the primary purpose of the study. However, results (**Table 1**) showing the trend where testing position did not change pennation angle as long as the ankle joint remain at neutral angle for both positions, where the lateral and medial heads of the muscle exhibited similar pennation angles for both.

CONCLUSIONS

Gastrocnemius muscle pennation angles have traditionally been measured when participants laying prone. Now, this angle can also been measured reliably in standing position. Measuring gastrocnemius pennation angle in standing do not require the traditional 20 minutes for body fluid equalization as long as people come to the testing station in an upright postural. Furthermore, pennation angle often are being used to discuss muscle mechanics and testing in upright position when loaded with body weight, provides us an observation closer to muscle contraction than laying prone.

Note: 1). N=96 (16 participants X both heads of gastrocnemius X three measurements) for the between days / between readers reliability data; N=96 (16 participants X both days X three measurements) for either lateral or medial heads at prone or standing positions.

P367 - SIMULATING RIBCAGE BIOMECHANICS: A SUBJECT SPECIFIC FEM OF AN EXPERIMENTAL SHEEP MODEL

[1]Nicolas Newell, [2]Caroline A Grant, **[2]J Paige Little**
[1]Department of Bioengineering, Imperial College London, UK
[2]Paediatric Spine Research Group, IHBI at Centre for Children's Health Research, QUT, Australia
Corresponding author email: j2.little@qut.edu.au

INTRODUCTION

The sternum and ribs play a significant role in providing stiffness to the thoracolumbar spine [1], however, the relative mechanical contribution of the ribs and intercostal soft tissue connections is less clear. In a prior biomechanical study from our group [2], the contribution of the sternum, ribs and intercostal soft tissues in influencing spinal stiffness was measured. Using these biomechanical data, the current computational study sought to develop a validated representation of ribcage mechanics, using an established workflow for creating subject specific finite element (FE) models of the thoracolumbar spine with ribcage [3].

METHODS

Biomechanical testing data for an osseoligamentous thoracolumbar sheep spine (Fig 1A) were used [2]. Briefly outlining this prior study, load cases representing forward flexion (29º) and axial rotation (27º) were applied to the spine using a robotic arm with the lowermost vertebral body (L7) rigidly potted and rotational motion applied to the uppermost thoracic vertebra (T1). The sheep spine was tested in four stages of dissection – i) *Intact*, ii) intercostals severed bilaterally (*NoInterC*), iii) sternum fractured at T2 (*NoStern*), and iv) ribcage resected leaving 50mm rib head (*NoRibs*). The rotational stiffness of the spine was calculated at each stage of dissection. Following spinal testing, ligament and annulus fibrosus samples were harvested from select thoracic and lumbar motion segments. Anterior longitudinal ligament samples were loaded in uniaxial tension (Precycle: 5 cycles to 10%, 0.5Hz; Loading: maximum strain 400% at 0.1/sec) and annulus fibrosus samples were loaded in unconfined compression (Precycle: 5 cycles to 5% strain, 0.4Hz; Loading: maximum strain 50% at 0.01/sec) to obtain force-displacement data [4].

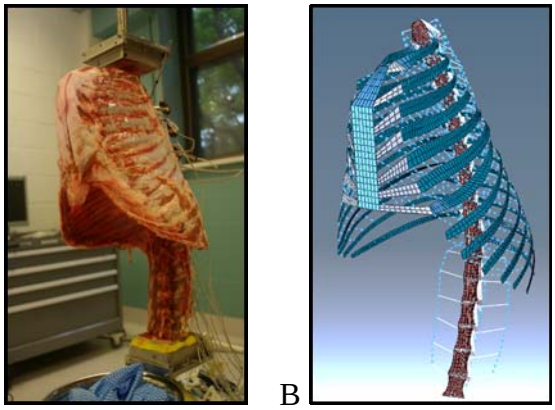

Figure 1: Sheep spine A. Experimental setup; B. FEM

Using custom image processing and FE pre-processing software, a geometrically and materially individualised FE model of the sheep osseoligamentous thoracolumbar spine was developed (Fig 1B). Material parameters describing the spinal ligaments (nonlinear elastic) and disc annulus fibrosus (Mooney-Rivlin hyperleastic) were based on experimental testing data for the sheep soft tissues. The remaining material parameters were derived from prior studies of human spinal tissues [3]. The osseous ribs, costal cartilage, osseous sternum, intercostal soft tissues, costo-vertebral and costo-transverse connections were all discretely represented at each spinal level to simulate the intact ribcage. This approach to simulating the costo-vertebral/transverse connections has been previously validated [5]. Loading conditions simulating the experimental testing were applied. The FE predicted spinal stiffness for the four stages of dissection was determined.

RESULTS AND DISCUSSION

The FE-predicted moment-rotation response was nonlinear for both flexion and axial rotation over all four stages of dissection – the same was true for the experimental data. The peak rotational stiffness for the *Intact* FEM was comparable to the experimental results for flexion (Experimental: 0.22Nmm/º; and FE: 0.20Nmm/º) and axial rotation (Experimental: 0.18Nmm/º; and FE: 0.16Nmm/º). The same was true for peak predicted stiffness for the *NoRibs* FEM during flexion (Experimental: 0.13Nmm/º; and FE: 0.17Nmm/º) and axial rotation (Experimental: 0.03Nmm/º; and FE: 0.05Nmm/º). However, there was minimal decrease in predicted FEM stiffness with successive removal of the intercostal connector elements (*NoInterC* FEM) and after simulated fracture of the sternum (*NoStern* FEM). By contrast, the experimental decrease in peak stiffness for the *NoInterC* and *NoStern* stages, relative to *Intact*, was 32% and 39% for flexion and 39% and 65% for axial rotation, respectively.

The FE predictions for successive dissection of the ribcage suggested that while the mechanics of the simulated thoracolumbar spine with either an intact ribcage (*Intact*) or intact costo-vertebral/transverse joints (*NoRibs*) were comparable to the physical specimen, accurately simulating the load-sharing contribution of the intercostal connections cannot be achieved by replicating only the anatomical structural connection between adjacent ribs. Adequately recapitulating the load sharing in the ribcage may require further knowledge of intercostal soft tissue mechanics or possibly the mechanical contribution of the fascia.

CONCLUSIONS

This study has highlighted the importance of accurately replicating both the anatomy and mechanical nature of osseous and soft tissue structures in the ribcage, particularly if models are to provide useful insight into spinal pathologies, injuries or surgery which involve disruption to the intercostal soft tissues.

P368 - MUSCULOSKELETAL LOADING AT THE TIBIOFEMORAL JOINT FOR SIT-TO-STAND (STS) MANEUVER

Alexandros N Mathioudakis, Shaniel Bowen, Malavika Suresh and Krystyna Gielo-Perczak
University of Connecticut
Corresponding author email: alexandros.mathioudakis@uconn.edu

INTRODUCTION

The ability to stand from a seated position, known as sit-to-stand (STS), is a fundamental skill for independent mobility and everyday functioning [1]. STS is executed effortlessly by healthy individuals, however individuals who suffer from debilitating conditions find it extremely difficult as the task demands high lower-limb motor control, muscle strength and coordination. Executing STS would require external assistance. This inability to perform STS can lead to decreased functioning and mobility – therefore a reduction in the quality of life.

The purpose of this study was to investigate musculoskeletal loading at the tibial-fermoral for a STS task, using our custom STS device. The STS device is a motorized seat which provides vertical as well as rotational motion through a platform attached to the top. It is comprised of high grade aluminum with a cushioned seat, consisting of water-pipe grade PVC. Primary tests had been run using simulation software such as AnyBody Technology to determine the amount of strain throughout the motion. The results of this study will be quantified by analyzing muscle activity in conjunction with reaction forces of the joint. We hypothesize that using this device will result in lower muscle activity and reduced reaction forces during the execution of the STS task.

METHODS

Thirty healthy young subjects (mean age = 18-25 years, height = 60-77 inches, weight = 125-225 pounds) provided written informed consent to participate in the protocol, which was approved by the local institutional review board.

Electromyography (EMG) measurements were taken by application of surface Trigno wireless EMGs (Delsys) to measure the muscle activity of the vastus lateralis (VL), biceps femoris (BF), and gastrocnemius muscles (GM). Force platform measurements were taken using the AMTI AccuSway Force Plate to measure and quantify the Center of Pressure (COP) velocity, COP displacement in medio-lateral and anterior-posterior planes, COP 95% ellipse area, and individual components of the respective ground reaction forces.

The anthropometric measurements of all the participants were taken for characterization purposes. The STS device was set-up so its height was equivalent to the vertical distance between the subject's heels to the popliteal fossa crease. The subject's hips and knees were bent at approximately 90° (± 5°) using a goniometer, and feet pointed forward while rested flat against the force plate and shoulder width apart.

A statistical analysis was performed between weight/height and muscle activity/balance parameters. The data were analyzed using BioAnalysis, EMGWorks, MATLAB, and Minitab.

RESULTS AND DISCUSSION

The STS device provides the user with an initial velocity, hence the STS maneuver performed by the user does now utilize the momentum gained by the device, which in return reduces the load on the muscles, and decreases the moments generated at the tibiofemoral joints. The STS device ultimately renders the STS maneuver effortless.

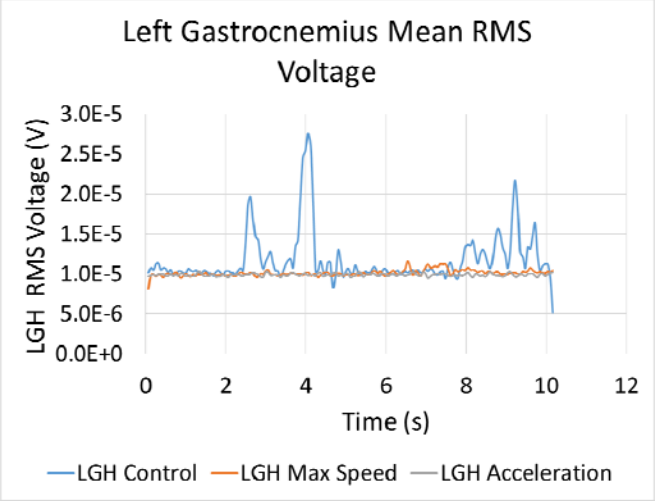

Figure 1: Left Gastrocnemius muscle activity, without assistance (blue), at instantaneous maximum speed setting (orange), and at the accelerated setting (grey).

From the experimental results shown in Figure 1, it is found that the accelerated STS device setting has the lowest muscle activity, while the unassisted case has the highest overall muscle activity; on the left gastrocnemius muscle. These results demonstrate the effectiveness of the STS device in assisting the STS maneuver.

CONCLUSIONS

By application of surface Trigno wireless EMGs (Delsys), and the AMTI Force Plate, a musculoskeletal loading study was performed which revealed lower muscle activity, and smaller reaction forces while using the STS device. Computational validation of the current work is underway by application of Anybody Modeling System, multiple other studies have made significant progress by the use of this software [2]. In future application, the STS device can be used to give grater mobility, improved motor control and coordination, and ultimately improve the quality of life for qualified patients.

INTRODUCTION

The Medial Longitudinal Arch (MLA) is a fundamental structure of the foot and its integrity is critical to an efficient foot mechanics. More than just supporting the body weight, MLA deformation works as a shock absorber by damping the forces passing through the foot [1]. Although foot posture is frequently assessed in clinical practice, accurate MLA measurement is pivotal to identify preventive actions and/or to pursue effective treatments for musculoskeletal conditions. There are several different methods for assessing MLA in static and dynamic conditions, however there is no consensus on which is the best and if these assessments have any mutual relationship. The aim of this study was to investigate the correlations between static and dynamic MLA measurements using different methods.

METHODS

Twenty-six healthy adults (20 females, 6 males; 25 ± 7 yrs old; 63.2 ± 15.3 kg; 164.2 ± 8.5 cm) were recruited and assessed (Ethics Committee approval protocol HCFMUSP #031/15). Footprints were assessed qualitatively in up-right posture on a podoscope and also acquired with the EMED® pressure plate (Novel GmbH, Germany) during double leg stance. The former were processed using Photoshop (Adobe) and the Arch Index (AI) [2] was calculated using the areas determined by ImageJ (National Institutes of Health, USA). The Arch Height Index (AHI) [3] was also measured by a caliper based on foot length, navicular height (NH), dorsum height and truncated foot. The Foot Posture Index (FPI-6) was assessed by a trained physiotherapist. Nine infrared cameras (OptiTrack FLEX: V100; Natural Point, USA) and the Rizzoli Foot Model [4] were used to determine MLA angle posture and deformation. MLA angle was measured in double leg stance, seated with unloaded foot and during walking. Each participant attended a single data collection session for all these foot measures. The relationship between MLA measurements was investigated via Spearman correlation coefficient.

RESULTS AND DISCUSSION

For the static measures of MLA, significant correlations were found between NH and AHI (r=0.41, p=0.04), and also between the podoscope- and the plate-estimated AI, in both the right (r=0.77, p<0.01) and left (r=0.63, p<0.01) foot (Table 1). Significant negative correlation was found in the double leg stance between MLA angle and podoscope estimated AI (r= -0.50, p=0.03). A linear regression model was used to predict MLA angle from plate-estimated AI (right foot: R^2 =0.56; left foot: R^2 = 0.41). In order to compare podoscope- and plate-estimated AI measures**,** Bland–Altman plot showed that only three subjects had values under the inferior confidence interval, demonstrating consistency of the measures**.** A fixed bias of 0.032 was found on the AI calculation, where the pressure plate measure revealed greater values than the podoscope measure. This finding is in accordance with the pressure plate sensibility to assess MLA angle, which considers each sensor activated when the load is above 5kPa, and then takes into account its value to calculate AI. This threshold value is probably not identified in the footprint on the podoscope, mainly at the midfoot.

CONCLUSIONS

We conclude that NH could be used to measure MLA deformation instead of AHI, because the calculations for the latter are also more demanding than for the former. The podoscope can be used to obtain a reliable AI in substitution of expensive pressure plates. The static foot measures should be used with caution in clinical practice because, in general, these did not show strong and significant correlations with the dynamic function of the MLA during walking or other weight bearing exercises.

INTRODUCTION

Understanding the mechanics of the spine during activities of daily living and workplace-oriented tasks (e.g. lifting and carrying) is important to explain and prevent injury. However, studying spine mechanics (e.g. muscle function and spinal loads) *in vivo* is very invasive, and, therefore, musculoskeletal models have been developed. These models have become important tools that have greatly advanced the field of biomechanics. OpenSim is a freely-available open-source modelling platform [1]. Recently, a full-body lumbar spine (FBLS) model was developed by [2] to analyse spinal loads during jogging. The purpose of our investigation was to validate a modified FBLS model for dynamic trunk movements using a published EMG-driven musculoskeletal model [3].

METHODS

One healthy male with no history of low back pain was recruited for this study (21 years; 67.5 kg; 168 cm). The participant was instructed to perform a series of loaded and unloaded tasks: one-arm sweeps (left and right; 5 kg), gait (unloaded, bilaterally loaded (2 x 20 kg), unilaterally loaded (left and right; 20 kg)), lateral bends (left and right; unloaded, loaded (20 kg)), trunk axial rotation and flexion-extension range of motion, quiet standing (eyes open and closed), standing while co-contracting, 45 degrees of trunk flexion (20 kg), box holds (close to chest and arms extended; 20 kg), and four squats with weights (~0, 5, 10, 15, 20 kg). For all tasks, EMG data were collected at 2040 Hz (Trigno, Delsys, USA) bilaterally from key muscles [3], full-body kinematic data were collected at 120 Hz with a 10-camera V5 system (Vicon, UK), and ground reaction force (GRF) data were collected at 2040 Hz by two force plates (FP 4060, Bertec, USA). Kinematic and GRF data were imported into OpenSim to perform scaling, inverse kinematics, static optimisation, and joint reaction analyses (L_4/L_5) on the FBLS model [2]. EMG data were processed and normalised to %MVIC [3]. Then, lumbar joint angles and net reaction forces from OpenSim, and normalised EMG data were imported into an EMG-driven model to calculate corresponding 3D spine forces [3]. Data were also processed with Visual 3D (V6, C-Motion, USA) to assess agreement in net joint moments (not reported).

RESULTS AND DISCUSSION

Over all tasks, good agreement was found between the EMG-driven model and the FBLS model for mean compression ICC(1,k)= .608, CI= .088 – .833, p= .015; mean AP shear ICC(1,k)= .704, CI= .312 – .874, p= .003; and maximum AP shear ICC(1,k)= .704, CI= .313 – .874, p= .003; a fair relationship was found for maximum compression ICC(1,k)= .490, CI= -.185 – .783, p= .058. However, when the co-contraction standing trial was removed (because static optimisation and the EMG-driven model were not expected to match for this trial), the ICCs became much stronger: mean compression ICC(1,k)= .854, CI= .654 – .939, p< .001; maximum compression ICC(1,k)= .786, CI= .492 – .911, p< .001; mean AP shear ICC(1,k)= .762, CI= .439 – .901, p= .001; and maximum AP shear ICC(1,k)= .777, CI= .470 – .907, p< .001. Mean compression values across all trials for both models are displayed in Figure 1.

CONCLUSIONS

Working towards a robust model to calculate joint forces and moments is essential to the fields of spine biomechanics and ergonomics. Here we have shown that the modified FBLS model developed by [2] provides similar outputs (absolute agreement and trends) to a previously published and validated EMG-driven model [3]. These results instil confidence that this FBLS model is an appropriate model to estimate spinal loading magnitudes and trends during loaded and unloaded dynamic trunk movements. Our future work with OpenSim will seek to incorporate EMG activation profiles to aid in the accuracy of the model during tasks that involve large amounts of muscular co-contraction.

INTRODUCTION

Assessing possible interactions between pectoralis minor muscle length, scapular protraction (SP) and thoracic spine curvature (thoracic kyphosis, TK) is part of the shoulder/upper limb rehabilitation process [1]. Pectoralis minor length can be easily measured by taking the distance between the coracoid process and the 4th rib using a measuring tape [1]; however, no simple, portable and affordable measuring system exists that may assist clinicians and researchers screening in real-time for excessive TK and SP. Photograph-based measurements of TK have shown high correlations with radiographic measurements, but it requires data processing using specific computer software [2]. Inclinometers may reliably measure TK and scapular upward rotation, but SP measurements are not available [3]. Current smartphones have embedded motion sensors (inertial central) that allow real-time quantification of linear and angular motion of the device in 3 planes of orientation. Despite its potential use in musculoskeletal rehabilitation, the measurement properties of the smartphone to assess thoracic spine and shoulder girdle orientations have not been investigated. The purposes of this research were to assess: a) intrarater reliability and agreement of smartphone-based measurements of TK and SP; b) the correlation and agreement between smartphone- and photograph-based measurements of TK; and c) the correlation between SP and pectoralis minor length normalized to a person's height (pectoralis minor index, PMI).

METHODS

Forty-one (n = 41; 21 males) asymptomatic volunteers without postural or movement impairments of the upper body [Age (mean ± SD) = 31.34 ± 13.27 years; Height = 1.67 ± 0.07 m; Body mass = 70.53 ± 12.37 kg] were assessed twice in a self-balanced standing upright position. Smartphone (iPhone 4, iOS 7.2) measurements were conducted using the native application of the device operative system, the Compass app. To measure the TK, the left longitudinal edge of the device was first placed in the vertical position and then in contact with the skin over the spinous processes of the upper (T1–T4) and lower portions (T8–T12) of the thoracic spine, forming the upper and lower thoracic angles, respectively. The sum of both angles formed the TK. To measure the SP angle, the device was first aligned perpendicularly with the thoracic spine (initial angular position) and then parallel with the spine of the scapula (final angular position). Both dominant (D) and non-dominant (ND) sides were assessed. The TK angles and the pectoralis minor length were also collected using photographs and tape measurements, respectively [1, 2], for comparisons with smartphone-based measurements. Intrarater reliability was estimated through $ICC_{2.1}$ and agreement with SEM and MDC_{95}. Agreement of TK measurements conducted with the smartphone and photographs was calculated using the Bland and Altman 95% limits of agreement (95%LoA). The correlation between measurement methods was assessed using Pearson's *r*. Specific software (SPSS v24 and GraphPad Prism v6) was used to conduct the statistical analyses and a significance level of $p < .05$ was considered.

RESULTS AND DISCUSSION

Intrarater reliability and agreement of smartphone-based measurements are presented in Table 1. Significant correlations ($p < 0.01$) were found between smartphone- and photograph-based measurements for TK angles [*r* (upper angle) = 0.93; *r* (lower angle) = 0.77; *r* (sum angle) = 0.89). Agreement between methods was satisfying despite some underestimation of the lower kyphosis angle by the smartphone (upper angle 95%LoA = [-5.5º, 3.1º]; lower angle = [-9.4º, 3.4º]; sum angle = [-10.4º, 2.7º]). Significant correlations ($p < 0.02$) were found between SP and PMI [*r* (D) = -0.48; *r* (ND) = -0.38], similarly to previous results where SP was measured using an electromagnetic tracking device [1]. The wide intrarater agreement estimates found in this study on SP may reduce the smartphone clinical applicability.

Table 1: Intrarater reliability ($ICC_{2,1}$) and agreement (SEM, MDC_{95}) of smartphone-based measurements.

Measure		ICC (95% CI)	SEM	MDC
Thoracic kyphosis angles	Upper	0.93(0.88–0.96)	1.6º	4.4º
	Lower	0.97(0.94–0.98)	0.9º	2.4º
	Sum	0.93(0.86–0.96)	1.5º	4.3º
Scapular protraction	D	0.70(0.50–0.83)	3.9º	10.7º
	ND	0.71(0.52–0.84)	3.9º	10.7º

SEM: Standard Error of Measurement; MDC_{95}: Minimal Detectable Change; D: Dominant; ND: Non-dominant scapula.

CONCLUSIONS

Smartphone-based measurements may have the potential to assess angular resting position variables of interest for shoulder/upper limb rehabilitation and research. Further studies, including the development of applications, are necessary to more definitely discern the applicability of smartphones inertial central as a measuring system of body segments angular position and motion.

P372 - EFFECT OF MECHANICAL PROPERTIES OF APONEUROSES ON STATIC AND DYNAMIC FORCE PRODUCTION IN MUSCLE-TENDON COMPLEX: FINITE ELEMENT SIMULATION

[1,2] **Toshiaki Oda**, [3]Takayuki Hisano and [4]Naoto Yamamura

INTRODUCTION

Aponeuroses located over the surface of muscle tissues in muscle-tendon complex have functions not only transferring force generated by muscle fibers but also deforming by visco-elastic mechanical properties of tissues. Thus, change in stiffness of aponeuroses will alter amount of deformation in muscle tissues connecting to aponeuroses and then influence their force production. In experimental protocols such as training and rehabilitation, however, it is so difficult to determine the effect from one parameter to others, since the selected intervention tasks would change many parameters simultaneously. In this work, we aimed to investigate the effect of non-linear mechanical properties in aponeuroses on force production capability and deformation in muscle-tendon complex using finite element simulation.

METHODS

The developed software (V-Biomech, RIKEN [3] for finite element analysis of biological tissues with non-linear large deformation model was used for simulation. This soft has a material model for muscle tissues with activation process as well as force-length-velocity relationship. Mechanical properties were set using Mooney-Rivlin material model. A 3 dimensional tetrahedral constitutive mesh model of unipennate muscle (200 mm length) including muscle fibers with pennation angle, aponeurosis and tendon tissues, was constructed. Different mechanical parameters from stiff [1], to compliant [2] were prepared for simulation. We tested static and dynamic contractions with full activation. In static conditions, initial stretches from -20mm to +50mm were applied, and the peak forces during isometric contractions at the length were computed. Then, the length-force relation curve was evaluated. In dynamic conditions, the muscle-tendon complex was shortened (concentric) and lengthened (eccentric) with different velocity with full activation, after +20 mm initial stretch for concentric conditions or -20 mm initial shortening for eccentric conditions. The generated forces in dynamic contractions were measured at neutral length, then the velocity-force curve was assessed.

RESULTS AND DISCUSSION

Figure 1 shows the typical results of length-force (a) and velocity-force (b) relationships of stiff and compliant conditions. In both of static and dynamic conditions, the active and total forces were larger in stiff condition than those of compliant condition. In static condition, the peak force in compliant condition was shifted to longer direction of length-force relationship. In dynamic condition, stiff condition showed larger force in all velocity including both of concentric and eccentric conditions. The present work suggested that stiff aponeuroses showed great advantage in maximal force production by 2 times than compliant aponeuroses in both static and dynamic conditions. The results of strain distribution in mesh model demonstrated that contractile elements in muscle fibers became shorter in compliant condition in many cases. This caused weak force production in contractile element, since contractile element should generate force within ascending limb in length-force relationship of muscle fibers. In dynamic condition, in addition to this, complex length and velocity distribution and variation in direction of force vectors observed in contractile elements in muscle fibers also affected the muscle force differences as a whole muscle-tendon complex. Interestingly, there are cases that internal deformation of muscle fiber was remarkably different while deformation of outer shape was not so different. These results suggest that the mechanical properties of aponeuroses would be one of the important determinants of muscle force production.

CONCLUSIONS

This study demonstrated the possibility that stiff aponeuroses would have great advantage in muscle force production among both static and dynamic conditions.

INTRODUCTION

Cervical strength and endurance is commonly used as a measure of muscular capacity to physically support the head and neck. Yet regional differences in the anatomy of the upper and lower cervical muscles are often not differentiated with strength and endurance measures. This study examined isometric strength (maximal voluntary contraction (MVC)) and endurance of cervical flexor and extensor muscles in healthy individuals at the craniocervical (CC) and cervicothoracic (CT) axes in the sagittal plane using a dynamometry method that accommodated regional differences in cervical muscular anatomy.

METHODS

Twenty females (mean (± SD) age 24.2 ± 3.16 years, body mass index (BMI) 21.58 ± 2.38 kg/ m2) and twenty males (age 26.1 ± 3.32, BMI 24.22 ± 3.05) with no history of neck pain participated in the study approved by the Institutional Human Research Ethics Committee.

MVC and endurance measures (time to task failure in seconds (s)) at 50% MVC were recorded in 4 directions (CC flexion (CCF), CC extension (CCE), CT flexion (CTF) and CT extension (CTE)) using a dynamometer (Figure 1).

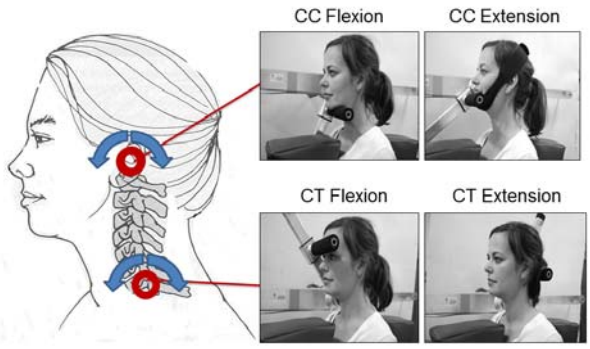

Figure 1: Dynamometry configuration demonstrating the axes of measurement permitting recording of craniocervical (CC) and cervicothoracic (CT) flexion and extension performance [1].

Strength (MVC in N m) and endurance (s) means (SD) in all 4 directions (CCF, CCE, CTF, CTE) were derived and six strength and endurance performance ratios calculated (CCE:CCF, CTE:CTF, CTF:CCF, CTE:CCE, CTF:CCE, CTE:CCF) for males and females separately. Group (male, female) data (MVC, MVC ratios, endurance, endurance ratios) were compared using a General Linear Model Multivariate Analysis with a Bonferroni correction for multiple comparisons. Preliminary analysis revealed gender differences in BMI ($p = .004$) and some discrepancy in age ($p = .07$) so these factors were included as covariates in the statistical modelling. An alpha of .05 was adopted.

RESULTS AND DISCUSSION

The most substantial finding of this study was the significantly greater endurance observed for the extensor muscles compared to the flexors (2 to 2.4 times greater). Endurance was similar between genders ($P > .11$) as were endurance ratios except the CT extension to CC flexion ratio that was significantly larger in females compared to males ($P = .03$). Consistent with our previous study [2] the cervical extensors produced considerably greater torque than the flexors (1.3 to 2 times greater MVC) with similar strength ratios between genders ($P > .06$), despite males being significantly stronger in all muscle groups ($P < .003$).

While the greater extensor compared to flexor strength may be explained by the differences in muscle cross-sectional area, the differences in endurance is not as easy to explain. Potentially the antigravity function of the extensor muscles in upright posture and the high concentrations of cervical extensor type I fibres may partly explain their greater capacity for endurance. The significantly greater CTE:CCF endurance ratios observed in females compared to males (3.1 versus 2.3) also suggests that there may be some gender differences in endurance parameters in healthy individuals. It should be acknowledged that findings are specific to the examined healthy younger adult population (average age 25 years).

CONCLUSIONS

In the rehabilitation setting greater strength and endurance capacity can be expected when evaluating the extensors compared to the flexors under normal circumstances. These differences should be considered when designing exercise programs with respect to exercise parameters (eg. load, repetition, duration) to train each muscle group.

P374 - RELATIONSHIPS BETWEEN WALKING SPEED, MOBILITY AND TRUNK MUSCLE SIZE

[1] Ryo Osaki [1] Akira Saito, [2] Fumiko Tanaka, [1] Mitsuru Higuchi, [3] Shigenobu Shibata, and [1] Yasuo Kawakami
[1] Faculty of Sport Sciences, [2] Organization for University Research Initiatives, and
[3] School of Advanced Science and Engineering, Waseda University

INTRODUCTION

It is known that the maximal walking speed decreases with aging, due to decreases of both the cadence (pitch) and stride length [1]. Therefore, in the elderly population, walking performance reflects individual physical fitness levels. Walking performance in the elderly has been assessed by functional mobility tests (e.g. timed up and go; TUG). One of major determinants of physical performance is the skeletal muscle size, and some studies have reported inverse relationships between trunk muscle size and age [2]. The psoas major (PS) is one of trunk muscles that plays a key role in maintaining walking speed by contributing to the leg swing initiation [3]. However, there have been few studies focusing on the relationship between trunk muscles size and walking performance. The purpose of this study was to investigate the relationships between trunk muscles size and walking performance in middle-aged and elderly populations. We hypothesized that muscle size of the PS would be related to walking speed and its determinants (SL in particular) in the elderly.

METHODS

70 healthy males (67.0 ± 7.5 years, 167.3 ± 6.4 cm, 66.2 ± 9.3 kg) and 73 healthy females (63.1 ± 9.9 years, 155.2 ± 5.8 cm, 54.5 ± 8.5 kg) participated in this study. For each subject, a cross-sectional image of the trunk was taken at the L4-5 level by magnetic resonance imaging. An anatomical cross-sectional area (ACSA) was measured for the rectus abdominis, lateral abdomin (internal oblique + external oblique + transversus abdominis), quadratus lumborum, PS, and erector spinae (lumbar multifidus + lumbar part of longissimus thoracis and iliocostalis lumborum). ACSAs of trunk muscles were normalized by the two thirds power of body mass ($cm^2/kg^{2/3}$). Walking performance was assessed by time and steps taken for 5-m maximal walking test, and walking speed, pitch and SL were calculated accordingly. A timed-up-and-go (TUG) test was performed to evaluate the functional mobility. TUG test score was the time taken for standing from a chair, a 3m maximal effort walk, and returning to and sitting on the chair. Pearson's correlation coefficients between measurements were calculated. Significance level was set at $p < 0.05$.

RESULTS AND DISCUSSION

ACSA of PS was significantly correlated with walking speed (r = 0.42), SL (r = 0.24: Figure 1) and TUG (r = -0.47) in females. However, in the males, no significant correlation was found between ACSA of PS and walking performance (Figure 1), whereas TUG (r = -0.39) was significantly correlated with ACSA of PS. ACSA of rectus abdominis was significantly correlated with walking speed (r = 0.25) and pitch (r = 0.26) in males and walking speed (r = 0.26), SL (r = 0.24) and TUG (r = -0.28) in females. ACSA of lateral abdominii was significantly correlated with walking speed (r = 0.25), TUG (r = -0.32) in males and SL (r = -0.24) in females. ACSA of elector spinae was significantly correlated with walking speed (r = 0.34), pitch (r = 0.25) and TUG (r = -0.34) but not in males. ACSA of quadratus lumbolum was significantly correlated with TUG (r = -0.23) only in females.

Muscle activity of rectus abdominis precedes heel contact, playing a role of trunk stabilization for a steady stance [4]. Our study demonstrated that walking performance in females was affected by muscle sizes of PS and rectus abdominis that possibly contributed to leg swing initiation and trunk stability during heel contact. On the other hand, no correlations were found between ACSA of trunk muscles and walking speed in males. The average walking speed in males was 2.2m/s, and up to and around this speed, muscle activity of iliacus and psoas are not significantly activated [5]. Together with the result of the correlation between PS size and TUG score in males, they may have been able to walk faster with proper activation of PS for larger stride length.

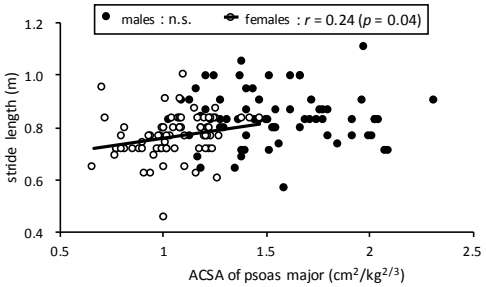

Figure 1: The correlations between ACSA of PS and SL.

CONCLUSIONS

The sizes of psoas major and rectus abdominis are associated with walking performance in female middle-aged and elderly individuals. In males, psoas major size was related with mobility test scores.

P375 - SCAPULOTHORACIC KINEMATIC AND SCAPULAR DYSKINESIS: COMPARISON OF TWO ANALYSIS APPROACHES

[1] **Denise Martineli Rossi**, [2]Renan Alves Resende, [1]Natália Borges Agostinho, [1]Isabela Forcin Favaro, [1]Gisele Harumi Hotta, [2]Sérgio Teixeira da Fonseca and [1]Anamaria Siriani de Oliveira
[1]University of São Paulo
[2]Federal University of Minas Gerais
Corresponding author email: denisemartineli@hotmail.com

INTRODUCTION

There are still several challenges to the evidence regarding scapular dyskinesis (SD) [1,2]. Establish what is 'abnormal' considering the high degree of variability within and between subjects, the possibility of individual's adaptive strategies, poor diagnostic measurements and the absence of a direct relationship between SD and shoulder symptoms [2].

Traditionally, studies compare groups focusing on the amount of scapular motion at selected points of humeral elevation by using angle-angle graphs. A dynamic systems approach, such as the Principal Component Analysis (PCA), may provide more information about variability and advance current understanding of 'abnormal' movement patterns [3,4]. Therefore, the purpose of this study was to compare scapulothoracic kinematic pattern between asymptomatic individuals classified as having and not having SD by using two analysis approaches.

METHODS

Forty-two asymptomatic individuals were evaluated if they had at least 120º of the humerothoracic range of motion and no shoulder pain history. All participants signed the consented term approved by local Ethics Research Committee (n. 29479614.0.0000.5440). Participants were classified as having or not SD by an experienced physical therapist during ten cycles of loaded forward flexion. Three-dimensional position and orientation of each subject's thorax, scapula and humerus were tracked using electromagnetic Liberty ® (Polhemus Inc) system according to ISB international recommendations.

Subjects performed ten cycles of forward flexion, and the last three trials were processed using The Motion Monitor software. The y-x-z sequence was used to describe the scapular orientation relative to the trunk: internal/external rotation, upward/downward rotation, anterior/posterior tilt. Angle-angle and PCA were processed using Matlab software. Angle-angle graphs included scapular orientation for selected humerothoracic angles (30˚, 60˚, 90˚ and 120˚) during raising and lowering arm in the sagittal plane. PCA was applied to determine the main features of original data defined as principal components (PCs) and their scores used as dependent variables for groups comparisons. Raising and lowering arm phases were evaluated separately considering the interval between 20º and 120º of humerothoracic angle. Statistical comparisons were processed on SPSS software.

RESULTS AND DISCUSSION

Twenty-three participants were classified as having SD (24 ±9 y; 1.7 ±0.1 m; 67.8 ±12.2 kg), and nineteen did not present SD (36 ±13 y; 1.7 ±0.1 m; 71.9 ±12.9 kg). Groups were not statistically different considering scapular kinematic by using angle-angle graphs (p>0.05). From all Principal Components (PCs) analyzed, the PC2 for upward and downward rotation during raising and lowering arm showed statistic evidences explaining 15.48% and 18.10% of data total variability, respectively. Group classified as having SD presented greater upward rotation (Low PC2) at the beginning and lower upward rotation at the end of raising arm (p=0,002; F=11,07) than the group without SD (High PC2) (Figure 1), i.e., lower total range of motion. The same pattern was found during the lowering arm phase (p=0,002; F=10,94).

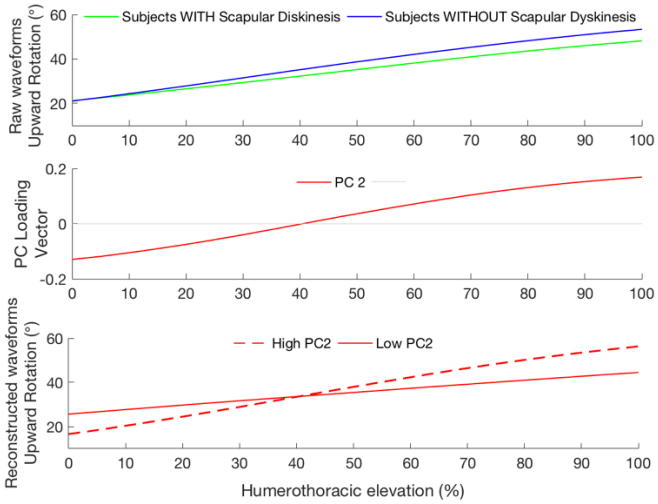

Figure 1: Principal Component Analysis applied to scapular upward rotation time series during humerothoracic elevation.

CONCLUSIONS

PCA analysis showed differences of scapulothoracic kinematic between asymptomatic with and without SD. Subjects classified as having SD presented lower total range of upward/downward scapular rotation during arm motions.

P376 - THE EFFECTS OF STEP WIDTH ON 3D LOWER LIMB KINETICS IN A SPRINT START

[1]**Paul Sandamas**, [2]Elena M. Gutierrez-Farewik and [1,3]Anton Arndt
[1,3]The Swedish School of Sport and Health Sciences

INTRODUCTION

On exiting the starting blocks, a sprinter's step width is greater than at any other time during the race [1]. Although sprinting has been extensively studied, the vast majority of studies have used a 2 dimensional (2D) approach. In order to fully examine the biomechanical effects of step width on performance a 3D approach is required. Therefore, the purpose of this study is to compare 3D lower limb kinematics and kinetics between a normal sprint start and a start where the first step is restricted to a similar width found in full speed running.

METHODS

Elite sprinters have been included in the study. This abstract depicts results from Sweden's top ranked female hurdler (former Olympic finalist), age 35 years, height 1.70m, weight 62.7kg, 100m personal best 11.3s (season best 11.5s). The study was approved by the Stockholm Regional Ethical Committee.

Ten maximum effort 10m block starts were performed indoors in a laboratory fitted with a Tartan running surface. Five trials were performed with the athlete performing her natural technique (Normal) and 5 trials were performed with the athlete running inside a 0.3m lane (Narrow). 3D kinematics where recorded with a 12 camera motion analysis system (250 Hz) (Qualisys AB, Sweden). First step ground reaction forces were recorded using a force plate (1500 Hz), (Kistler, 9281EA).

The subject was equipped with 80 markers prior to running. The markers were labelled using Qualisys Track Manager software (Qualisys AB, Sweden). After labelling, all data were processed with Visual 3D (C-Motion Inc, USA). A 3D full body model was constructed and inverse dynamics were performed to calculate the net internal joint moments and power. Although power is a scalar, it was decomposed into its components from the three planes for the sake of analysis. As one subject is shown here, the mean values are compared but no statistical analysis was performed.

RESULTS AND DISCUSSION

The results are presented as mean ± 1 standard deviation (SD) for the Normal trials followed by the Narrow trials.
Although the step width was different (0.303 ± 0.023 and 0.208 ± 0.028m), step length (1.087 ± 0.013 and 1.091 ±0.042m) and first stance contact times were similar (0.212 ±0.006 and 0.216 ±0.0131s). First step toe-on and toe-off fore-aft whole body centre of mass (CoM) velocities were also similar (3.12 ± 0.04 and 3.17 ± 0.04, 4.42 ± 0.161, 4.42 ± 0.115 m/s respectively).

The ensemble mean and SD moment and power graphs revealed the following differences. During the first $^{1}/_{12}$ of the stance phase, the Narrow trial moments were greater in the frontal plane hip and ankle and transverse plane knee moments whereas during late stance the sagittal plane ankle moments were greater for the Normal trials (Figure 1, top row).

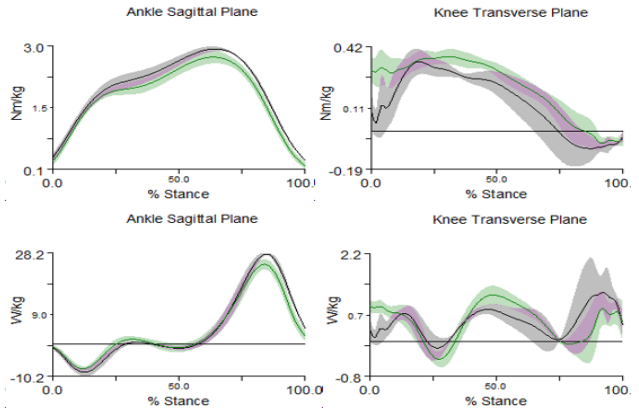

Figure 1: Ankle and knee moments (top row) and power (bottom row) for Normal trials (black) and Narrow trials (green) during stance. Positive moments reflect ankle plantar flexion and knee internal rotation. Power generation is positive. Data represent mean (solid line) ± 1 SD (shading).

The power graphs showed a greater transverse plane knee profile in the Narrow trials for the first $^{1}/_{12}$ of the stance phase and greater sagittal plane ankle power for the Normal trials during late stance (Figure 1, bottom row). The athlete's normal foot plant appears to allow the ankle to generate greater power in the sagittal plane which in turn could indicate that the restricted stance may inhibit the role of the plantar flexors to produce positive ankle power.

Debaere et al., [2] have described that the important role of the knee in the sagittal plane during first stance is power generation. For the Narrow trials, the greater knee internal rotation moment and power during initial stance is in phase with the greater hip abduction moment, which could suggest that slightly greater muscular effort was required to stabilise the knee before it was able to produce peak power in the sagittal plane.

CONCLUSION

A narrow first step reduced ankle power production during late stance for this elite level athlete. Inclusion of data from further elite sprinters will help elucidate whether these observations are representative.

P377 - EFFECTS OF LANDING TECHNIQUE ON GROUND REACTION FORCES AND JOINT KINEMATICS IN SPECIFIC ATHLETIC GROUPS

Sanli G. [1,2], Tatar Y.[2],Yucesoy C.A.[1]
[1]Institute of Biomedical Engineering, Bogazici University, Istanbul, Turkey
[2]Faculty of Sports Sciences, Marmara University, Istanbul, Turkey
Corresponding author email: goktug.sanli@marmara.edu.tr

INTRODUCTION

Jumping and landing movements are frequently performed in most sports. Ground reaction forces greatly increase at the contact and subsequent deceleration phases in landing [1]. The resulting mechanical stress on the musculoskeletal tissues can cause injuries if not absorbed and dissipated effectively. Therefore, correct technique providing an efficient deceleration of movement is crucial.

Studies on the effects of different foot placement strategies during landing showed significantly less maximal vertical ground reaction force (MVGRF) and loading rates (LR i.e., maximum vertical force/time to maximal vertical force from initial contact) with forefoot landing (FFL) technique compared to toe-heel landing (THL) in traceurs (parkour practitioners)[2]. This has been considered to be the result of increased knee and hip flexion occurring in this technique. However, no kinematic measurements were done to rationalize this view-point.

Traceurs frequently perform impactful FFL in their practice, whereas wrestlers rarely perform any landing. The goal is to compare the effects of FFL and THL techniques on MVGRF and joint kinematics in traceurs, wrestlers and non-athletes.

METHODS

4 male traceurs (age=18±1.4 years; body mass=66.7±1.9 kg; and height=1.74±0.06 m), wrestlers (age=19.3±0.5 years; body mass=77.5±13.6 kg; and height=1.75±0.05 m) and, non-athletes (age=18.5±06 years; body mass=66.1±3.9 kg; and height=1.72±0.08 m) participated in the study.The participants were asked to drop off from a platform (0.75 m) without jumping and to land on a force platform performing 3 trials for each landing technique. A high-speed (145 Hz) camera (VDS Vosskühler, CCD-1300QHS, Germany) was used for kinematic analyses. Markers were placed on anatomical reference points to analyze maximum flexion angles of ankle, knee and hip joints from fully extended position (0^0).

MVGRF and LR were calculated from the force platform recordings at 400Hz. Mean values of 3 trials of each technique were calculated. Subsequently, group means and standard deviations (SD) and mean percent differences for the studied metrics were computed to assess effects of landing techniques and groups.

RESULTS AND DISCUSSION

For all groups, MVGRF and LR were significantly higher in THL technique, compared to those in FFL (Table 1): by 40% and 61% in wrestlers, 24% and 60% in traceurs; and 34% and 74% in non-athletes, respectively. This may be ascribed to higher activity of ankle musculature in FFL, leading to a higher energy dissipation in the knee and hip joints [3]. MVGRF data are in concert with [2]. However, in contrast to earlier assumptions, there was no significant increase in knee and hip flexion angles in FFL, compared to THL. Moreover, hip flexion even decreased in FFL in non-athletes and traceurs (by 22% and 15%, respectively). The higher maximum ankle flexion angle in FFL, indicate less dorsi-flexion, as a consequence of the technique.

Table 1: Group means and SD of Max GRF and joint angles

Group	Landing Technique	MVGRF (BW)	Loading Rate (BW/S)	Max Hip Flexion Angle (^{0})	Max Knee Flexion Angle (^{0})	MaxAnkle Flexion Angle (^{0})
Wrestler	FFL	2.7±0.2	41.8±3.7	20.3±13.6	32.4±13.6	11.3±6.6
	THL	4.6±0.6	106.2±25.5	30±13.5	26.6±12.2	29.6±5.1
Traceur	FFL	2.8±0.3	38.9±5.8	32.2±8	40.8±3.6	18.5±7.3
	THL	3.7±0.6	97.5±38.6	40.7±13.5	39.4±3.7	32.6±2.9
Non-athlete	FFL	2.7±0.3	41.4±13.8	25.7 ±9.2	50.4±14.1	20.6±1.9
	THL	4.2±0.4	160.8±115	40±6.2	51.2±11.8	37.2±2.8

Higher maximal joint flexions shown in non-athletes compared to the remainder groups indicate that they collapsed more during the landing. This is ascribed to the athletes' capacity for higher muscle cocontraction, which increases joint stiffness, and limits joint flexion[4,5].

CONCLUSIONS

The FFL technique was shown to reduce maximal ground reaction forces in all groups in the absence of any increase in maximum knee and hip flexion angles. Higher joint flexion angles in non-athletes, compared to athletic groups indicate a different landing strategy for energy dissipation in the lack of muscular adaptation to training. Future studies with a higher number of subjects are indicated for further analyses.

P378 - GAIT BIOMECHANICS AND HIP JOINT CONTACT FORCES OF PATIENTS WITH CAM-FAI

[1, 2]**Trevor N Savage**, [1]Hoa X. Hoang, [1]David J Saxby, [1]Claudio Pizzolato, [1]Edin K Suwarganda, [3]Michelle Hall, [3]Tim V. Wrigley, [3]Kim L Bennell, [2]David J Hunter and [1]David G Lloyd

INTRODUCTION

Femoroacetabular impingement (FAI) is a morphological condition of the hip joint producing impingement between the femur and acetabulum and resulting in cartilage damage and pain. FAI has been proposed as a risk factor for hip osteoarthritis (OA), particularly in young healthy adults [1]. There are three variations of FAI morphologies: Cam, Pincer and a combination of the two, referred to as 'Mixed'. It has been suggested that Cam-FAI morphology has the strongest association with OA [1]. Cam-FAI involves thickening of the femoral head and neck, and is thought to cause the labrum to separate from the acetabular rim, resulting in delamination and degradation of adjacent acetabular cartilage.

Gait analyses of FAI patients suggest altered gait biomechanics, with significant differences in frontal and sagittal range of motion (ROM) [2],but the samples studied were predominantly male (71%). Moreover, hip joint contact forces have not been evaluated in an FAI population and little is known regarding changes in the neuromechanics of hip muscles and their contribution to locomotion.

Neuromusculoskeletal (NMS) models can be used to investigate internal hip joint biomechanics (i.e. muscle and articular contact forces) during locomotion and contribute to our understanding of best practices for treatment of Cam-FAI. As most gait research has been done in males, this study aimed to investigate gait biomechanics in both male and female Cam-FAI patients. Consequently, we plan to investigate hip joint contact forces, using an electromyogram (EMG)-informed NMS models and will present these results.

METHODS

Fifteen Cam-FAI patients with an alpha angle >55° participated after consulting an orthopaedic surgeon with FAI symptoms.

Patients underwent gait analysis with a 12-camera (Vicon, Oxford Metrics, UK) motion capture system and in-ground force plates (AMTI, Mass, USA). Several walking trials were performed at a self-selected pace. Surface EMG was collected from 14 muscles of the affected leg.

Gait data were processed and OpenSim v3.3 was used to calculate joint angles, joint moments and muscle tendon unit (MTU) kinematics [3]. The 14 EMGs were mapped to 34 MTUs of an EMG-informed NMS model [4]. Model parameters were calibrated using the lower-limb moments, EMG and MTU kinematics from selected walking and squat trials [4]. Once calibrated, a hybrid EMG-informed NMS model [4, 5] was used to estimate muscle and hip joint contact forces.

RESULTS AND DISCUSSION

Data processing is ongoing and preliminary results of 8 Cam-FAI patients, 4 males and 4 females (32.3±8 yrs), are presented. Mean gait speed was 1.4±0.3 ms^{-1}, with no differences in gait speed between sexes. We found no differences in mean hip flexion ROM (48.5±5.8°) or mean hip adduction ROM (21.9±4.2°). Measured ROM of this cohort was similar to that for healthy controls reported elsewhere [3]. Peak hip flexion moments were 0.7±0.2 Nm/kg, but tended to be higher in females (Figure 1) but there were no significant differences between sexes in any lower-limb moments. Average peak vertical and anterior-posterior hip joint contact forces were 2±0.5 BW and 0.4±0.2 BW, respectively.

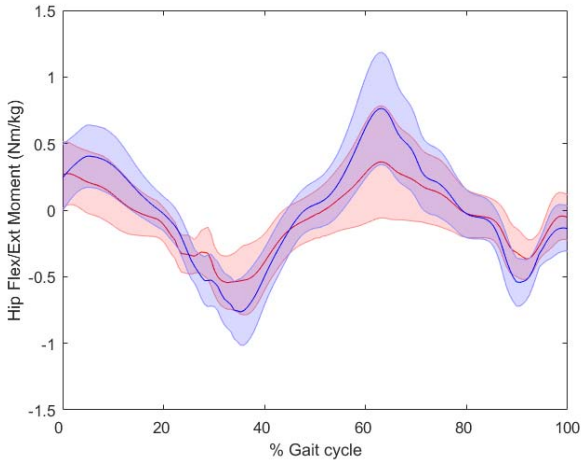

Figure 1: Averaged hip flexion/extension moments (Nm/kg) during gait in males (red) and females (blue).

CONCLUSIONS

We did not find differences in gait biomechanics between male and female Cam-FAI patients. Hip joint contact forces were at the lower end of values reported from direct measurements of elderly hip replacement patients [6]. Data processing is ongoing, and a larger sample size, including comparisons with healthy controls, will clarify pathological gait biomechanics in FAI patients to identify differences between the sexes, FAI-patients and healthy individuals. The use of EMG-informed NMS modelling will also evaluate hip contact forces and neural control solutions in this population.

P379 - FOOT FEM MODELS FOR PLANTAR ULCER PREVENTION: COMPARISON BETWEEN JOINT REACTION FORCES AND MUSCLE FORCES AS BOUNDARY CONDITIONS

[1]Annamaria Guiotto, [1]Alessandra Scarton, [2]Tiago Malaquias, [3]Ilse Jonkers, [2]Jos Vander Sloten, [1]Claudio Cobelli, [1]**Zimi Sawacha**
[1] Dept of Information Engineering, University of Padova, Italy

INTRODUCTION

People with diabetes can develop many different foot complications with the worst being diabetic foot, which compromises the function and structure of the foot and may lead to plantar ulcers and amputations. Several authors have demonstrated a close relationship between neuropathy and foot biomechanical alterations that, leading to an increased plantar pressure (PP), might determine the ulcerations [1]. In the last decades several 3D foot finite element models (FEMs) have been developed to investigate diabetic foot biomechanics and aetiology, aiming to improve prevention therapies. The usefulness of FEMs resides in the possibility of estimating the stresses of the internal tissues, otherwise not measurable in vivo. The aim of this work was to perform a sensitivity study changing the boundary conditions on two subject specific foot FEMs: a diabetic neuropathic (DNS) and a healthy (HS) one. With this purpose, simulations in 3 different conditions were run to identify the best configuration for the FEMs.

METHODS

FEMs were created for a DNS (age 71, BMI 37 kg /m^2) and a HS (age 31, BMI 20.15 kg /m^2) according to the procedure described in [2]. Gait analysis was performed as in [3] for acquiring subject specific experimental data to be used as boundary conditions in the FEMs. The experimental setup included a 6 cameras stereophotogrammetric system (BTS S.p.A., 60 Hz), 2 force plates (Bertec Corp., FP4060, 960 Hz) and 2 PP systems (Imagortesi, 150 Hz). The simulations of FEMs were driven on 4 significant instants of the stance phase of gait (initial contact, loading response, midstance and push off) by considering as boundary conditions the experimentally acquired foot kinematic and: A. experimental ground reaction forces (GRF) [2] (FEM-GRF); B. musculoskeletal modeling (MSM)-derived joint kinetics (FEM-JR); C. MSM-derived muscle forces and GRF (FEM-MUSC).

RESULTS AND DISCUSSION

In Figure 1 the results of the simulations in term of errors on peak PP estimation with respect to experimentally measured PP are reported, in percentage of the experimental PP. It can be noticed that for the HS the results of the FEM-MUSC are sensibly better than the others (from initial contact to midstance the mean error is 15% instead of 29% and 47% of the others) with the exception of push off phase. It must be reported that FEMs-MUSC used for this study include only foot extrinsic muscles. It should be mentioned that while in FEM-GRF and FEM-JR more degrees of freedom in links between the bones are locked due to the fact that no muscles are inserted to guide movements, in FEM-MUSC those degrees of freedom are released thus determine the larger errors in push off phase simulations. This could be avoided by adding intrinsic foot muscles in FEMs as they act strongly in keeping the arches of the foot. For the DNS FEM, it is interesting to notice that errors of FEM-MUSC simulations are of a comparable magnitude with respect to FEM-GRF and FEM-JR simulations (mean errors of about 30%). However improvements can be observed in results of FEM-MUSC when considering that this model always overestimated the peak PP and this brings type 1 errors in identification of patients at risk for foot ulceration, which are considered safer in term of ulcers prevention. The results reported herein agrees with those reported in the study of Chen who showed that inclusion of gastrocnemius and soleus, were crucial for an appropriate estimation of the PP peaks [4].

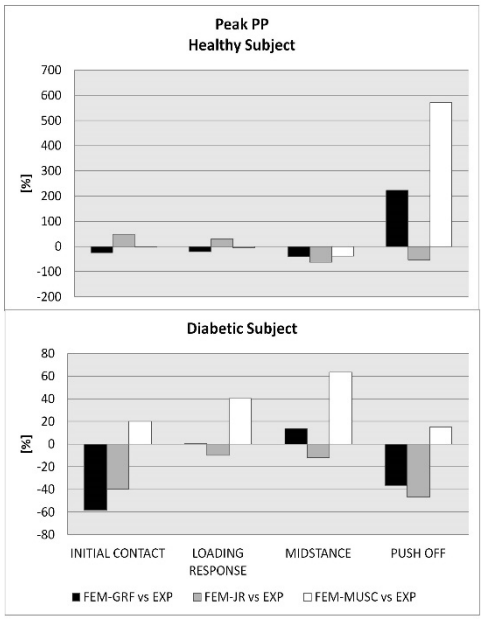

Figure 1: Results of the simulations for the 2 subjects in the 3 conditions: errors in percentage of the experimental data.

CONCLUSIONS

Although the analysis is restricted to two subject specific cases, preliminary results showed improvements in the simulations of FEMs muscle forces driven. The future developments will consider the inclusion of intrinsic foot muscles in FEMs and MSM derived muscles forces for these muscles as in [5].

P380 - CONTACT FORCES IN ACL RECONSTRUCTED KNEES ARE RELATED TO 2- AND 4-YEAR CARTILAGE T_2 VALUES

[1]**David J Saxby,** [2]Xingyang Wang, [2]Kim L Bennell, [2]Karine Fortin, [2]Tim V Wrigley, [3]Flavia M Cicuttini, [1]David G Lloyd and [2]Adam L Bryant

[1]Griffith University; [2]University of Melbourne; [3]Monash University
Corresponding author email: d.saxby@griffith.edu.au

INTRODUCTION

Anterior cruciate ligament (ACL) rupture and reconstruction (ACLR) are risk factors for knee osteoarthritis (OA) [1]. Post-ACLR, tibiofemoral contact forces are reduced in magnitude [2] and associated with future knee OA [3], while cartilages have elevated T_2 relaxation times [4], indicative of anisotropy and collagen loss, and increased water content. To date, relationships between ACLR tibiofemoral contact forces and cartilage T_2 values have not been reported. As walking is the primary behavioural determinant of the knee's mechanical environment, we hypothesized larger walking tibiofemoral contact forces would be related to larger current and future T_2 values in full-thickness, superficial and deep layers of ACLR tibiofemoral cartilages.

METHODS

We tested 28 individuals (age: 29.8±6.3 years; height: 1.73±0.1 m; mass: 73±13 kg) with one single-bundle hamstrings ACLR at 2-3 years following initial ACL injury (baseline) of which 16 individuals (age: 30±6.7 years; height: 1.72±0.1 m; mass: 72±14 kg) were tested 2 years later (followup). Participants underwent ACLR <6 months following initial ACL injury, had no meniscal pathology, and had no other surgically treated articular structures.

A 3T magnetic resonance (MR) unit (Siemens Magenetom Verio, Germany) imaged ACLR knees with sagittal multi-echo spin echo sequence: slice thickness 3 mm, inter-slice gap 3 mm, five echo-repetition times of 13.8, 27.6, 41.4, 55.2, and 69.0/1200 ms; flip angle 180°, field of view 159 mm, in-plane resolution 0.42×0.42 mm and acquisition time 8 min 16 s. Tibiofemoral cartilage T_2 maps were developed using manufacturer-supplied software (Siemens Syngo MapIt, Germany) and manual segmentation of each image using Osirix software (Pixmeo SARL, Switzerland). Full-thickness cartilage was equally divided into superficial and deep layers using custom Matlab (Mathworks, Mass., USA) code. Mean T_2 values were taken from the middle five slices of each tibiofemoral compartment for each layer.

Participants completed gait analysis <1 week from baseline MR imaging. Walking biomechanics were determined using OpenSim [5] and combined with electromyograms to calibrate and execute a neuromusculoskeletal model [6] of muscle and tibiofemoral contact forces. Peak tibiofemoral contact forces were averaged from three repeat trials. Baseline, followup, and change-in (i.e. baseline−followup) T_2 values were regressed onto baseline contact forces.

RESULTS AND DISCUSSION

One trained examiner (XW) performed all segmentations, yielding intra-class correlation coefficients of 0.94-0.99 for all regions. Larger baseline lateral contact forces were related to lower T_2 values in the lateral femoral superficial (b=-0.009, R^2=0.32, p=0.01) (Figure 1A) and full-thickness layers (b=-0.008, R^2=0.22, p=0.04). Larger baseline lateral contact forces were related to lower followup T_2 values in the lateral femoral deep layer (b=-0.008, R^2=0.54, p=0.006) (Figure 1B). Conversely, larger baseline lateral contact forces were related to larger T_2 values at the followup time point in the lateral tibial superficial layer (b=0.01, R^2=0.58, p=0.004). We found no relationships between baseline medial contact forces and any medial T_2 values, and change-in T_2 values in any compartment.

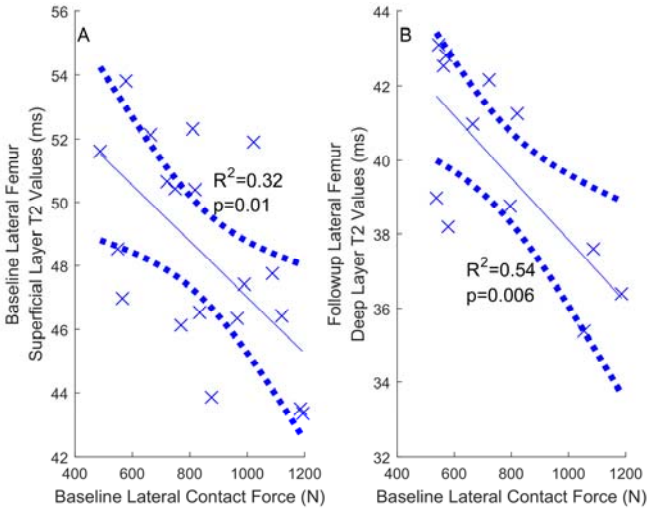

Figure 1: (A) baseline lateral contact forces associated with baseline lateral femur superficial layer T_2 values, and (B) follow-up lateral femur deep layer T_2 values.

CONCLUSIONS

Larger baseline lateral contact forces were related to lower T_2 values in lateral femoral cartilage at both baseline and followup. This conflicts with our hypotheses and consensus opinion, i.e. increased contact force drives cartilage degeneration in knees at risk of OA. In contrast, larger baseline lateral contact forces were related to increased followup lateral tibial cartilage superficial layer T_2 values, consistent with our second hypothesis and the consensus opinion. Further investigation into the relationships between cartilage strain fields and regional T_2 maps is warranted.

P381 - ACCURATE MEASUREMENT OF HUMAN SOLEUS MORPHOLOGICAL PARAMETERS USING DIFFUSION TENSOR AND T1 MAGNETIC RESONANCE IMAGING

[1,2]**Marius Schlippe**, [1]Kangqiao Zhao, [3]Sven Petersson and [1,2]Ruoli Wang
[1]Dept. of Mechanics, Royal Institute of Technology, Stockholm, Sweden
[2]Dept. of Women's and Children's Health, Karolinska Institutet, Stockholm, Sweden
[3]Dept. of Diagnostic Medical Physics, Karolinska University Hospital Huddinge, Stockholm, Sweden
Corresponding author email: schlippe@kth.se

INTRODUCTION

Morphological parameters of a muscle, e.g. fascicle length (FL) and pennation angle (PA), impact the muscle's force generation capacity. These parameters vary between individuals and can be modified due to neurological pathologies. Therefore, accurate measurements of human muscle morphological parameters *in vivo* are needed and clinically relevant. The approach presented in the study aims to tackle the inaccuracy of conventional 2D ultra-sonographical measurements by using 3D diffusion tensor imaging (DTI). The morphological parameters of the soleus muscle from an example subject after stroke were presented.

METHODS

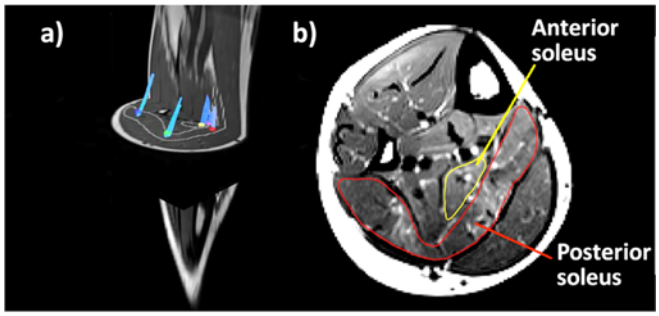
One hemiplegic subject after stroke (male, age: 31 yrs, body weight: 70 kg) was scanned using a 3T MRI scanner (Siemens Trio) while the subject was lying in a supine position with 30° knee flexion and 80° ankle plantarflexion. The T1-weighted images were obtained with a voxel size of 0.84x0.84x5 mm and the DTI images with a voxel size of 2.5x2.5x2.5 mm (20 gradient directions). The reconstruction of muscle fascicles and calculation of morphological parameters (fascicle length and pennation angle) were conducted using a previously reported method [1]. The post-processing protocol consisted of several steps [2]:

1. Muscle segmentation from T1-weighted images
2. Diffusion tensor and T1-weighted image registration
3. Region of interest (ROI) identification and fascicle tracking from DTI images
4. Fascicle length and pennation angle determination

Due to its complex multipennate architecture, the soleus muscle was segmented into two compartments: the posterior and anterior compartment. Muscle parameters were identified in three ROIs for each muscle compartment (lateral, central and medial location of the posterior compartment; anterior, central and posterior location of the anterior compartment). FL is defined as the length of fascicles from the superficial/anterior aponeurosis to the deep aponeurosis or median septum and it was assumed that all fascicles ended at the muscle surface of the segmented volume. PA was determined as the angle of the fascicles relative to superficial/deep aponeurosis (posterior soleus) and relative to anterior aponeurosis and median septum (anterior soleus).

RESULTS AND DISCUSSION

The estimated morphological parameters were in the range of previously reported values obtained by 3D modelling of a cadaveric human soleus [3]. An overview of the fascicle tracking, muscle segmentation and mean values of FL and PA is shown in Figure 1.



c)	Parameter	Less affected leg	Affected leg
Post. soleus	Mean FL ± S.D. [mm]	37.35 ± 4.40	41.99 ± 2.39
	Mean PA ± S.D. [°]	22.57 ± 4.54	22.29 ± 2.96
Ant. soleus	Mean FL ± S.D. [mm]	37.97 ± 2.44	44.50 ± 3.19
	Mean PA ± S.D. [°]	11.18 ± 2.39	14.14 ± 1.04

Figure 1: (**a**) Fascicle tracking at different locations of the soleus muscle (**b**) Segmentation of the posterior and anterior compartment of the soleus muscle (cross-sectional view) (**c**) Mean values (including standard deviation) of fascicle length and pennation angle, estimated in three ROIs.

Compared to the less-affected side, FL was found slightly longer at all locations of the posterior and anterior soleus in the affected side. Moreover, PA of the anterior soleus was found larger in the affected side. However, PA of the posterior soleus was similar between both sides.

CONCLUSIONS

T1-weighted and DT-MR images were used to estimate 3D muscle morphological parameters of the posterior and anterior soleus of a post-stroke subject. The estimated parameters agree with previously reported values and it has been shown that the proposed method can be successfully used for the measurement of muscle morphological parameters *in vivo*. Furthermore, our preliminary results have indicated that the morphological parameters of the soleus may differ between the affected and less-affected side after stroke, though further investigation is necessary.

P382 - DOES OBESITY AFFECT THE BIOMECHANICS OF THE FOOT? A PRELIMINARY COMPUTATIONAL AND EXPERIMENTAL STUDY

[1] **Bahavathy Kathirgamanathan**, [1]Pujitha Silva and [2]Justin Fernandez
[1]University of Moratuwa, Sri Lanka

Corresponding author email: k.bahavathy@gmail.com

INTRODUCTION

Obesity causes excess repetitive loading on the foot. The repetitive loading on the foot can damage the soft tissue and cause changes in the bone structure. Excessive loading on the foot can lead to further problems such as hyperuricemia, gout, immobilization, low back pain, and hip and knee osteoarthritis [2].

Finite Element Modelling (FEM) is a powerful tool which allows the internal structure of the foot to be analysed. Although finite element studies on the obese foot are rare, several experimental studies have been undertaken to analyse the effects of obesity on the plantar pressure and morphology of the foot. As most foot pathologies begin internally, FEM can serve as a means of identifying foot issues before they become a problem [3]. A finite element study will provide a method of validating previous experimental studies and can aid to provide new information on what happens inside the foot.

Hence the aim of this study is to characterize the differences in the biomechanical behaviour of the foot for obese and non-obese subjects using a finite element approach and the experimental techniques of plantar pressure and gait measurements.

METHODS

10 subjects with a normal BMI (18-25kg/m^2) and 8 subjects with an obese BMI (≥28kg/m^2) classified using adjusted WHO guideline values for an Asian population [1], were gait tested using the Kairos 3D motion capture system. Foot parameters and patient info was collected for classification purposes. Through an analysis of the gait trials, an obese subject was selected for the computational modelling.

The medical imaging software, Mimics Research 18.0 was used to segment the MR images of the selected 21 year old male with BMI of 29.6 to create an anatomically correct 3D geometry. Density segmentation techniques based on Hounsfield units was conducted. The bone structure was segmented into four sections: forefoot (phalanges and metatarsals), midfoot (cuneiforms, cuboid, and navicular), rearfoot (calcaneous and talus), and ankle (part of tibia and fibula). The fat, muscle, and skin were lumped together as soft tissue.

The model was post-processed and meshed using the software 3-Matic 10.0. Tetrahedral elements were used for all parts. A non-linear analysis was conducted of the segmented model using the FE modelling software, Abaqus v.6.14. The bone was modelled as homogenous, isotropic, and linear elastic and the soft tissue was characterized as non-linear and nearly incompressible. A ground was added as a rigid body. Kinematic constraints were used to define interactions between bone and soft tissue. Experimentally found plantar pressure measurements were used to validate the non-linear modelling procedure. A schematic showing the outcomes of each step of the modelling procedure can be seen in Figure 1.

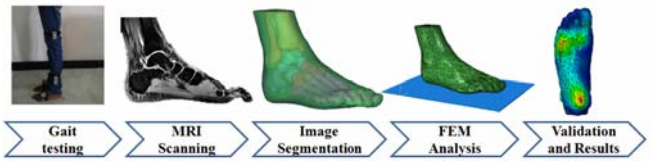

Figure 1: Outcomes from each stage of the modeling process.

RESULTS AND DISCUSSION

Comparison of the Normal (BMI: 21.91±4.08, Age: 22.8±2.49) and the Obese (BMI: 31.04±5.16, Age: 24.2±5.54) subjects through the initial gait trials showed some differences in the walking patterns of obese and non-obese such as the stride length (N: 1.19±0.12 m, O: 1.11±0.07 m, p= 0.03) and in the cadence (N: 50.87±4.68 steps/minute, O: 45.12±3.60 steps/minute, p<0.01).

The FE model of the obese foot shows greater peak plantar stresses compared to a normal foot. The internal bone structure of the obese subject also has greater peak stresses at the calcaneous and metatarsals compared to that of a normal subject. The largest stresses were observed at metatarsal 2 and metatarsal 3.

CONCLUSIONS

Some differences in the biomechanical behaviour of the foot were observed through the gait measurements and FEA results. The experimental results suggest that obese subjects are adapting their walking patterns due to the added load. Adaptations observed include smaller step size and less mobility in joint angles. The FE model showed the obese subject to have greater stresses on the foot plantar as well as the internal bone structure, suggesting that long term obesity could lead to the development of foot pathologies. The adjustments in the walking pattern observed are likely an outcome of these higher stresses where the subject is trying to compensate with smaller and shorter steps.

P383 - MUSCLE PHYSIOLOGY REDUCES THE FEASIBLE TORQUE SET DURING HUMAN GAIT

Aravind Sundararajan and Jeffrey Reinbolt
University of Tennessee

INTRODUCTION

All neuromusculoskeletal systems can be mathematically described as linear mappings from a neural command space to an eventual mechanical wrench space [1]. In nature, the set of feasible neural command inputs is larger than the set of feasible mechanical outputs [2] and different sets of neural commands can achieve the same motion. The culmination of mechanical actions that a joint system produces can be described as the endpoint wrench space. To achieve any particular endpoint wrench set during motor tasks, neural commands must define actions producing muscle forces, which in turn produce joint torques. The hypothetical set of all possible joint torques is referred to as the Feasible Torque Set (FTS) [2]. The FTS sensitivity to physiological parameters of muscle fiber length (l^m) and fiber velocity (v^m) is not well understood. Identifying relationships between force-length-velocity properties and FTS contributes to our understanding of neural control.

In this study, we used OpenSim [3] modeling and simulation to examine the FTS for the human lower-limb joints during normal gait and determine how sensitive the FTS is to different models of muscle physiology, including l^m and v^m. We hypothesized that simulations accounting for l^m would reduce the FTS compared to those assuming maximum isometric muscle forces ($\boldsymbol{F}_0^m$); in addition, simulations accounting for both l^m and v^m would reduce the FTS further.

METHODS

For proof-of-concept, simplicity, and reduced computational costs, we used a two-dimensional gait model with 10 degrees of freedom and 18 muscles available in OpenSim. The model was scaled to the anthropometry of the subject (75 kg, 1.8 m). Inverse kinematics determined model kinematics matching experimental marker data of the subject walking at 1.2 m/s on a treadmill. A residual reduction algorithm adjusted model kinematics and inertial properties to minimize dynamic inconsistencies between the model dynamics and experimental ground reaction forces. Computed muscle control determined muscle excitations and resulting model states for a forward dynamic simulation.

The gait simulation's model and states were used to investigate the effects of l^m and v^m on the FTS for 3 cases of varying muscle physiology inclusion. For no muscle physiology (case 1), muscle forces were simply $\boldsymbol{F}_0^m$. For l^m effects (case 2), muscle forces with activations of 1 were computed along an inextensible tendon when model velocity states were set to 0 and joints locked at each time frame of position data. For both l^m and v^m effects (case 3), muscle forces were computed as in case 2, but model velocity states were from gait and joints unlocked. To isolate v^m effects alone, muscle forces were found by subtracting case 2 from 3. In all cases, the matrix of muscle moment arms about each joint was computed ($\boldsymbol{R}^m$) and used to compute the joint torques ($\boldsymbol{\tau}^m = \boldsymbol{R}^m \cdot \boldsymbol{F}^m$). The FTS was determined by the Minkowski sum of all possible joint torques of the hip, knee, and ankle producing a 3D convex polyhedron, or zonohedron. Zonohedra volumes for the varying muscle physiology cases were compared and we evaluated our hypotheses by conducting one-tailed *t*-tests at the 0.01 significance level.

RESULTS AND DISCUSSION

The FTS's during gait were affected (represented by smaller zonohedra volumes) by including muscle physiology model components (Figure 1). The FTS was largest overall with no muscle physiology considerations (case 1). The FTS was reduced ($p < 0.01$) by 34%, on average, when including l^m effects (case 2) and reduced ($p < 0.01$) by 46%, on average, when including l^m and v^m effects (case 3). Relative volume changes with l^m and v^m effects were 11.5% larger over the entire gait cycle than those with l^m effects alone during both stance (13% larger) and swing (9.5% larger).

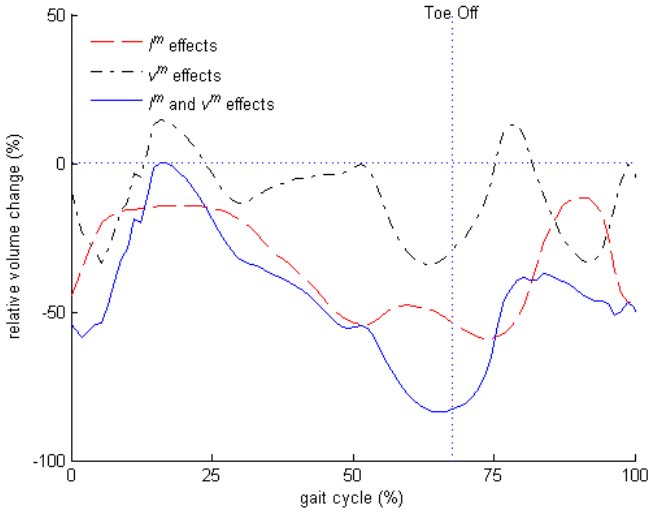

Figure 1: Muscle fiber length, l^m, (*red*) and fiber velocity, v^m, (*black*) effects on hip, knee, and ankle feasible torque sets (FTS) during gait, represented by zonohedron volume changes relative to the FTS using maximum isometric muscle forces without muscle physiology considerations. Muscle fiber length and velocity effects (*blue)* reduce the FTS volumes below the non-physiological case during gait.

CONCLUSIONS

Muscle physiology substantially reduces the lower-limb FTS during gait, and l^m effects are more significant than v^m. To obtain a better understanding of FTS behavior during dynamic movements, it will be necessary to consider additional modeled parameters, such as tendon compliance. Future work to investigate mappings from neural command space to endpoint wrench space should consider tendon compliance as well as the muscle fiber length and velocity. Identifying the function of FTS during movement provides insights to improve our understanding of complex neural control for behavioral tasks.

P384 - SUBJECT-SPECIFIC MUSCULOSKELETAL SIMULATION OF OSTEOARTHRITIS TO ESTIMATE MUSCLE FORCES AROUND THE HIP DURING ABNORMAL GAIT

[1]**Daisuke Tawara**, [2]Hiroki Sawa, [3]Takako Momose, [3]Masatoshi Oba and [3]Yutaka Inaba

INTRODUCTION

Because lower extremity muscle forces in abnormal gait in hip osteoarthritis are closely related to the gait motion, muscle strength and disease seriousness [1], subject-specific prediction is necessary to assess muscle forces around the hip. A motion capture for gait and musculoskeletal simulation are potent approaches to predict muscle forces and elucidate a relationship between their forces and changes in gait posture/decrease of muscle strength. In this study, we measured gait motion of patients using a motion capture system and developed musculoskeletal models around the hip which has low isometric muscle forces assuming it is a case with disease progression. We also reflected muscle strength based on muscle volume using CT images of the patient and calculated muscle forces during the gait motion. The potency of our prediction for muscle forces to understand/assess the mechanism/progress of osteoarthritis gait was discussed.

METHODS

Gait motion and floor reaction forces of 2 patients; models A (68 years old, 155 cm and 56 kg) and B (71 years old, 145 cm and 49 kg) on which 25 markers were attached, were measured using the Vicon 512 (Vicon Motion Systems) and a force plate. Then, 318 muscles around the hip and spine except for legs in a musculoskeletal model were defined by adapting each segment geometry which corresponds to the body size on the Anybody Modeling System (AnyBody Technology Inc.). The segments are equivalent to bones as rigid bodies and mass was distributed to each segment according to its ratio for the weight. First, we calculated muscle forces during walking of the 2 models using an optimization technique as follows [2] because the number of muscles were greater than that of the freedom of joints and muscle forces were not determined only by equilibrium equation of forces:

$$G = \sum_{i=1}^{n} \left(f_i / N_i \right)^3 \rightarrow \min. \qquad (1)$$

subject to: $\boldsymbol{M} = \boldsymbol{rf}$, $f_i \geq 0$ $\quad i \in \{1, \cdots, n\}$ (2)

where N_i, f_i, n, $\boldsymbol{M}$, $\boldsymbol{r}$ and $\boldsymbol{f}$ are a maximum isometric force which the i-th muscle generates; i.e. a muscle strength, muscle force, number of muscles, vectors of joint moments, moment arm and muscle forces, respectively. Second, to assess the difference of muscle forces depending on the disease severity: in slight/severe disease cases, we calculated muscle forces by decreasing the N_i of hip abductor muscle group to 50 % using the model A. Third, to evaluate effects of the N_i of muscles which were different depending on subject, we made 3D models of representative muscles based on CT images using the model A, measured its volume and length, and calculated the N_i as follows:

$$N_i = L_i S_i P \,, \qquad S_i = V_i / L_i \qquad (3)$$

where L_i, V_i , S_i and P are a length, volume, cross-sectional area of the i-th muscle and the maximum isometric force per unit area, respectively.

RESULTS AND DISCUSSION

The difference of the calculated force of Gluteus medius, which was important for walking between the models was characteristic. The magnitude of the muscle forces of both models were lower in the left leg than the right leg relating to the existence of the osteoarthritis in the left leg. The Connect time to ground of the left/right legs of model B was different notably, reflecting individual abnormal gait. Comparison of muscle forces between slight/severe disease cases is shown in Fig.1. In the severe case, muscle forces of Gluteus medius decreased 86%, Gluteus minus increased to 161% than in the slight disease case, respectively, and other muscle forces changed correspondingly, implying compensatory force generation. In addition, reflecting cross-sectional area of muscles which differed between the left/right legs of the patient, muscle forces such as musculus rectus femoris, gluteus maximus and gluteus medius changed dominantly. These muscles corresponded to important ones for hip joint motion, indicating that our results were practical and valid.

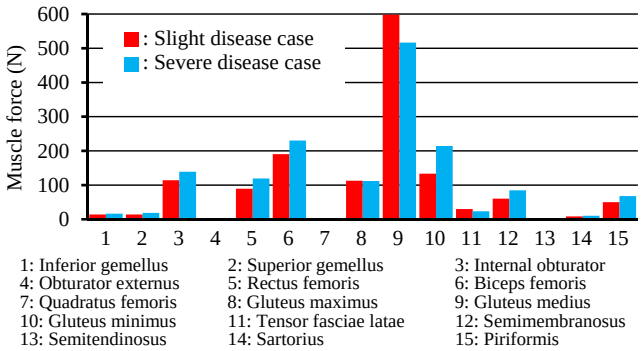

Figure 1: Muscle forces between the slight/severe cases.

CONCLUSIONS

Subject-specific musculoskeletal simulation of osteoarthritis was performed. Our approach could predict practical muscle forces, take account of the disease progression and find the mechanism of the compensatory force in body, suggesting its high potency to understand osteoarthritis gait motion.

P385 - DIFFERENCES OF HAND AND ARM MOVEMENTS WITH DOMINANT AND NON-DOMINANT HAND DURING DAILY ACTIVITIES

[1] **Akio Ueda**, [2] Hiroshi Kurumadani, [2] Natsumi Suefuji and [1] Toru Sunagawa
[1] Graduate School of Biomedical & Health Science, Hiroshima University

INTRODUCTION

Motor weakness is a major sequela of stroke patients. Most of the stroke patients who affected their dominant hand are forced to change their dominant hand [1].

Compensatory movements are frequently observed in the stroke patients with right-hand dominance when using the non-dominant hand. Compensatory movements may be a critical factor limiting recovery following brain damage [2].Therefore, it is necessary to choose from the training about daily activities with less compensatory movements in motor rehabilitation.

However, it is not clear which joint of the upper extremity contribute primarily to compensatory movements during daily activities.

The purpose of this study was to clarify which joint of the upper extremity contributed to compensatory movements when performing daily activities with the non-dominant hand in comparison to the dominant hand in healthy persons.

METHODS

Twenty-seven healthy right-handed volunteers (10 males, 17 females, age=22.0±1.3) participated in the study. We excluded participants if they reported a history of a current upper extremity injury or a previous surgical intervention of their upper extremity.

Participants accomplished the nine tasks on daily activities: Writing, writing a sentence; Scissors, cutting by scissors; Pages, turning over the pages; Open PET, opening PET lid; Close PET, closing PET lid; Cup, filling the cup; Chopsticks eating with chopsticks, Spoon, eating with spoon; and Button, button clothes. They performed these tasks with both the dominant and the non-dominant hand in the sitting position and repeated it five times for each task.

We used six accelerometers (LOGICAL PRODUCT, LP-WS0904) and recorded acceleration and angular velocity data during the task. These sensors were attached to the following body parts: both upper arms, forearms, and hands, with elastic belt. The resultant acceleration and angular velocity were calculated for each body part. We detected the initial motion and the end of the motion using the resultant angular velocity data and extracted five motions of each task.

The activity of each body part was calculated as the integration of the acceleration for each motion of each task and computed the mean of five times.

The activity of the elbow and the wrist joint were calculated as the difference of the activity between the forearm and the upper arm and between the hand and the forearm, respectively. The activity of the shoulder joint used the activity of the upper arm data. We calculated the ratio of the activity of each joint.

We analyzed the ratio of the activity of each joint between the dominant and the non-dominant hand by paired t-test (IBM SPSS version 23.0). Statistical significance was accepted at values of $p<0.05$.

RESULTS AND DISCUSSION

The ratio of the activity of each joint is shown in the Table1. The ratio of the activity of the shoulder joint was significantly increased during Chopsticks and Spoon. The ratios of the activity of the shoulder and the wrist joints were significantly increased during Scissors. The ratio of the activity of the elbow joint was significantly increased during Open and Close PET. There were no significant differences in the ratio of the activity of each joint during Button, Cup, Pages and Writing.

CONCLUSIONS

There were patterns of compensatory movements of each joint of the upper extremity when performing daily activities with the non-dominant hand.

P386 - NO IMPACT OF TRAINING-RELATED TENDON ADAPTATION ON TENDON FUNCTION DURING WALKING

Charlie M. Waugh, Thuraya Alktebi, Alex Scott
Dept. of Physical Therapy, University of British Columbia, Vancouver BC, Canada
Corresponding author email: cmwaugh@mail.ubc.ca

INTRODUCTION

It is well known that tendons are responsive to mechanical loading and unloading, and their mechanical properties are often the target of intervention programs. However, the tendon's mechanical properties also govern its function. Changes in tendon mechanical properties could therefore have substantial influence on energy-saving mechanisms during activities utilizing the stretch-shortening cycle, but has received surprisingly little attention; the impact of such changes have only previously been modelled [1]. In order to understand the potential impact of changes in tendon properties on tendon function during walking, we investigated Achilles tendon (AT) function *in vivo* with respect to a resistance training intervention designed to elicit significant increases in tendon stiffness.

METHODS

14 men and women (29.8±6.9 y) completed a 12-week plantarflexion strength training intervention designed to increase AT stiffness. Pre- and post-training intervention, participants walked shod at their preferred velocity on a fully-instrumented treadmill during which ground reaction forces (GRF), movement kinematics and gastrocnemius medialis muscle-tendon junction (MTJ) displacement were captured synchronously using 3D motion capture software and ultrasound imaging, respectively. Ankle joint moments were estimated using an inverse dynamics approach and AT forces calculated as the ratio of ankle joint plantarflexor moment to AT moment arm length.

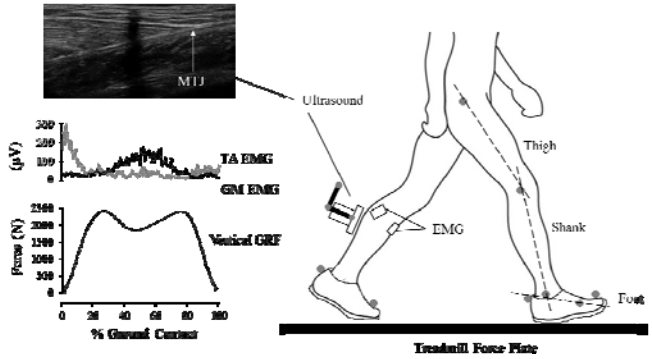

Figure 1: Experimental set-up. Grey dots on body represent placement of motion capture markers; ultrasound graphic includes 3-marker rigid body for transforming 2D MTJ coordinates into the 3D reference coordinate system. MTU length changes were estimated from changes in ankle and knee angles given by lower leg segments. AT length changes were estimated from MTJ and heel coordinates. GRF and EMG data represent averaged data during the ground contact phase of the gait cycle.

Peak AT force, stress, strain, hysteresis and elastic strain energy were averaged from six consecutive step cycles. Dynamic displacement, velocity, work and power of the MTU, muscle and tendon were assessed with respect to subdivisions of the ground contact phase. The ATs from both legs were examined in each participant, which was included as a possible covariance factor in all statistical analyses. Repeated measures MANOVA tests were used to examine 1) changes in AT force-related variables following strength training and 2) changes in MTU, muscle and tendon function during phases of the ground contact period.

RESULTS AND DISCUSSION

Plantarflexor training induced a mean AT stiffness increase of 31.0±33.9% ($p \leq .001$). All statistical tests were non-significant for a main effect of time (before and after training), therefore no follow-up tests were conducted.

Table 1. Variables calculated pre- and post-intervention.

	Pre	Post	% Δ
Force (N)	3039.1±639.6	3320.2±914.7	9.3
Excursion (mm)	31.9±7.4	31.7±6.6	-0.5
Strain (%)	8.6±5.2	8.1±3.9	-5.9
Stress (MPa)	52.0±11.7	56.4±16.9	8.4
Hysteresis (%)	61.0±13.3	57.4±13.2	-5.9
Strain Energy (J)	5.4±3.2	5.6±3.5	2.9

To our knowledge, this is the first time that *in vivo* muscle-tendon function has been investigated in relation to substantial increases in tendon stiffness as a result of a training intervention. Of the host of variables measured, very little appeared to have been impacted by changes in AT stiffness, implying that muscle-tendon function during walking is relatively insensitive to substantial changes in this property. Our findings are supported by modelling studies which predict that a wide range of properties can successfully optimise the efficiency of the muscle-tendon unit [1]. Importantly, large increases in AT stiffness as a result of such interventions do not appear to have a negative impact on muscle-tendon function during walking activities.

CONCLUSIONS

Our findings provide an important foundation for investigating the functional consequences of training adaptations and may be of particular relevance for clinical and ageing populations where walking capacity is a critical contributor to quality of life. For activities such as running and jumping, which involve elevated portions of the tendon stress-strain relationship, the functional implications of increased AT stiffness warrant future investigation.

P387 - INDIVIDUAL MUSCLE ACTIVITIES WITHIN FOREARM DURING D-W MUSCLE TESTING

INTRODUCTION

Finger, thumb, and hand motions are intricately controlled by complex muscle activities in the forearm. Observation of muscle cooperative activities or muscle synergy is important for evaluating the physiological functions. The authors have developed the electromyography computed tomography (EMG-CT) for the measurements of muscle activity distribution within a cross section of the forearm on the basis of surface EMG signals around the forearm [1]. In previous study, the muscle activities in the forearm were measured by EMG-CT during external loadings applied to each finger and thumb in the various directions [2]. Daniels and Worthingham's muscle testing (D-W muscle testing) [3] is used for evaluating the individual muscle functions in clinical practice. Hence, the present study aims to elucidate the individual muscle activities in the forearm during the D-W muscle testing for each forearm muscles by using EMG-CT.

METHODS

Three male subjects (23.7±0.5 years old) participated in the experiments. A customized EMG-CT band (Harada Electronics, JP2016-131689A), comprising 40 pairs of bipolar electrodes placed circumferentially, was positioned at the middle of the forearm to detect the surface EMG distributions. The fingers, thumb, and wrist motions for forearm muscles were examined following to the D-W muscle testing: finger metacarpophalangeal (MP) extension for extensor digitorum (EDC), extensor indicis, and extensor digiti minimi (EDM) (Fig. 1(a)), finger proximal phalanges (PIP) flexion for flexor digitorum superficialis (FDS), finger distal phalanges (DIP) flexion for flexor digitorum profundus (FDP), thumb interphalangeal (IP) flexion for flexor pollicis longus (FPL), thumb IP extension for extensor pollicis longus (EPL), thumb abduction for abductor pollicis longus (APL), wrist flexion for mainly flexor carpi radialis (FCR) and flexor carpi ulnaris (FCU), and wrist extension for extensor carpi radialis longus (ECRL), extensor carpi radialis brevis (ECRB), and extensor carpi ulnaris (ECU). The subjects were instructed to maintain the initial posture against the external loadings. An EMG conduction model [1] in the cross section of the forearm was constructed using a circle cross-section with the measured circumferential length. The distribution of muscle activity (mA dipole/s·mm^2) was calculated from the surface EMG singnals and the model [1]. The loadings were applied 5 s three times with 5 s intervals. The averaged muscle activity distribution during each loading was calculated.

RESULTS AND DISCUSSION

Figure 1(b) shows a typical muscle activity distribution during the index finger MP extension against the flexion loading to the index finger at MP. The color scale was normalized with respect to the maximum value in the loading. For instance, as shown in Fig. 1(b), the high muscle activity was detected in the region where EDC and EDM were arranged. It corresponds to the target muscles in the tests. FDS and FDP region was also slightly active, suggesting antagonist activities. During the fingers and wrist motions, the muscle activities were almost the same in all subjects and the high activities were detected in each target muscle region. On the other hand, the individual differences were observed during the thumb motions. The intrinsic muscles may assist the motions. It suggests that the D-W muscle testing evaluates the muscle functions relating to the fingers and wrist motions especially. The study demonstrated the complex individual muscle activities in the forearm during the D-W muscle testing by using EMG-CT.

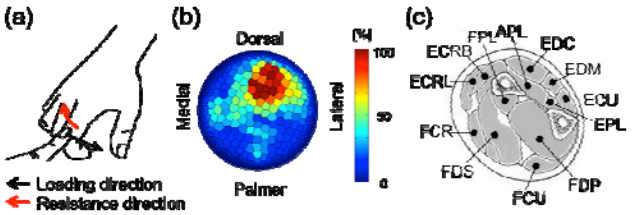

Figure 1: An example of (a) loading directions and (b) muscle activity distributions in Daniels and Worthingham's muscle testing. Flexion loading was applied to index finger at MP for EDC, extensor indicis, and EDM [3]. Figure (c) shows a typical arrangement of muscles in the forearm [4].

CONCLUSIONS

In the fingers and wrist motions of D-W muscle testing, the activities of each target muscles were detected; on the other hand, the individual differences were observed in the thumb motions.

P388 - INVESTIGATION OF POSSIBILITY TO PROMOTE RECOVERY OF MUSCLE HARDNESS AND SORENESS BY USING ARTIFICIAL CO_2-HOT SPRING BATH

INTRODUCTION

In European countries, the hot spring water containing high concentration carbon dioxide (CO_2 ≥1000 ppm), CO_2-hot spring, has long been applied to the patients suffering from cardiovascular diseases in balneotherapy. Clinical observations reported the effects of CO_2-hot spring immersion on human body, such as flushing of the skin, skin blood flow improvements, and blood catecholamine levels and heart rate decreases. Animal experiments using recently developed artificial CO_2-hot spring maker revealed that the heart rate reduction during immersion in the CO_2-water was caused by an inhibition of sympathetic nerve activity [1]. The heart rate reduction by CO_2-water immersion may be induced by neuronal information generated in the skin and transported through the spinal cord to the brain [2]. Those results imply that an immersion into CO_2-hot spring may produce some other effects on physiological functions by the efferent signals from the skin. On the other hand, experiments in human subjects indicated that flexibility of the body was facilitated by bathing into artificial CO_2–hot spring [3]. Furthermore, near-infrared spectroscopy (NIRS) applied to the human subjects revealed that repeated immersion of the forearm into CO_2-water augmented the local muscle O_2 consumption and blood flow. Taking all of these results into account, CO_2-water bath may facilitate a recovery from muscle fatigue. To inspect this hypothesis, we investigated whether the immersion of extremities including agonist muscles into artificially made CO_2-water (CO_2 ≥1000 ppm) influences recovery of muscle hardness and soreness in fatigue after resistance exercise.

METHODS

The healthy male college students (n=12) participated in this study (Age 19-26 yrs, height; 173.5±5.0 cm, weight; 64.9±6.9 kg). Before the experiment, all procedures and any potential risks were explained to each subject, and an informed consent document was signed previous to participation. This study was approved by Japanese Red Cross Hokkaido College of Nursing Review Board for Health Sciences Research Involving Human Subjects. The subjects performed 100 times calf raise resistance exercise and immersed lower legs into tap-water or artificial CO_2-water at 35 °C for 10 minutes after exercise. On exercise day, a hardness of the medial head of gastrocnemius dominant muscle was evaluated 3 times with indentation method, at 5 minutes before, immediately after and 10 minutes after the exercise. Simultaneously, muscle soreness was assessed using a 100 mm visual analogue scale where the subject was instructed that 0 mm indicated no pain at all, while 100 mm was an indication of 'unbearable' pain. Subjects were asked to rate their muscle soreness experienced during each measure by making a mark on a 100 mm line. Resistance exercise was performed only the first day. Lower legs water immersion (tap-water or CO_2-water) were performed every 24h for 5 consecutive days after the resistance exercise. Following the exercise day, muscle hardness and soreness were measured before and after lower legs water immersion once a day. Statistical evaluation of the data was done by repeated-measures two way ANOVA, using Tukey test for post hoc multiple comparisons, where appropriate. Significance level was set at the $p < 0.05$.

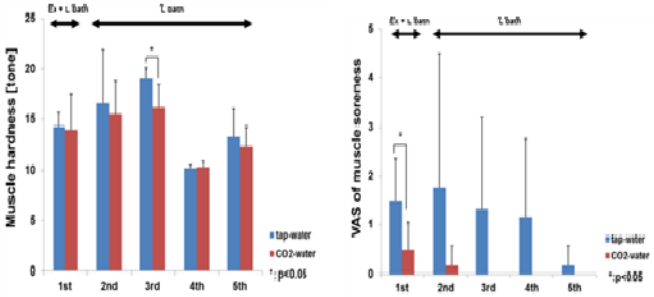

Figure 1: Changes of muscle hardness (left) and soreness (right) in lower leg bath for 5 days.

RESULTS AND DISCUSSION

Muscle hardness peaked at the third day after the exercise. Muscle hardness at the third day was significantly smaller in CO_2-water treatment group than in tap-water treatment group, and the difference between two groups disappeared after the peak day. Muscle soreness of the CO_2-water treatment group was significantly smaller than that of the tap-water treatment group, and was lasting only for 2 days after exercise, in comparison with 5 days in tap-water group. These results imply that an immersion into high concentration CO_2-water after the exercise may contribute to rapid recovery from the muscle fatigue.

CONCLUSIONS

The present study suggested that high concentration artificial CO_2-hot spring bathing may contribute to rapid recovery from the muscle fatigue.

ACKNOWLEDGEMENTS

P389 - BIOMECHANICAL PROPERTIES OF FEMORA OBTAINED FROM STROKE-PRONE SPONTANEOUSLY HYPERTENSIVE RATS

[1] **Ei Yamamoto**, [1] Kumiko Takemori and [1] Hiroyuki Ito
[1] Kindai University

INTRODUCTION

The number of patients with lifestyle-related diseases such as hypertension is annually increasing in Asia as well as in the United States and Europe. The hypertension induce vascular morbidity and nephropathy associated with changes in calcium metabolism [1]. As the secondary factor, the hypertension possibly affects the properties and structures of musculoskeletal tissues such as bone. It has been reported that the healing of bone fracture is delayed in hypertensive subjects as compared with healthy ones [2]. Epidemiological data reveal bone abnormalities in the patient with hypertension [3], however the mechanisms responsible for them remain unknown. Bone fractures are ultimately a kind of mechanical event. Thus, a quantitative assessment for bone biomechanical performance is essential both clinically and biologically. A better understanding of the factors that determine bone strength in hypertensive patient is needed to prevent the bone fractures in order adults. We hypothesized that hypertension is related to impaired material and structural properties of bones. To examine this hypothesis, the stress-strain relations and microstructure of the femora obtained from the experimental animal model of hypertension were determined by means of mechanical tests and X-ray micro-computed tomography analyses.

METHODS

Stroke-prone spontaneously hypertensive rats (SHRSP group) of 8 weeks of age, and the age-matched Wistar rats (Control group) were used for the experiments. After soft tissues around the femur were removed, ring-like specimens were sliced off from the midshaft of the femur using a rotating diamond saw. Bone tissues were kept submerged in a physiological saline water during machining to minimize load- and heat-induced damage. The final length of each specimen was measured with a micrometer. The nominal length of the specimen was approximately 3 mm. The cross-sectional area of the specimen was measured using an image analyzer. A conventional material tester (AGS-H, Shimadzu, Kyoto, Japan) having polished stainless steel platens was used for compressive loading tests. Platen surfaces were lubricated with mineral oil prior to each loading. To minimize the effects of the machine compliance of the material tester, the specimen deformation was measured by a laser micrometer. Bone specimens were immersed in a physiological saline solution of 37˚C during the mechanical testing. The proximal portion of the femur was used for X-ray micro-CT analyses. Cross-sectional images of the trabecular bone were obtained at the femoral neck portion.

RESULTS AND DISCUSSION

Figure 1 shows the stress-strain relations of cortical bones in the Control and SHRSP groups. The compressive strength in the SHRSP group was 60.7 ± 7.1 MPa (Mean ± S.D.). These values were approximately 82% of the compressive strength in the Control group (73.9 ± 13.7 MPa). There was a significant difference in the strength between the Control and SHRSP groups. These results indicate that hypertension is closely related to the material properties of cortical bone. Figure 2 shows the trabecular structure of femoral neck in the SHRSP and Control groups (8 weeks old). Trabecular bone in the SHRSP group has a higher porosity than that in the Control group. In the present study, we investigated the bone properties only at 8 weeks of age. To understand the effects of the duration of hypertension, it is necessary to conduct the mechanical test for bones obtained from elderly animals. Moreover, the mechanisms of the bone absorption process are suggested in the future studies.

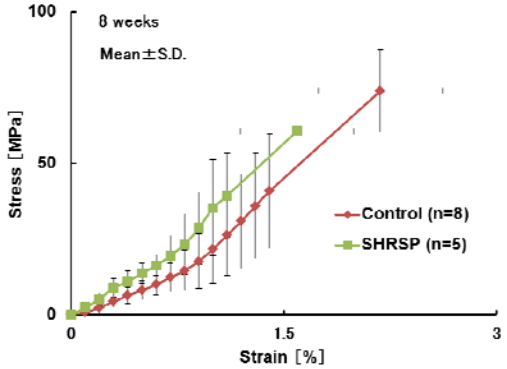

Figure 1: Stress-strain relations in the SHRSP and Control groups.

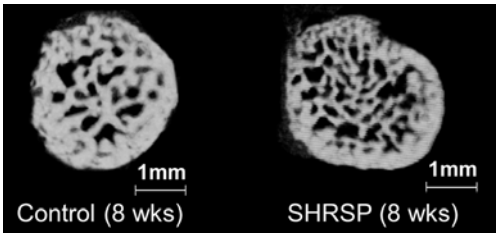

Figure 2: Trabecular structure in the SHRSP and Control groups.

CONCLUSIONS

There was a significant difference in the compressive strength between the SHRSP and Control groups, indicative of the direct evidence suggesting a possible link between hypertension and osteoporotic bone fracture.

P390 - DOMINANT NEGATIVE CX43 MUTANTS IN OSTEOCYTES AFFECT RESPONSE TO HINDLIMB UNLOADING IN MICE

[1]**Dezhi Zhao**, [1]Ruofei Liu, [1]Peng Shang, [1]Pengfei Yang, [2]Jean X. Jiang and [1]Huiyun Xu*

INTRODUCTION

Gap junctions and hemichannels play important roles in communication between adjacent cells or between cells and extracellular environment, respectively. Two transgenic mouse models with the overexpression of dominant negative Cx43 mutants were generated [1]. The R76W mutant blocks the gap junction channel, but has enhanced hemichannel function, and the Δ130-136 mutant inhibits activity of both types of channels.

In this study, we aim to understand the function of Cx43 dominant mutants in response to mechanical unloading by subjecting 10-weeks-old R76W, Δ130-136 and wild-type (WT) C57BL/c mice to hindlimb suspension (HLS) for four weeks. The bone structure, bone material properties and dynamic bone formation of hindlimb bones were determined by microCT, three-point bending and bone histomorphometry analysis, respectively.

METHODS

The mice were divided into control and unloading groups and tested randomly for next 4 weeks. After unloading testing, the femurs and tibias were isolated. The structures properties of cortical and trabecular bones of femur from suspended and control mice were evaluated using microCT. Trabecular bone was sampled with 10μm VOI started from the growth plate. And cortical bone was sampled with a VOI positioned for 5μm started at 55um from the growth plate. The mechanical properties of mice were examined by using a 3-point bending test. All the mice were injected with calcein at 10mg/kg body weight 2 weeks before sacrificing and followed by the second injection 10 days later. The mineralizing surface (MS/BS), mineral apposition rate (MAR) and bone formation rate (BFR/BS) were determined. All data were statistical analysis with GraphPad Prism 5 statistics software (GraphPad).

RESULTS AND DISCUSSION

Our results showed that mechanical unloading significantly increased bone loss of all mice, but the trabecular thickness (Tb.Th) of Δ130-136 transgenic mice decreased more than that of R76W and WT mice (Figure 1). Given that both R76W and Δ130-136 mice have impaired gap junctions, the lesser decrease in R76W mice is likely due to functional hemichannels in R76W mice, which partly attenuate the effect of unloading on trabecular thickness.

The three-point bending analysis showed that mechanical unloading decreased the material properties of all mice, including elastic module (Figure 1), ultimate load and stiffness. Also the changes of transgenic mice were less than that of WT mice, but the difference was not significant. Previous study has shown that Cx43 knockout leads to restraining of sensitivity for mechanical unloading. Here in our study, the inhibition of gap junctions and hemichannels similarly reduced the decrease of mechanical properties.

The dynamic histomorphometric showed a decrease of MAR and BFR/BS in WT and Δ130-136 mice, whereas an increase in R76W mice, which might be the function of enhanced hemichannels. More investigation is warranted.

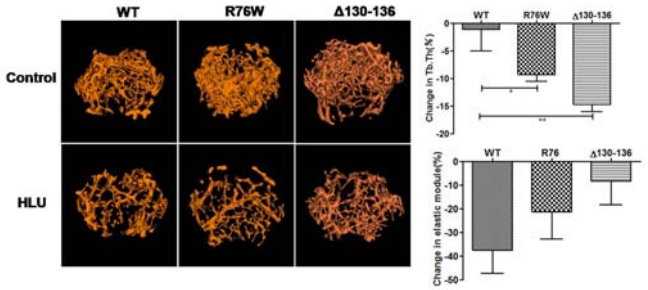

Figure 1: Mechanical unloading affected femoral trabecular thickness and mechanical property.

CONCLUSIONS

The results of Micro-CT, three-point bending and histomorphometric analysis suggested that Cx43-formed gap junctions and hemichannels play important roles in biological response of bones to unloading.

INTRODUCTION

It has been well documented that bone adapts to its mechanical environment. However, the dynamic alterations of bone structure and properties, as well as its non-mineral components, across the disuse period has not been detailed investigated. The purpose of the present study was to outline the modulation effects of a moderate mechanical loading on the discordant responses between bone mechanical properties and structural parameters. Moreover, in ultra-scale level, how collagen fibers of cortical bone response to disuse was studied with a hindlimb unloading animal model.

METHODS

A hindlimb unloading model and an *in vivo* tibia axial loading model in rats was adopted. 75 male, 5-month old, SD rats were randomly assigned to three groups: baseline control group (BC, n = 7), age-matched group (AC, n = 28) and hind limb unloading group (HU, n = 40). During 28-day intervention, the left tibia of rats in both groups remained untreated, referring to Age-matched Control Unloaded (ACU) and Hindlimb Unloading Unloaded (HUU). The right tibia of the rats in both groups, referring to Age-matched Control Loaded (ACL) and Hindlimb Unloading Loaded (HUL), was was loaded with the mechanical loading. On experimental day 0, 7, 14, 21 and 28, the loading amplitude that can engender 800 με bone strain at the medial mid-diaphysis of the right tibia at each time point were characterized using strain gauge approach. Sinusoidal loading with corresponding amplitude was applied to the right tibia throughout the following 7 days. On day 0, 7, 14, 21 and 28, animals were sacrificed for sample collection of bilateral tibia. Bone Mineral Density (BMD), trabecular bone microarchitecture and mechanical properties were assessed. The morphological characteristics of collagen in the shell of cortical bone was scanned with Atomic Force Microscope (AFM), following with the dissolve procedure with EDTA.

RESULTS AND DISCUSSION

The body mass of the rats from AC and HU group remained constant across 28 days. There was no significant difference between the AC and HU group at each time point. The mechanical load to engender 800 με of tibia strain did not change over the experimental time period for ACL tibia (p = 0.35). At day 14, the force amplitude between the ACL and HUL was statistically different (p = 0.0013). At day 14, BMD of both HUU and HUL tibia was lower than ACU (p = 0.0003). Likewise, BMD of HUU tibia was lower than ACL tibia (p = 0.0062). The similar trend remained until day 21. At day 21, BMD of ACU tibia was still higher than the HUU (p = 0.027) and HUL bone (p = 0.0015). No significant difference on BMD between HUU and HUL tibia was found (p = 0.24). Bone Mineral Content (BMC) of HUU tibia was the lowest in all groups at day 14 (p = 0.0009 *v.s.* ACU, p = 0.0005 *v.s.* ACL and p = 0.018 *v.s.* HUL). At day 21, BMC of both HUU and HUL tibia were lower than ACU bone (p = 0.0097). At day 14, BV/TV of HUU and HUL tibia was lower than ACU. By contrast, Tb. Sp of HUU and HUL tibia was larger than ACU. No significant difference on BSA/BV, Tb. Th, CWT and Tr. N was found among groups. The density of type I collagen and crosspoint between adjacent fibers in bone were barely altered by disuse. No significant difference on D-periodic spacing of collagen fibers between groups was observed. By contrast, dramatic changes in collagen fibers orientation was found after unloading (Figure 1).

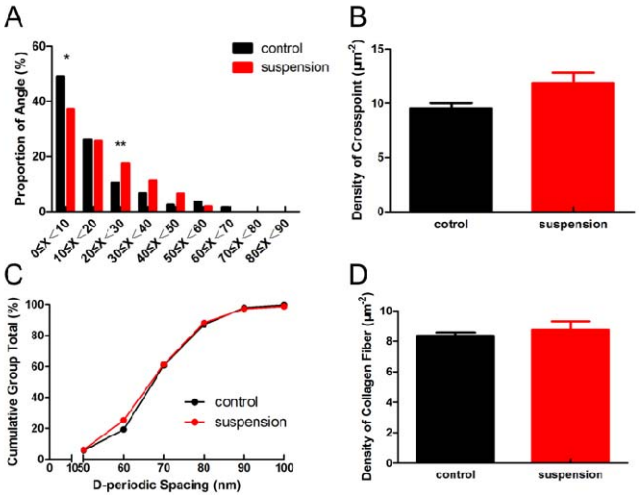

Figure 1: The alterations of collagen fibers in cortical bone after 28-day mechanical disuse. A: The angle of collagen fibers to represent its orientation. B: The density of crosspoint of collagen fibers. C: The D-periodic spacing of fibers. D: The density of all collagen fibers. *: $p < 0.05$, **: $p < 0.01$.

CONCLUSIONS

Moderate mechanical stimulation failed to alter the mechanical response of tibia in the control group to loading, but was capable of reversing the detrimental effects of unloading on bone. It was therefore indicated that physiological mechanical strain play specific roles to bones under different loading situations. The alteration of collagen fibers in bone may contribute to bone mechano-adaptation process. Future studies on the response of collagen fibers in bone to mechanical stimulation are to be expected.

P392 - A FAST WAVE IN ULTRASOUND IS INFLUENCED BY CHARGE DENSITY OF BONE FLUID FLOW

[1] **Young June Yoon**
[1] Hanyang University
Corresponding author email: yoon.youngjune@gmail.com

INTRODUCTION

Two ultrasound waves are observed when wave penetrates the cancellous bone. Williams [1] introduced the Biot theory or so called poroelasticity theory to cancellous bone and showed that two waves are observed in cancellous bone. Yoon and his colleague [2] showed that the shape of trabeculae significantly affect the velocity of wave propagation by using Biot theory.

Poroelasticity has been used for elucidating the bone fluid flow stimulating bone cells and these bone cells communicate each other. The electrokinetic effect is another parameter in bone remodeling process. These two – bone fluid flow and electrokinetic effect - are coupled each other. The strain generated potentials induce the charged bone fluid flow through canalicular network and excessive positive charges move along the bone fluid flow, which is called streaming potential.

Thus the general bone poroelasticity equation is combined with the charge density in electrokinetic effect of bone, and the fast wave is determined by charge density.

METHODS

The governing equations for the poroelasticity theory are given by Neev and Yeatts [3] include the charge density q_s and q_f, which are charge densities of solid and fluid. However, in the paper Neev and Yeatts [3], it is shown that these two quantities are almost identical and we will set these two quantities to be identical for future calculation.

$$\rho_{11}\ddot{u}+\rho_{12}\ddot{U}-Nu_{i,jj}-(A+N)u_{j,ji}-QU_{j,ji} +b(\dot{u}_i-\dot{U}_i)+q_s\Phi_{,i}=0 \quad (1)$$

$$\rho_{22}\ddot{U}_i+\rho_{12}\ddot{u}_i-(RU_{j,j}+Qu_{j,j})_{,i}-b(\dot{u}_i-\dot{U}_i) +q_s\Phi_{,i}=0 \quad (2)$$

$$\left\{q_f\left(RU_{j,j}+Qu_{j,j}\right)-\varepsilon b\left[\dot{\Phi}+(\beta G/\varepsilon)\right]\Phi\right\}_{,ii}=0 \quad (3)$$

, where *N*, *R*, *Q*, and *A* are poroelastic parameters, *u* and *U* are displacements of fluid and solid constituents, and the variable b is defined by $\phi^2\mu/K$, where μ is the fluid viscosity, K is the permeability of bone fluid, and ε is the permittivity, and the ϕ is the porosity. After we define $P\equiv A+2N$, the poroelastic parameters or, so called Biot parameters P, Q, and R are given by

$$P=\frac{\phi(K_s/K_f-1)K_b+\phi^2K_s+(1-2\phi)(K_s-K_b)}{(1-\phi-K_b/K_s+\phi K_s/K_f)}+\frac{4G}{3}, \quad (4)$$

$$Q=\frac{(1-\phi-K_b/K_s)\phi K_s}{1-\phi-K_b/K_s+\phi K_s/K_f}, \quad (5)$$

and

$$R=\frac{K_s\phi^2}{(1-\phi-K_b/K_s+\phi K_s/K_f)}. \quad (6)$$

K_i is the bulk modulus of i, where i is substituted for solid (s), fluid (f) and bone (b).

RESULTS AND DISCUSSION

Figure 1 shows the variation of fast wave velocity against porosity and charge density. The charge density as well as the porosity affect the fast wave velocity. However, the slow wave velocity and attenuation are not sensitive to the charge density. As we already know that the fast wave moves along the trabecular struts and the slow wave moves along the fluid in pores. Then we can simply conclude that the excessive charge ions are attached on the trabecular struts and increase the fast wave velocity and attenuation. Since the charge ions are gathered on the trabecular struts, which recruit the osteoblasts to be attached.

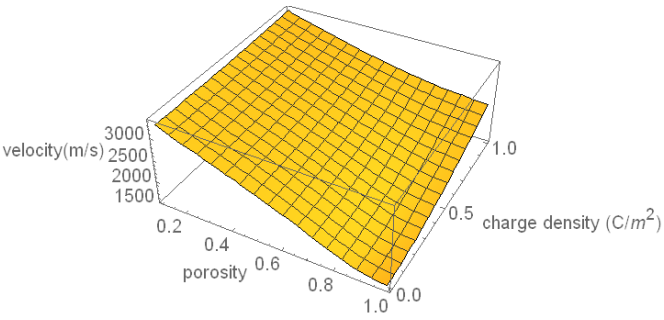

Figure 1: The fast wave against porosity and charge density

P393 - EFFECT OF CHANGE IN AN ADJACENT MUSCLE LENGTH ON THE SHEAR MODULUS OF THE RESTING MUSCLE - EVIDENCE FOR EPIMUSCULAR FORCE TRANSMISSION IN HUMAN MUSCLES

Yasuhide Yoshitake, Daiki Uchida, Hiroaki Kanehisa
National Institute of Fitness and Sports in Kanoya
Corresponding author email: y-yoshi@nifs-k.ac.jp

INTRODUCTION

The muscle force is transmitted in series to the aponeurosis, tendon, and bone, resulting in movement of limbs. The muscle force would be also transferred between extramuscular connective tissue structures, between synergistic muscles, and between antagonistic muscles. These observations have been termed as "epimuscular force transmission" [1]. Epimuscular force transmission has until now mainly been shown in animal models while few studies have demonstrated in human in vivo because of methodological limitations. From the limited information, the occurrence of force transmission between triceps surae muscles in vivo was suggested by the displacement of fascicles determined by means of ultrasound images [2]. However, the triceps surae muscles are connected to a common distal tendon (Achilles tendon), and therefore it is impossible to conclude if the displacement of fascicles is due to mainly epimuscular force transmission. Therefore, whether intermuscular force transmission occurs in humans is presently unknown.

Recent technological developments for assessing muscle mechanical characteristics, in particular, ultrasound shear-wave elastography, enables us to noninvasively measure the muscle shear modulus (muscle stiffness) with simple operations and high reproducibility [3]. A series of studies revealed that muscle shear modulus measured by shear wave elastography is linearly related to both active and passive muscle forces [3].

By using ultrasound shear-wave elastography, the present study aimed to elucidate whether intermuscular force transmission occurs in human muscles. We hypothesized that if no epimuscular force transmission occurs from an adjacent muscle in humans, the shear modulus of the other muscle (resting muscle) should not be altered. To test this, the present study determined the shear modulus of the resting muscle while passive force exerted by an adjacent muscle was manipulated. In this study, we changed passive force of an adjacent muscle by changing passively the muscle length (joint angle).

METHODS

Thirteen healthy men (21.6 ± 2.7 yrs) participated in the study. The biceps brachii longus (BB: adjacent muscle) and the brachialis (BRA: resting muscle) were chosen in this study because they are neighboring muscles with different tendons that are connected to different bones, indicating that length of the adjacent muscle can be manipulated without change in muscle length of the resting muscle.

Subjects were seated upright in a chair with the right upper arm abducted to an angle of 90º with the forearm in a horizontal position, and the elbow joint was flexed to 160º (fully elbow extension; 180º). In order to manipulate the muscle length of BB only, forearm was passively set at the supination, neutral, and pronation positions. Shear modulus of BB and BRA during rest were measured with an Aixplorer ultrasound scanner (Ver.7; Supersonic Imagine) at each forearm position.

RESULTS AND DISCUSSION

As expected, shear modulus of BB was largest at pronation (15.4 ± 3.9 kPa), followed by neutral (13.9 ± 2.7 kPa) and supination (10.6 ± 1.3 kPa) positions ($P < 0.05$ between all positions; Fig. 1A). This result represents that the changes in muscle length are closely associated with passive muscle force of BB. In contrast, shear modulus of BRA (resting muscle) showed reverse order, i.e., largest value at supination (11.9 ± 3.2 kPa), followed by neutral (10.4 ± 2.0 kPa) and pronation (9.9 ± 2.0 kPa) positions ($P < 0.05$ between all positions, Fig. 1B). This result indicates that shear modulus of the resting muscle was altered by changing passively the length of an adjacent muscle.

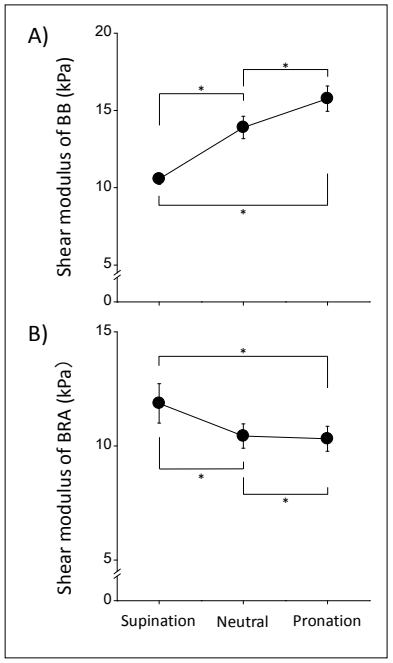

Figure 1: Shear modulus of the biceps brachii (*A*: BB) and the brachialis (*B*: BRA) at each forearm position during rest.

CONCLUSIONS

The results of the current study indicate that intermuscular force transmission is present in human muscles.

P394 - COMPARISON OF THE EXPERIMENTAL AND THEORETICAL RELEASE PARAMETERS OF A PLAYER WITH 99 % SUCCESS RATE IN BASKETBALL FREE-THROW SHOTS

[1] **Yuki Inaba**, [1]Munenori Murata and [2]Kazutoshi Kudo
[1]Japan Institute of Sports Science
[2]The University of Tokyo
Corresponding author email: yuki.inaba@jpnsport.go.jp

INTRODUCTION

Enhancing the numbers of shots made is critical for winning a basketball game. There are multiple trajectories that a successful shot can follow from a certain release position since the diameter of the goal ring is about twice as large as that of a basketball [1]. The combination of release speed and angle that result in a successful shot was investigated theoretically by numerical analysis across various conditions of release height and spin [2,3]. Additional studies have investigated the trajectory of a shot experimentally and assessed release angles and speeds, and ball arrival positions [4,5]. However, since the theoretical and experimental approaches were not conducted simultaneously, it is not understood how players release the ball under practical conditions in comparison with theoretical successful release conditions. Thus, the purpose of this study was to compare theoretical successful release conditions with actual release variables to reveal the release conditions that result in higher percentage of successful shots. For this purpose, we compared the data of a highly-skilled basketball player with that of a less experienced player.

METHODS

A professional male basketball player (Expert), who played for the Japanese professional league from 2005 to 2016 (height: 1.67 m, weight: 75 kg) and one healthy male player (Non-Expert) who had experience in playing basketball at a high school club for three years (height: 1.74 m, weight: 78 kg) participated in this study. They attempted 100 free-throw shots. Forty-eight reflective markers were attached to the players, and nine to eleven reflective marks were randomly attached on the surface of the basketball. Shooting motion and trajectories of a ball were captured with three-dimensional motion analysis system using 20 cameras (MX-series, VICON).

The release positions, angles, and speed of the center of the ball, spin rate, and ball arrival positions (the position of the ball center at the height of the ring) were computed from the obtained positional data of the attached marks on the surface of the ball. Since we observed a significant influence of air drag and lift force, the drag and lift coefficients were determined by optimization to minimize the least-squares deviation between the actual ball trajectory and trajectory that was calculated by solving the equation of the motion of the ball including the terms of lift and air drag force. We calculated the ball trajectory at given combinations of release speed and release angle using the mean release position, spin rate, and drag and lift coefficients of the 100 shots of each player. A shot was regarded as successful if the ball arrival position was within the boundary where it could go through the ring without touching the rim (swish) or barely touching the rim (swish ± 50 mm region).

RESULTS AND DISCUSSION

The ball arrival position (mean±SD) was 14 ±50 mm short and 18 ± 49 mm left of the center of the ring for the Expert who successfully made 99 shots out of 100 shots, and 48 ± 139 mm short and 8 ± 108 mm left for the Non-Expert who made 61 successful shots. The mean arrival positions by both players were almost equal to the center of the ring, while the SD was smaller for the Expert. This indicates that less variability and greater repeatability contributed to a higher percentage of success. When the theoretical successful region and actual shots were compared, it was found that the Expert had smaller variability in release parameters compared to the Non-Expert, and those were mostly within the successful region (Figure 1). The margin for error in release angle at mean release speed was 10.6 degree for the Expert and 3.8 degree for the Non-Expert, and that in release speed at mean release angle was 0.14 m/s for the Expert and 0.20 m/s for the Non-Expert. Thus, the Expert chose the region with a greater margin for error in release angle while the Non-Expert in this study chose the region with a greater margin for error in release speed.

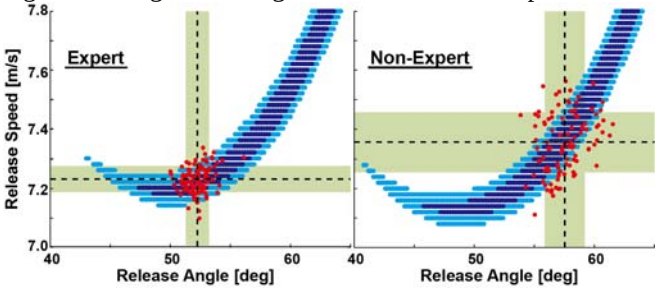

Figure 1: Theoretical successful combination of release angle and release speed (dark blue: swish, light blue: swish ± 50 mm) and experimental data (red). Black dash line shows the means and the light green area shows the standard deviations of release angles and release speeds of 100 shots.

CONCLUSIONS

A higher percentage of successful shots can be achieved by reducing the variability in release parameters and choosing such parameters that permit a greater margin for error according to the variability characteristics.

P395 - EFFECTS OF AGE ON FORCE STEADINESS: A LITERATURE REVIEW AND META-ANALYSIS

[12]**Nathalie M.C.W. Oomen** and [2]Jaap H. van Dieën

INTRODUCTION

Biological variability is inherent to the human motor system, and is reflected in variability or unsteadiness of muscle force which is typically defined as the coefficient of variation of actual force around a submaximal isotonic target [1,2]. Previous literature has shown inconsistent evidence regarding changes in steadiness with ageing [3,4]. If force steadiness is a limiting factor in motor control, a decrease in steadiness with ageing may underlie decreased motor performance in many motor tasks among older adults. Therefore, the effect of age on the steadiness of force was reviewed in the literature and a meta-analysis was performed to determine the effect size of age. Furthermore, to account for differences in effect sizes the following determinants were investigated: sample size, age difference, tested muscle groups and target force levels.

METHODS

Twenty studies were included in this systematic review, of which twelve provided sufficient data to determine the pooled effect size for the effect of age. The effect of sample size on dichotomized effect sizes (significant vs. non-significant) was determined. Furthermore, effects of age difference between age groups, dominance of investigated limb, muscle group, muscle location (proximal vs. distal and upper vs. lower extremity) and target force level on effect size (categorized as small, medium, or large) were investigated.

RESULTS AND DISCUSSION

A large pooled effect size of age was found (r_{total} = 0.67, 95% CI [0.61; 0.72]) (see Figure 1). Differences in significance of effects were not related to sample size, indicating that differences in conclusions were not due to differences in power between studies. Differences in effect size categories were related to muscle group (χ^2= 24.15; $p < 0.01$), proximal vs. distal muscle location (χ^2= 12.13; $p < 0.01$) and target force level (H=11.02; $p < 0.01$). Also, an interaction effect of muscle group and target force level was suggested.

CONCLUSIONS

This study showed a large pooled effect size of age on force steadiness, which was determined by muscle group and target force level. Large and consistent effects were found at the lowest target levels, which decreased and became less consistent at moderate-to-high target levels. Small distal muscles showed effects over the entire force range, and large proximal muscles showed effects only at low target levels. The effect of age on force steadiness can best be explained by motor unit loss occurring with ageing and this effect can partially explain decreased motor performance associated with ageing.

P396 - THE EFFECTS OF FATIGUE ON THE MOTOR EVOKED POTENTIAL OF THE INFRASPINATUS

[1]Joseph H Cordell, [1]Kelly J Jantzen, [1]David N Suprak, [1]William McGinnis, [1]Josh LaRussa and [1]**Jun G San Juan**

INTRODUCTION

Fatigue of shoulder muscles has shown to alter scapular kinematics during humeral elevation [1]. Of the shoulder muscles, the infraspinatus is involved in external rotation and stabilization of the humerus. Instability of the humerus, due to fatigued shoulder muscles, could increase the chance of shoulder injury such as impingement.

The central nervous system influences the activation of motor neurons and the contractility of muscles. Signals from the motor cortex cause the response from muscles, but this response is not instantaneous. There is a latency between the stimulation of the motor cortex and activation of muscle contractility. There may be an effect on latency and motor evoked potential (MEP) of a muscle after being fatigued.

The purpose of this study is to examine the change, pre- and post-fatigue, in muscle activation latency and MEP amplitude of the infraspinatus.

METHODS

A total of 17 subjects participated in this experiment. Aged 22 ± 2.1 years old. Average height 176.5 ± 9.51 cm and average mass of 74.4 ± 14.8 kg. All subjects were recruited from the campus of Western Washington University.

The right infraspinatus was monitored with dual surface electrodes with an inter-electrode distance of 1.75 cm apart with a Noraxon TeleMyo desktop direct transmission electromyography (EMG) system. Transcranial magnetic stimulation (TMS) was performed with a figure-of-8-coil using Magstim BiStim system to stimulate the motor cortex. Optimal stimulation was found by mapping of the motor cortex by stimulating multiple points on a 5x5cm grid every 1 cm around C1 to locate the spot that most excites the target muscle. C1 is the position over the motor cortex on the contralateral side of the right infraspinatus when following the international 10 20 electrode placements for electroencephalography [2]. During mapping and recording of data, the subject held their right arm horizontal to the floor at 45° of scapular abduction to cause a 6-10% activation of maximum voluntary contraction in the infraspinatus. Active motor threshold (aMT) is the lowest setting on the TMS device that will elicit an MEP from the target muscle. During data collection, 120% of the aMT was used during recording.

When the optimal spot and active motor threshold for infraspinatus activation was found, twelve pre-fatigue stimulations were recorded, followed by a fatigue protocol, and then twelve post-fatigue stimulations. The fatigue protocol consists of the subject holding their arm at their side, pinching a rolled towel between their right elbow and torso, and having the elbow flexed at 90° while the forearm is in a semi-prone position while holding onto an elastic band in the right hand. Subjects were instructed to externally rotate (ER) their shoulder rapidly with as full range of motion. The experimenter held the other end of the elastic band to provide resistance. After the subjects had failed to move into ER because of fatigue, ER force was measured. When force production was decreased by 25%, measured by a Microfet2 handheld dynamometer, the post-fatigue stimulations began.

RESULTS AND DISCUSSION

Muscle activation latency did not show a difference between pre- and post-fatigue with an average change of -0.2 ms (p=0.77). The MEP amplitude has shown an average decrease of 111.4 uv, (p=0.43) but was not statistically significant. The peak to peak latency within the MEP, measured by the time between the minima and maxima of the MEP, has shown statistically significant (p=0.005) increase from an average of 4.5 ms pre-fatigue to 5.9 ms post-fatigue with an effect size of 0.68 (Figure 1).

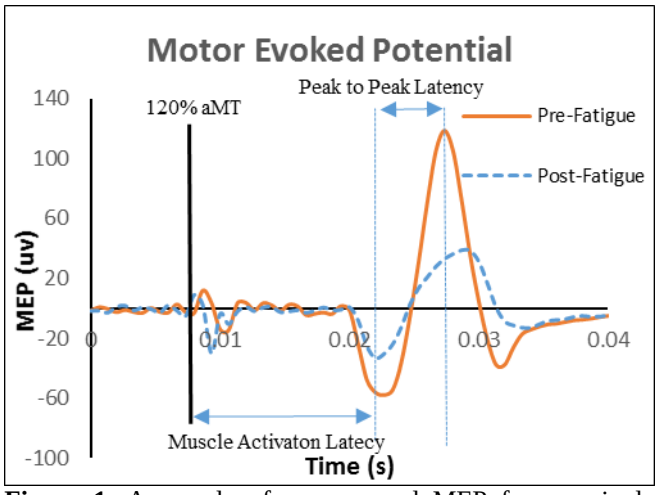

Figure 1: A sample of an averaged MEP from a single subject. Peak to peak latency is shown to change from 4.6ms pre-fatigue to 6.6ms post-fatigue

CONCLUSIONS

Latency between the stimulation of the motor cortex and activation of muscle contractility has shown no difference after the fatigue protocol. There is a trend to the change in MEP amplitude but did not show statistical significant. The peak to peak latency has shown to have a significant increase. The increase in time to the same stimulus, post-fatigue, might mean that the muscle has a longer activation in a fatigued state. This change in activity could lead to alteration in shoulder kinematics. The infraspinatus might influence a decrease in stabilization depending on its interactions with other shoulder musculature.

P397 - POST-MORTEM SWINE THORACIC KINEMATIC RESPONSE UNDER BLAST THREAT

INTRODUCTION

Current conflicts and homeland security operations present an increased risk of improvised explosive devices, threat that principally affect air-filled organs such a lung. In order to better protect soldier from shock-waves, there is a need to develop an adapted injury criterion and before this to evaluate the response of biological model against that threat.

The objective of this study is to provide some robust data to quantify the thoracic response of post-mortem swine under different blast loadings.

METHODS

Seven female post-mortem swine (54.5±2.6kg), whose abdominal viscera were replaced by four natural sponges while thorax and its organs were still intact, were exposed to five different shock-waves, from no injury to 50% of lethality according to the Bowen curves [1]. The animals were exposed side-on to the threat and against the ground, the spherical explosive charge of C-4 was suspended 2m above the swine ribcage.

The swine were instrumented with an accelerometer on the 8-9th rib (from the top) directly exposed to the shock-wave, and a target was mounted on it in order to track the ribcage displacement. A piezo-resistive pressure sensor was placed next to the accelerometer in order to measure the reflected pressure. Two pencil probes were also used to measure the incident threat that faced the swine. In addition, a high-speed camera recording at 40,000fps was installed to visualize the shock-wave interaction with the animal and to track the ribcage displacement.

An overview of the experimental set-up is proposed in figure 1, five C-4 masses were used to conduct 47 experimentations and to analyze results in terms of thoracic kinematic parameters and intra and inter swine results' reproducibility.

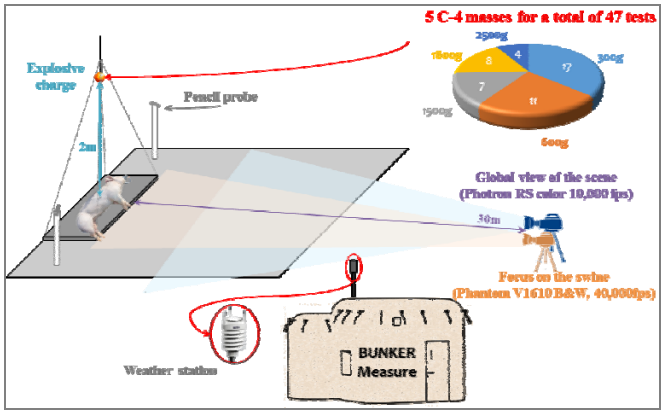

Figure 1: Experimental setup

RESULTS AND DISCUSSION

Forty-seven experiments were performed, leading to 423 profiles in terms of incident and reflected pressure/impulse, acceleration Γ, velocity V and displacement D of the ribcage.

The main results are:

- Intra and inter-species reproducibility;
- For maximum incident impulses from 50kPa.ms to 160kPa.ms, the following ribcage responses have been recorded:
  - Γ_{max} (m/s²): [5728 ± 939 - 40988 ± 3311];
  - V_{max} (m/s): [2.5 ± 0.25 - 10.3 ± 0.6];
  - D_{max} (mm): [4.8 ± 0.9 - 19.4 ± 2.8].
- Relations have been established between kinematic parameters and the maximum of incident impulse

In addition, it has been observed that the threshold of lung injury defined by Cooper [2] in terms of Γ_{max} (10,000m/s²) is in accordance with the data obtained, but the limits defined for the viscous criterion in the automobile field (1m/s for AIS3+) and for non-lethal weapons (0.8m/s) seems not adapted for the blast threat. Indeed, the value obtained for lung injury threshold is 0.061m/s and it goes to 0.34m/s for 50% of lethality.

CONCLUSIONS

Forty-seven reproducible experiments have been performed on seven swine exposed against the ground, side-on to shock-waves of increasing intensity. The obtained data are reproducible and simple relations between the kinematic parameters (plus the viscous criterion) and the incident impulses have been obtained.

The huge set of data recorded from that study could be used to validate FEM of swine under that threat in order to develop a new tolerance limit for lung at tissue level.

P398 - TRACKING THE ALVEOLAR WALL WITH OPTICAL COHERENCE TOMOGRAPHY

[1]Samuel Richardson, [1]Amir Hajirassouliha, [1]Matthew D. Parker [1,2]Martyn P. Nash, [1,2]Andrew J. Taberner, [1]Merryn Tawhai, [1,2]Poul M. F. Nielsen

INTRODUCTION

Of all the internal organs, the lungs exhibit the strongest connection between physiological function and mechanical behaviour. Better understanding of the alveolar wall — in particular, how the mechanical constituents of the alveolar wall interact with the geometry of the alveoli — is key to improving diagnostic measurements of lung function, and therefore understanding of disease progression [1]. This is especially relevant to the older population, as the normal decline in lung function which occurs with age is virtually indistinguishable from early disease, leading to frequent misdiagnoses in the elderly.

Lung tissue is extremely delicate, making it challenging to characterise its mechanical properties without damaging the tissue. Thus, current models of the lungs are weakly parameterised, as material measurements are made on cut or stretched tissue which do not represent the lungs in vivo state, where pre-tension plays a significant role.

This project focuses on non-destructively imaging the lungs, with the aim of quantifying the mechanics of the tissue; specifically, the alveolar wall. An optical coherence tomography (OCT) imager was developed to capture 3D images of rat alveoli non-destructively. A real-time pressure control system was developed to enable measurement of high resolution pressure-volume (P-V) loops. The high spatial resolution of the OCT, coupled with the real-time pressure control, allows for acquisition of stable volume scans of the lungs at physiologically relevant pressures.

METHODS

Sprague-Dawley rats were used in this study for two key reasons: their similarities to humans in alveolar air-space enlargement with age [2], and their relatively large alveoli (~90 μm diameter) compared with lung size (~20 mL) [3], which enables the visualisation of alveolar deformation by OCT (which has a voxel size of ~15 μm^3). Key physiological measurements were changes in volume with pressure and alveolar topology. Initial studies were performed on excised lungs that are intubated under real-time pressure control developed on a National Instruments compact rio (CRIO). Techniques have been developed to make use of tissue from rats that have been euthanized.

Lungs were collapsed upon dissection from the rats. Before imaging, to recruit the collapsed alveoli, lungs were fully inflated to 3 kPa and held until inflation stopped. If inflation halted before full alveolar recruitment, pressure was cycled sinusoidally between 1 kPa and 3 kPa. The lungs were then fully deflated and inflated to record a full P-V loop; followed by a range of physiologically occurring pressures for 3D OCT imaging [4].

A phase-based Savitzky-Golay gradient-correlation (P-SG-GC) [5] tracking algorithm was used to process the 3D OCT images and determine the changes in volume of the alveoli resulting from the changes in pressure.

RESULTS AND DISCUSSION

Figure 1.A shows an inflated left lobe. An inflation device was designed and tested that gives volume and pressure resolutions of ±5 μl and ±0.05 Pa respectively. This allowed for quasi-static imaging of lungs with OCT ex vivo as shown in Figure 1.B.

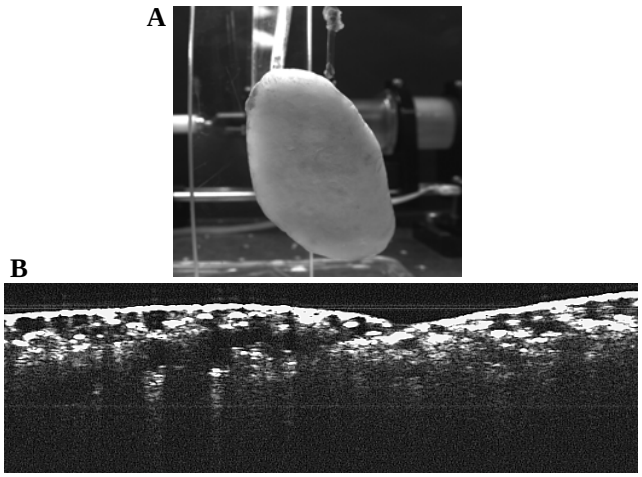

Figure 1: A: left lobe of rat lung, at 2.5 kPa. B: 2D OCT image of rat lungs.

2D OCT images were stitched into 3D volumes and tracked between the pressure states. 3D subvoxel displacement measurements enabled tracking of geometry as the volume of the alveoli change with pressure.

CONCLUSIONS

Optical coherence tomography is a powerful tool for the non-destructive measurement and tracking of alveoli. P-SG-GC tracking provides accurate measurement of displacements in response to changes in inflation pressure.

P399 - FOUR-BAR KNEE JOINT FOR KNEE-ANKLE-FOOT ORTHOSIS (KAFO)

[1] **Ganesh M Bapat**, [2]Sujatha Srinivasan
[1,2]Indian Institute of Technology Madras, Chennai, India
Corresponding author email: sujsree@iitm.ac.in

INTRODUCTION

A KAFO with a locked or offset single-axis knee is used for stabilizing standing and walking in people with quadriceps muscle weakness. While these knees are simple, low-cost solutions, a locked knee results in an unnatural gait with excessive loads, and an offset knee can compromise stability on uneven terrain. A stance control orthosis (SCO) is an improved version of a KAFO that tries to mimic normal walking by locking during stance and allowing swing flexion, but SCOs are expensive and out of reach for many potential users. A four-bar mechanism (4BM) can potentially provide better functionality in a KAFO by virtue of its moving centre of rotation. A 4BM has been used in knee braces to mimic the anatomical knee centre, and in prosthetics to provide stance stability and swing phase ground clearance [1, 2]. However, the literature shows that the use of the polycentric nature of a 4BM in a KAFO has not been explored. In this work we present an approach for optimal design of a 4BM for an orthosis.

METHODS

To improve the gait of people with quadriceps muscle weakness, maximum stability during stance and reduced effort during initiation of swing flexion is required. The hip moment required for ensuring stability during stance and for ease of initiating flexion during the push-off phase of walking is used as a criterion. Using an approach similar to Radcliffe [2], the hip moment is expressed in terms of the location of the knee centre, which is the instant centre (IC) of rotation of the 4BM, with respect to the load line (the line from the hip joint to the centre of pressure (COP) on the ground). Our objective is to minimize the hip moment required at heel contact and toe off, expressed as follows:

$$\mathbf{M_h = PL\ (x/y)} \ldots\ldots\ldots\ldots\ldots\ldots (1)$$

where, M_h is the required hip moment, P is the load along the load line, L is the distance from the hip joint to the COP along the load line, x is the normal distance of the IC from the load line, and y is the height of the IC from the COP along the load line. The factor (PL) is user specific, but remains constant for a particular user. Hence, the (x/y) ratio is the deciding factor for optimization. Constraints used for optimization are as follows:

1) Grashof criterion for a 4BM
2) Size constraints on the link lengths
3) Constraint to maintain proportionality of the 4BM for the purpose of alignment

MATLAB™ (R2014a) software is used for optimal synthesis of the 4BM. Genetic algorithm (GA) with elitist strategy is used for optimization.

RESULTS AND DISCUSSION

The synthesized 4BM is a Grashof class-I double rocker mechanism as shown in Figure 1. The 4BM locks the knee joint based on mechanics principles as compared to actual locking systems present in existing SCOs. The new four-bar design provides stable stance phase knee flexion up to 5º even in the absence of a stabilizing hip moment. Further, a user can voluntarily control the stance stability for 4-5º additional flexion, assuming that the user is capable of generating at least 50% of the average hip moment (60-120 Nm) required during normal human walking [3]. With this available hip strength, users can control knee stability by applying a small hip extension moment, even when they land on a flexed knee, a likelihood on uneven terrain. Thus, stability issues arising during community ambulation with an offset knee joint can be overcome with a stance stable four-bar orthotic knee joint.

Increase in stance stability demands a greater effort to flex the knee during push-off. However, with this four-bar, the hip flexion moment required during push-off to initiate swing phase is within the range of available hip muscle strength of the user population considered for this design. For such users, an orthosis with 4BM providing voluntary stability in stance and flexion during swing can function as a mechanically operated SCO.

Figure 1: Potential four-bar knee configuration for KAFO

CONCLUSIONS

The new orthotic four-bar knee joint could be a functionally superior alternative to conventional single axis knee joints, and provide a simple and cost-effective alternative to SCOs available in the market. Challenges include aligning the mechanism on the two sides of the uprights and minimizing pistoning forces due to shank-shortening with a 4BM. Future work includes clinical trials with KAFO users and design modifications based on feedback.

P400 - DEVELOPMENT AND APPLICATION OF A *3D* THERMOGRAPIC IMAGINIG SYSTEM TO IMPROVE SOCKET FITTING IN BELOW-KNEE AMPUTEES

Andrea G. Cutti[1], Tonia Ricci[2], Angelo Cappello[2], Gennaro Verni[1]

[1]INAIL Prostheses Center, Vigorso di Budrio, Italy
[2]University of Bologna, Bologna, Italy
Corresponding author email: ag.cutti@inail.it

INTRODUCTION

Optimal socket fit is an essential pre-requirement to allow below-knee amputees regaining activity and participation in daily life. However, the design and implementation of a socket can be challenging when the stump presents poor skin quality, painful bony prominences or the patient lacks sensitivity due to peripheral neuropathy.

We think that thermographic (TG) imaging can be a practical solution to increase comfort, reduce the number of trial sockets and increase quality of life in these patients.

A protocol has been previously documented [1], which relies on the sequential acquisition of TG images in multiple views before and after walking with the prosthesis under assessment. Then, pre-post images are registered (superimposed with the use of custom-made thermographic markers), and a differential image is calculated for each view. The differential image highlights hot and cold spots. Hot spots can either be associated with areas of known increased mechanical stress in agreement with prosthetist' will, but can also be unwanted stress areas.

One of the limitation of the current protocol is related to the post-processing phase. The CPO must view separate images, and mentally reconstruct the 3D geometry of the stump, taking notice of the abnormalities image-by-image. Therefore, the aim of this study was to develop and test a *3D thermographic application*, that fuses 3D scanning with TG images. This allows to incorporate all the knowledge in a single 3D model with "thermographic color".

METHODS

The following constraints were assumed for system development:

1) it should be based on a 3D scanner, a 2D thermographic camera, a set of thermographic markers, a "spinning platform" [1] and an image fusion software;
2) the 3D scanner should be cost-affordable, easy to use, fast in acquisition and post-processing, and allow the operator to move around the patient for image collection;
3) thermographic markers are small 3D printed cubes (side=5mm) of ABS material placed on the stump by the CPO;
4) the "spinning platform" is a rotating platform used to rotate the patient during 2D image acquisition, while keeping the 2D thermographic camera still;
5) the image fusion software should be based on an available platform, low-cost and easy to use.

The protocol consists of the following sequential steps:

1) the patient walks for 15 minutes;
2) the prosthesis is donned and markers are applied;
3) multiple 2D thermographic images are collected;
4) the patient rests for 20 minutes;
5) step 3 is replicated;
6) the 3D scanning of the stump is completed;
7) 2D images are fused on the 3D model;
8) the temperature information on the pre- and post-walking 3D models are subtracted to highlight hot and cold spots;
9) the model is virtually examined or sent to a 3D color printer for building a physical thermographic model.

For 3D scanning we selected a Microsoft Kinect combined with the software Skanect [2]. A FLIR A320 was used for TG image collection (320 x 240 pixels) and temperature data were mapped to colors with a custom-made MATLAB software. Pre- and post-walking images were fused onto the 3D mesh using the freeware MESHLAB, so that each vertex was associated with a color. A neural network was used to trace back colors to actual temperatures. Finally, the 3D model with the differential information was obtained. The procedure was tested on a below-knee amputee. The accuracy of the whole process was analyzed by looking at the temperature associated to the makers, which is expected to be constant pre-post walking.

RESULTS AND DISCUSSION

An exemplary differential image is provided in Figure 1, with red indicating hot spots and blue indicating cold spots. The analysis of markers' temperature showed a worst case spatial error of 5mm, which appears acceptable for socket refinement.

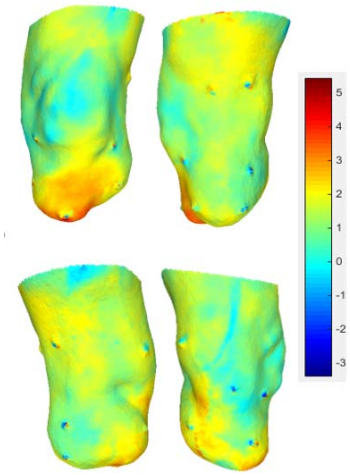

Figure 1: 3D model with differential (pre-post walking) temperature information.

CONCLUSIONS

The unique 3D system that we developed is easy to use, and accurate; it has the potential to diffuse in the clinical routine and forms the bases for a breakthrough in socket optimization.

P401 - ANTHROPOMORPHISM INDEX OF MOBILITY FOR HAND PROSTHESES

[1]**Immaculada Llop-Harillo**, [1]Antonio Pérez-González and [1]Verónica Gracia-Ibáñez
[1]Universitat Jaume I, Castellón (Spain)
illop@uji.es

INTRODUCTION

Evaluating the functional similarity of hand prostheses with the human hand (HH) is essential for improving current anthropomorphic hand designs. Feix et al. [1] proposed a metric for comparing the anthropomorphic motion capability of robotic and prosthetic hands, the Anthropomorphism Index (AI), but its computation is cumbersome and based only on the position and orientation of the distal phalanges in different grasp types (GT). The importance of the different GTs for personal autonomy of the patients in activities of daily living (ADL) has been studied previously [2], being pulp pinch (26%), extension grip (20.8%), tripod pinch (10.4%) and transverse volar grip (8.7%) the most relevant GTs for a non-dominant hand to reinforce bimanual grasping. Principal component (PC) analysis has been used by Gracia-Ibáñez et al. [2] to reduce to five main PC the degrees of freedom (DOF) of the HH in ADL: finger arching (FA), closure (C), palmar arching (PA), lateral pinch (LP) and opposition (O). Besides this, underactuation in artificial hands allows to use less actuators than DOF while keeping versatility to adapt GT to different object shapes. Based on that previous research, we propose here an index for the anthropomorphism of an artificial hand, based on the comparison of the topology of the whole hand (joints and DOFs) and on the possibility to control these DOFs independently (degree of actuation, DOA). The computation of the index referred to as anthropomorphism index of mobility (AIM) weights each DOF depending on its importance for grasping in ADL.

METHODS

The DOFs of the HH were classified into four different groups for defining the AIM: finger flexion-extension (12 in HH), finger abduction-adduction (4 in HH), palmar arching (3 in HH) and thumb opposition (5 in HH). AIM was defined with Equations (1) and (2):

$$AIM = \sum_i (r_{DOF\_i} \cdot k_{DOA\_i} \cdot w_i) \quad (1) \qquad w_i = \sum_j r_{ij} \cdot s_j \quad (2)$$

where i is each of the four groups of DOFs, r_{DOFi} represents the ratio of DOF of the artificial hand to the human hand in group i, k_{DOAi} is a coefficient between 0 and 1 dependent on the DOA for the DOFs in group i and w_i (Eq. 2) is a weighting coefficient between 0 and 1 depending on the relative relevance of the DOFs of group i for grasping in ADL. To define k_{DOAi}, Pugh's method used in concept design evaluation [3] was employed to convert an ordered list of methods of actuation of the joints, depending on their relative independent motion capability, into a numeric coefficient, obtaining: 1 for total active control of the DOF; 0.75 for underactuated DOFs with tendons or elastic elements; 0.5 for DOF coupled with linkages; 0.25 for DOF with passive motion not actuated; 0 for DOF absent. The weighting coefficient w_i was obtained with Eq. 2., where r_{ij} is the relative contribution of the group of DOF i (i=1,2,3,4) in the PC_j (j=1,2,3,4,5 corresponding to each of the five main PCs obtained in [2]) and was computed as the sum of absolute values of the coefficients of PC j for the group of DOF i divided by the sum of the absolute value of all the coefficients of this PC. To obtain s_j used in Eq. 2, a set of grasping tests was performed on 4 subjects. Twelve different objects from the YCB Set [4] (3 for each of the 4 most relevant GT for ADL [2]) were selected, and grasped three times by each subject, while hand angles were registered using an 18-sensor CyberGlove®. The value of the score s_j was obtained with a weighted averaging of the normalized scores of the PC_j in each hand posture during the experiments. The relative relevance of each GT for autonomy [2] was used for weighting.

The AIM was compared for different low-cost 3D printed prosthetic hands, including IMMA hand [5]. The AIM was also assessed comparing with results of AI obtained in [1].

RESULTS AND DISCUSSION

The s_j obtained from the experiment was: 34.7% (FA), 26.8% (C), 16.2% (PA), 18.7% (LP) and 3.6% (O). The resultant w_i was 59% for finger flexion-extension, 18.4% for finger abduction-adduction, 5% for palmar arching and 17.6% for thumb opposition. The AIM obtained for the hands used in [1] was: SensorHand® Speed 13.6% (AI is 0.25%), Michelangelo® hand 35.7% (AI is 2.8%), FRH-4 hand 38.2% (AI is 5.2%). The different hands are ranked equally by both metrics, although the magnitudes are different. The AIM obtained for low-cost 3D printed hand prostheses was: IMMA hand (63.3%), Cyborg Beast (41%), Flexy-Hand (59.8%), K1 (41%) ADA (57.8%).

CONCLUSIONS

A metric of anthropomorphism was proposed, simpler than the AI, which can be useful for concept design and comparison of artificial hands. Further research will focus on new metrics considering range of motion of the joints, relative length of the phalanges, orientation of the joints axes or virtual finger oppositions able with the hand.

P402 - DESIGN IMPROVEMENT OF A SIX-BAR PROSTHETIC KNEE PROTOTYPE

INTRODUCTION

Amputation of lower extremities, whether it is transtibial (amputation between knee and foot) or transfemoral (amputation between hip and knee) will limit the amputee's mobility and require them to use leg prosthetic to perform daily activity. In Indonesia, most leg prosthetics are out of reach for amputees coming from lower-middle income. Above knee prosthesis usually costs from $2000 to $48000 depending on the complexity and manufacturing. Because of that, many of the amputees used simple single axis knee leg prosthetic. While it is cheaper, it cannot function well and represents poor gait. ITB has been developing polycentric knees that are affordable and have a good representations of human gait, one of them being six-bar knee leg prosthetic. In this research, evaluation of the design was conducted to derive design modifications and improvements.

METHODS

The design process starts with determination of design requirements and objectives (DR&O). DR&O is made based on discussions and interviews with several amputees and also consideration of ease of manufacturing and final cost. After defining DR&O, functions and sub-functions for the design are determined. After the list of functions and sub-functions is finished, variation of design improvements are created and evaluated. From these designs, decision has to be made on which design comply the most with DR&O. Detailed concept design then was created to include dimensions, detailed geometry, and material selection. After that, we create a prototype by machining processes. The prototype was then evaluated.

RESULTS AND DISCUSSION

There are five main points of the DR&O: cost, physical form, performance, fabrication, and maintainability.

Two main functions of the prosthetic knee are: The prosthetic knee should flex and extent smoothly during swing phase. Swing speed is determined by mechanical properties of knee, including swing moment, friction, and other resistance that may be present. Prosthetic knee must be stable as the user's weight move forward during stance phase. Important sub-functions of the prosthetic knee are knee-socket pyramid adapter joining mechanism, Stephenson's six-bar linkage system [1], bearing linkage joints, and knee-pylon joining mechanism with integrated clamp.

The material selected for top and bottom links is HDPE, not Nylon as in previous prototype [2], due to ease of machining and better precision. The resulting prototype is shown in Figure 1.

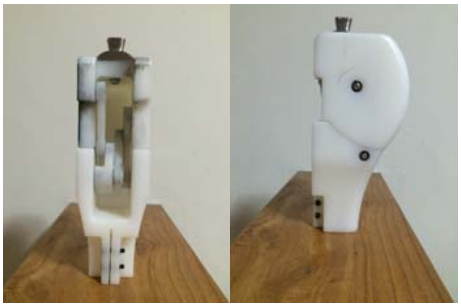

Figure 1: The new Six-bar Prosthetic Knee Prototype.

CONCLUSIONS

The improvement and prototyping of the six-bar prosthetic knee have been carried out successfully. The new male pyramid adapter is aesthetically better with more accurate dimensions. It also does not exhibit worn-out effects after usage. The integrated clamp also provides better aesthetic and functions and have fewer components. The top and the bottom links curved form also looks better. The decreased thickness of anterior, link 1, and link 2 makes the prototype more compact. However, the new prototype are found to be still in need of improvement. For example, the top and bottom link still has inaccurate dimensions due to the difficulty in machining plastic parts as compared to metal. On the other hand, the male pyramid adapter, which is made of metal, has accurate dimensions. There is also contact that hampers motion at 6 degree flexion due to geometry of the top link and the bottom link. The dimension of the shaft is inaccurate, causing misalignment in the knee movement. The new prototype still need some improvements, but this prototype could be used as a reference for further research and improvement of six-bar prosthetic knee.

ACKNOWLEDGEMENTS

This work is part of an ongoing research project with the aim to develop affordable leg prosthetic for transfemoral amputees in Indonesia. Authors gratefully acknowledge the support of Ministry of Research Technology and Higher Education who have made this work possible through *Penelitian Unggulan Perguruan Tinggi* (*PUPT*) scheme research grant for year 2015 – 2017. The authors would also like to thank volunteer amputees for their participation in this project as well as for their valuable inputs.

P403 - LIMB KINETICS WITH PASSIVE AND POWERED ANKLE-FOOT ORTHOSES IN PATIENTS WITH LOWER LIMB TRAUMA

[1,2] **Elizabeth Russell Esposito**, [1,2] Jason M Wilken
[1]Center for the Intrepid, Brooke Army Medical Center
[2]Extremity Trauma and Amputation Center of Excellence
Corresponding author email: Elizabeth.m.russell34.civ@mail.mil

INTRODUCTION

Ankle-foot orthoses (AFO) are commonly prescribed to provide functional assistance for patients with lower limb injuries or weakness. Their passive mechanical elements can provide some energy return to improve walking ability, but cannot restore plantar flexor push-off. Powered AFOs provide an assistive torque about the ankle to address the inherent limitations of passive devices [e.g. 1-3] but current designs have yet to be implemented on a large scale clinically. The aim of this study was to compare mechanical work and efficiency in passive and a new powered AFO design in patients with lower extremity trauma.

METHODS

Three individuals with unilateral lower extremity trauma requiring surgical reconstruction and continued AFO use participated in this case series. Subjects had at least a 20% deficit in ankle plantarflexion strength and were capable of walking without an assistive device. All wore a passive AFO for walking and activities of daily living. A crossover study design compared gait mechanics at a standardized speed (based on leg length) in 4 AFO conditions: 1. **None** (shoes only), 2. Blue Rocker (**BR**, Allard, USA), 3. Intrepid Dynamic Exoskeletal Orthosis (**IDEO**), and 4. PowerFoot Orthosis, **PFO** (BionX Medical Technologies, Inc.).

The BR was an off-the-shelf carbon fiber AFO with cuff below the knee, lateral strut and flexible foot plate. The IDEO was a custom carbon fiber AFO with cuff below the knee, lateral strut and rigid foot plate [4]. The PFO was a custom device engineered for each patient and damping and power were tuned based on patient feedback and observation. It was untethered and a battery pack on the subject's waist provided external power. The device was an extension of previously reported powered efforts [5].

Total power on the affected and unaffected limbs was calculated using a unified deformable (UD) segment model to quantify power for structures below the knee. UD power was integrated over time to calculated mechanical work (J/kg) and a dimensionless efficiency metric was then calculated as the ratio of positive to negative work. Effect sizes (d) were calculated and d>0.8 denoted a large effect.

RESULTS AND DISCUSSION

Net positive work was greatest in the PFO (d>1.2 for all comparisons) and lowest in the BR (d>1.1 for all comparisons) (Figure 1). In the PFO positive work was comparable between affected and unaffected limbs (d<0.8). There were no large effects in positive work between wearing an IDEO and not wearing an AFO (d=0.7). The affected limb in the BR generated consistently less negative work than the other conditions (d>1.4). Negative work was comparable between limbs (d<0.8) for all conditions except the BR, where the affected side was, on average, 27% less.

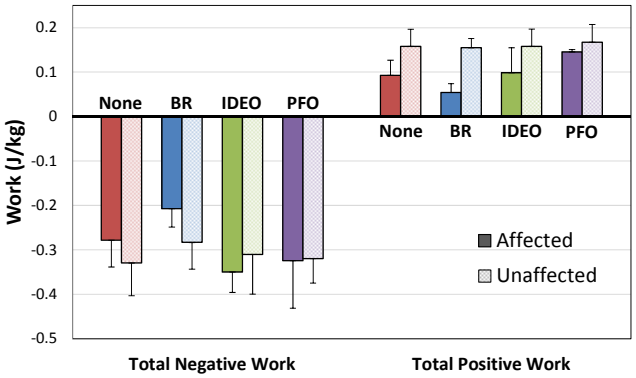

Figure 1: Mechanical work calculated using a unified deformable (UD) segment model. Error bars are 1 SD.

The PFO increased efficiency (+/- work ratio) during walking compared to all other conditions ($d \geq 1.4$). The only other large effect on the affected limb was with BR compared to None, with BR less efficient (d=1.1). Efficiency was also consistently less on the affected limb for all AFO conditions ($d \geq 1.7$) except the PFO (d=0.5). There were no large effects between AFO conditions on the affected limb ($d \leq 0.4$). Patient preferred their daily use AFO (2 IDEO, 1 BR). All participants indicated that mass and size were concerns with using the PFO.

CONCLUSIONS

A novel PFO resulted in more biomimetic mechanical work and efficiency than commercially-available and custom passive AFO models. Of the two passive devices, the custom, carbon fiber IDEO provided greater positive mechanical work than the commercially-available BR. Although the powered AFO provided some biomechanical benefits, further improvements are warranted to improve patient satisfaction.

P404 - DEVELOPMENT OF BILATERAL ROBOTIC PELVIS ORTHOSIS FOR POST STROKE REHABILITATION

[1] **Nobuo Sakai**, [2]Katsuki Hayashi, [2]Hiroyuki Wakuno, [2]Takafumi Matsuda, [2]Yuki Koba

INTRODUCTION

In Japan, the national populational survey indicated that population composition of seniors more than 65 years reached 27.3% in 2016. Therapeutic robots are expected as the framework for quantitative and intensive rehabilitation [1]. The retrieving of pelvis motion have been one of the principal tasks in a therapeutic menu [2] before moving to the other functional tasks. So, authors constructed the robotic pelvis orthosis. The pelvis motor orthosis was controlled by therapists with control wheel and by the motion of the other pelvis orthosis. Each device was connected the other by bilateral master-slave control (or multi-lateral control within control wheel and two pelvis motor orthosis). In this report, the visualizations of the force and motion are presented, and the potential of the system is discussed.

METHODS

For wearable robots, wearability is one of the compromise problems, because a soft contact to human body sometimes means a deficit of force transmission. In this study, special handling locations, called 'key point' by therapists, were introduced for the contact point to a human body. Then, the motions of the handling were captured and analyzed to seek the rotation axis of the robotic. The motion axis was driven by servomotor with a torque sensor and controlled by a wheel handle with a servomotor. In the clinical setting, force perception by therapists is an important factor to facilitate patient's body. In this study, the control wheel handle and the motor orthosis were connected by bilateral master-slave control, in which therapists can perceive the force of patient. For the control method, disturbance observer and external force observer with load cell were utilized with position, velocity, and force feedback system. Therapist's demand for this system was not the power assistance but the augmentation of the perception. So, the motion of the wheel was enlarged, while the force was assisted. The other input device was the other pelvis orthosis for a therapist, in which therapist can perceive patient's motion via the therapist's robotic orthosis and facilitate patient's motion in a face to face or side by side seating. In this situation, the motions and forces between patiants and therapists were completely captured by bilateral controll system, while a superviser intervention could be available by the handling wheel.

RESULTS AND DISCUSSION

In this paper, we show an example case in which two people wore the robotic orthosis and transmit force and motion via bilateral control. Fig. 1 shows a visualization of motion and force in two persons. The orange and blue line shows the pelvis motion of the master person and slave person. As the functionality of the two robotic orthoses was almost same, the word master and slave is a logical one. A person wearing blue clothes was the master and gray clothes the slave, but both of persons were not a therapist in this case. Measured forces from master and slave device are shown in red and sky-blue lines. By the nature of action and reaction forces, the force lines are shown on opposite sides. At 3 s, a trigger force by the master motion led a reactional force to the slave person. Although it seemed that slave person obeyed the motion of the master person, the force value was apparently small within a value enough to tell each motion. Subjects were perceived motions and forces each other. In this case, the motion profile was comprehensive, but the force profile was very complexed.

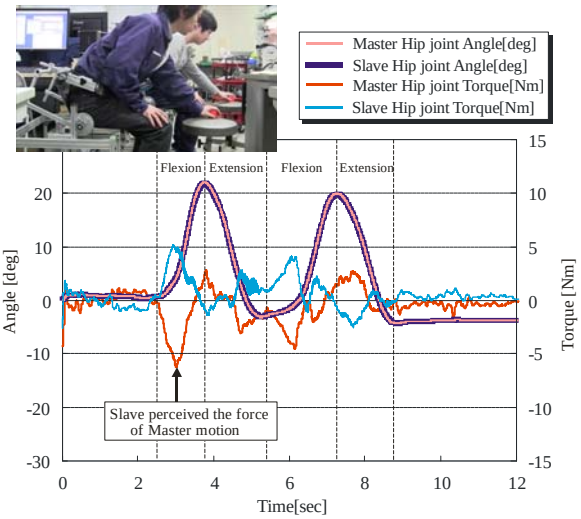

Figure 1: Visualization of force and motion in reach-to-grasp tasks by robotic pelvis orthosis. Two persons wore the robotic pelvis orthoses which were connected by bilateral master-slave control.

CONCLUSION

The bilateral master-slave robotic orthosis system was successfully developed in the current state. The motions and forces between master and slave device were visualized by the control system, which would be available for quantification of the rehabilitation and also useful as a teaching tool. The facilitation technique by therapist will be captured and visualized by the robotic orthosis. In the future, some diagnosis method would be required for our pelvis robotic orthosis system.

P405 - POSSIBILITY OF VOLUNTARY ELBOW FLEXION IN PATIENTS WITH COMPLETE QUADRIPLEGIA WITH C4 CERVICAL CORD INJURY USING HYBRID ASSISTIVE LIMB (HAL®) TECHNOLOGY

[1]**Yukiyo Shimizu**, [2]Hideki Kadone, [3]Shigeki Kubota, [3]Tetsuya Abe, [3]Toru Funayama, [4]Aiki Marushima, [1]Tomoyuki Ueno, [1]Yasushi Hada and [3]Masashi Yamazaki

INTRODUCTION

Patients with complete quadriplegia after high cervical spinal cord injury (SCI) are fully dependent on others in activities of daily living (ADL) [1]. Neurological recovery is rare [2]. The rehabilitation plan should include environmental control systems to compensate for loss of independence in performing ADL. Therefore, the use of assistive technology can improve their quality of life.

The single-joint hybrid assistive limb (HAL®-SJ; Cyberdyne Inc., Japan) was developed for elbow or knee joint motion support. The small power unit on the lateral side of the joint consists of angular sensors and actuators. The primary control system is based on the motion intention and uses the bioelectric signals generated by the patient's muscle activities.

We hypothesized that the HAL-SJ for SCI patients with complete quadriplegia could restore active elbow movement.

METHODS

Participants

Two male patients were enrolled in this study. First was 19 years old and at 3 years 8 months post injury. Second was 75 years old and at 1 month post injury. Clinical evaluation before intervention revealed that both cases were grade A on the American Spinal Injury Association (ASIA) impairment scale (AIS) and ASIA motor score of 0 points.

HAL-SJ intervention

The intervention on each side included 10 sessions. Each session with the HAL-SJ lasted 50 min, including rest, attachment, detachment of the device, and evaluation before and after intervention. The intervention targeted both sides in Case 1, whereas only the left side was targeted in Case 2.

Clinical Assessment

Clinical assessments were conducted before and after the intervention. A Trigno Lab wireless electromyography (EMG) movement sensor system (Delsys, USA) was used to evaluate the muscle activities of the trapezius, biceps brachii, infraspinatus, and triceps brachii muscles before and during the HAL-SJ sessions. The activity of each muscle was evaluated using EMG, which was collected at 2000 Hz and filtered with a 30- to 400-Hz band-pass filter. An activation envelope was computed using a 200-ms moving window average, using scripts on MATLAB 8.2 (Mathworks, USA).

RESULTS AND DISCUSSION

Case 1

Surface EMG before the intervention revealed no voluntary contraction in the bilateral upper arms, but revealed voluntary contraction in the bilateral trapezius. The electrodes for flexion and extension were placed on the right and left trapezius, respectively (Figure 1). Initially, voluntary right elbow flexion with a HAL was performed with motion intention from the right trapezius in accordance with shoulder elevation. Over time, isometric contraction of the trapezius was performed; therefore, only elbow flexion was performed without shoulder elevation.

After the sixth session, EMG of the biceps revealed voluntary contraction. Following which, voluntary right elbow flexion with the HAL-SJ could be performed using the right biceps activities. After the tenth intervention, the patient could contract the right biceps voluntarily; therefore, the intervention on the left side was implemented as well.

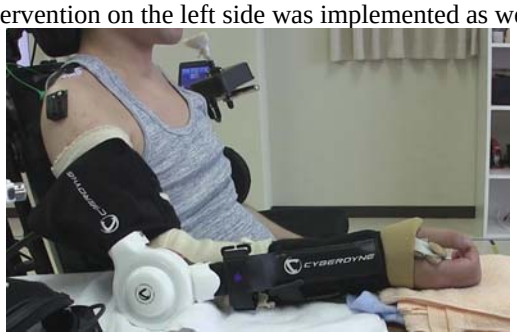

Figure 1: The HAL-SJ using trapezius activities in Case 1.

Case 2

As in Case 1, EMG showed no voluntary contraction in the bilateral upper arms, trapezius activities were also used for elbow flexion at first. After the first session for the left side, voluntary contraction of the left biceps was observed. After the third session on the left side, contraction on both sides of the biceps was detected. From the sixth session, left biceps contraction was used for the flexion of the left elbow.

CONCLUSIONS

In this study, the HAL-SJ was used to produce active elbow flexion in patients with complete quadriplegia, based on the voluntary motion intention detected from the trapezius. Both patients could contract the bilateral biceps voluntarily after the HAL-SJ intervention. Voluntary elbow flexion using HAL-SJ might provide systematic feedback, including motor learning effects.

P406 - CONCEPTUAL DESIGN OF THE 2ND ITERATION OF BART LAB LL-EXO

Peerapat Owatchaiyapong and Jackrit Suthakorn
Center for Biomedical and Robotics Technology
Department of Biomedical Engineering, Faculty of Engineering, Mahidol University Corresponding author email: jackrit.sut@mahidol.ac.th

INTRODUCTION

The patients, who had the spinal cord injury (SCI) at L3, cannot control their lower limb parts. They had to use a wheelchair for moving however the infrastructure in many countries is not support enough for the wheelchair. In addition to the support of wheelchair problems, patients have to spend more time and money to treat them for the pressure sore and joint stiffness. The BART LAB Lower Limb Exoskeleton (BART LAB LL-EXO) was introduced and developed for solving those problems.

The BART LAB LL-EXO is an ongoing project. The 1st iteration was proposed. The robot was developed for group of patients who cannot control their knee and ankle. The patients have to attaching the BART LAB LL-EXO1suit with their leg and operate by swung their hip as normal when they want to walk. However the robot has the limitation, a little bit heavy with only walking function [1]. The BART LAB LL-EXO1 is shown in Figure 1.

Figure 1: BART LAB LL-EXO1 [1]

Moreover, the medical consult and the survey result from group of people such as patient, doctor, physiotherapist, prosthetist and orthoptist [2] show that in many case patients also cannot control their hip and more functions are requested for the daily life.

The 2nd iteration, BART LAB LL-EXO2, was designed to improve the performance and met requests from the survey [2]. The robot consists of 4 functions (walk, turn left/right, sit to stand and stand to sit) and be operated by EEG and EOG signals to serve patients daily life.

Conceptual Design

To improve the robot performance, the limitation of 1st iteration and survey result are concerned and analyzed. The analyzed result shows that the robot function and the active joints are not fit with the real patient condition, SCI at L3 condition is also effect to the hip movement. And also the ranges of motion of each robot joint are not covering the new robot functions. Thus, the BART LAB LL-EXO2 was designed and developed to fit with those new requirements. To fulfill them, the robot will consist of 10 DOFs, 6 DOFs are main active joints with the torque compensation mechanisms to perform walk, sit to stand and stand to sit, 2 DOFs are also active joints without the compensation mechanism to perform the turn movement and the less are passive joints for a body balance. The robot is operated by a user brain signal and eyes movement in term of the EEG and EOG signal, respectively. The conceptual design of the 2nd iteration is shown in Figure 2.

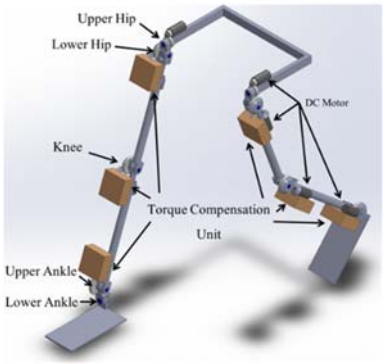

Figure 2: the conceptual design of BART LAB LL-EXO2

CONCLUSION

The robot is re-designed to fit with the new information and survey result and reduce the overall weight of the robot. The robot performance is improved to fit with the patient condition and daily life. Next step the robot will design in detail by the CAD program and build up for testing.

ACKNOWLEDGEMENTS

This project is full-financially supported by the National Research Council of Thailand. The medical consult and leg model are supported by the Sirindhorn School of Prosthetics and Orthotics, Faculty of Medicine Siriraj Hospital, Mahidol University. Authors would like to thank all BART LAB members.

P407 - KINEMATIC AND KINETIC GAIT ANALYSIS USING KINECT AND OPENSIM

[1] **Ryosuke Akaguma,** [1] Masahiro Fujimoto and [1] Akinori Nagano
[1] Ritsumeikan University
Corresponding author email: sh0047fs@ed.ritsumei.ac.jp

INTRODUCTION

Since its release Kinect has shown great promise as a physical function assessment tool. Previous studies have demonstrated the validity and reliability of Kinect for assessing kinematic parameters during gait [1, 2], demonstrating its potential for clinical use. As a decline in muscle function is a key contributor to gait impairment [3], clinical gait assessment should also include quantitative assessment of muscle activities during gait, which requires kinetic gait analysis. However, there are no preceding studies that performed kinetic analysis as well as kinematic analysis using Kinect sensors. OpenSim, open-source software to analyze dynamic movements, can be utilized to perform both kinematic and kinetic gait analysis. The purpose of this study was to construct a framework of kinematic and kinetic analysis of gait using Kinect with the aid of OpenSim.

METHODS

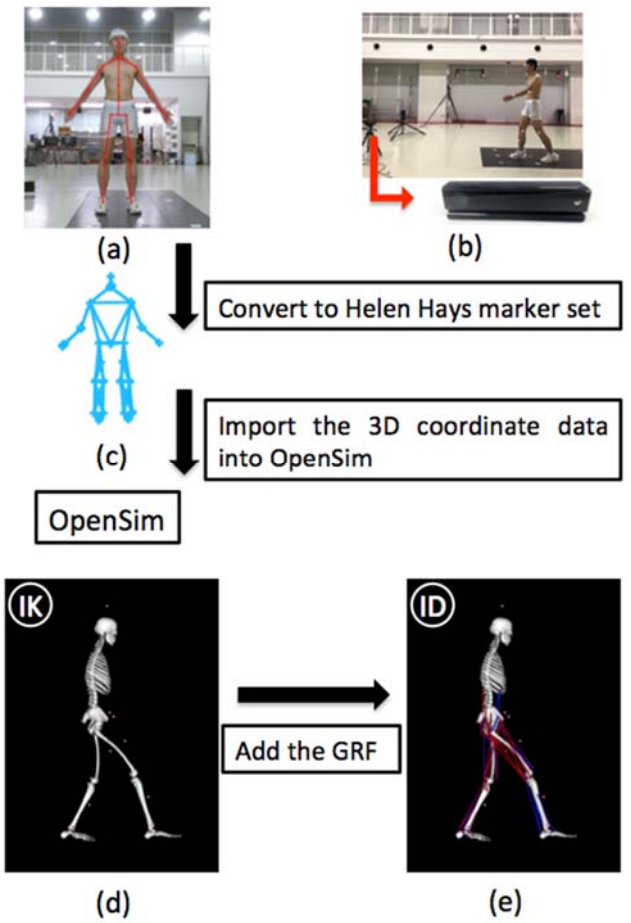

Figure 1: (a) Stick picture and image of the subject obtained with Kinect. (b) Experimental environment: the subject started gait approximately 4m apart from Kinect. (c) Conversion to Helen Hays marker set: The landmarks detected by Kinect were converted into Helen Hayes marker set. (d) Snapshot of IK analysis using OpenSim: The kinematic data from Kinect were imported into the subject's body model. (e) Snapshot of the ID analysis using OpenSim: GRF data were added to the IK analysis data. Muscle color indicates simulated activation from deactivated (blue) to activated (red) level.

Instruments

- Kinect v2 (Microsoft, 30Hz)
- 8 force plates (Tech Gihan TF-4060-B, 750Hz)
- 18 camera optical motion capture system (Motion Analysis MAC3D, 250Hz)
- OpenSim ver. 3.3
- Image Processing Toolbox and Image Acquisition Toolbox in MATLAB

Experimental setups and data analysis framework

1. Participant: One male (Age: 22 years, Height: 177.2 cm, Body mass: 68 kg).
2. Data collection: 3D coordinate data were obtained using Kinect during gait. Ground Reaction Forces (GRFs) were obtained from the force plates.
3. Synchronization: The 3D coordinate data obtained from Kinect and optical motion capture system were time synchronized utilizing cross-correlation of two trajectory data sets of the right knee obtained from Kinect and from the marker attached on the right knee.
4. Conversion to anatomical landmarks in the Helen Hayes marker set: 3D coordinates of the anatomical landmarks in the Helen Hayes maker set were calculated based on the 3D body landmark data obtained from Kinect and the data obtained with anthropometric measurements.
5. Data analysis: Inverse Kinematic (IK) and Inverse dynamic (ID) analyses were performed using OpenSim.

RESULTS AND DISCUSSION

The 3D coordinate body landmark data during gait were obtained from Kinect. The data were then imported into OpenSim and were processed through the IK and ID analysis engine with the framework outlined above in the Methods section, in which lower limb joint torque and power during gait were calculated. The constructed framework allowed us to easily perform kinematic and kinetic analyses in a short period of time. We are currently validating resultant kinematic and kinetic variables by comparing them with those obtained from the optical motion capture system.

CONCLUSIONS

This study constructed a framework for kinematic and kinetic analysis of gait utilizing Kinect and OpenSim. We confirmed that the 3D coordinate body landmark data from Kinect could be imported into OpenSim with this framework. This framework could be utilized to analyze dynamic motions other than gait, including sit-to-stand and turning, which would be useful for clinical assessment. Further work is needed to make the whole process more automated toward even faster and easier implementation of the process.

P408 - TECHNIQUE IMPLEMENTED BY INDIAN CRICKET FAST BOWLERS TO MAXIMIZE BOWLING SPEED

[1]KA Thiagarajan, [1]Tvisha Parikh, [1]Sai Aditya, [1]Anees Sayed, [1]MB Gnanavel, [1]S Arumugam
[1]Sri Ramachandra University
Corresponding author email: drkatn@srassc.in

INTRODUCTION

The success of a fast bowler, in the sport of cricket, is primarily dependent on their ball release speed. A faster ball release speed reduces the reaction time the batsman has to decide and execute the shot, and hence ball release speed can be used as a measure of performance in a fast bowler [1].

The contribution of the fast bowling technique to the ball release speed has been studied in literature. Straighter front knee during front foot contact (FFC) phase [1], larger front foot braking force [1], rapid front foot loading rate [1], shoulder angle at ball release (BR) & FFC [2], run-up speed [2], knee angle at BR [2] and upper trunk flexion between FFC and BR [2] have been identified as technique parameters which contributed to faster ball release speed in previous studies.

The previous biomechanical studies in fast bowlers were however conducted in bowlers from Australia and England. Technical differences which contribute to faster bowling speed have not been studied in fast bowlers from Asia. The aim of this study was to study the contribution of biomechanical parameters to bowling speed in Indian fast bowlers.

METHODS

Twenty five fast bowlers (Age = 21.24 ± 4 years; height = 1.79 ± 0.05 m; body mass = 73.6 ± 8.3 kgs) playing in a state's (Tamil Nadu, India) 1st and 2nd Division cricket league, were selected to take part in this study. 15 technique parameters which have been associated with faster bowling speeds were identified from literature.

The bowlers were required to ball 6 deliveries at a good length while their bowling action was being captured with 16 Vicon (MX-T20s) 3D cameras and the ground reaction force was measured using AMTI force plates. The fastest delivery from each bowler was selected for this study. Forward stepwise linear regression was performed using SPSS software, to identify the key kinematic and kinetic parameters which could predict the ball release speed.

RESULTS AND DISCUSSION

Out of the 15 parameters selected, Plant angle at FFC, Knee flexion at BR, Run-up speed and Maximum knee flexion between FFC and BR were selected by the regression equation to be able to predict 62.6% of variation in the ball release speed (Table 2). Plant angle at FFC was the best individual predictor of ball release speed, explaining 29.8% of variation in ball release speed (Table 2).

Table 1: Regression equations for the ball release speed using stepwise linear regression

# of Parameters	Technique Parameters	Coefficient	P value	Percentage Explained
1	Plant angle at FFC	0.965	0.003	29.8
2	Plant angle at FFC	1.007	0.001	38.3
	Knee flexion at BR	0.084	0.053	
3	Plant angle at FFC	0.619	0.031	54.5
	Knee flexion at BR	0.121	0.004	
	Run-up Speed	6.395	0.007	
4	Plant angle at FFC	0.574	0.028	62.6
	Knee flexion at BR	0.328	0.002	
	Run-up Speed	6.463	0.003	
	Maximum Knee Flexion	-0.266	0.029	

Abbreviations: front foot contact (FFC), ball release (BR)

CONCLUSIONS

The results of this study suggest that a large Plant angle at FFC (front foot is further in front of the pelvis), straighter Knee flexion at BR, higher Run-up speed and lower maximum knee flexion could lead to a faster ball release speed.

Large plant angle was previously associated with a large horizontal impulse, which correlated significantly to faster ball release speed [3]. This study is agreement with previous literature [3], as the plant angle was found to be the best individual predictor of ball release speed. The negative coefficient of Maximum Knee flexion suggests that a bent knee between FFC and BR will lead to a faster ball release speed. This may seem contradictory to what was previously suggested in literature, but a bent knee in conjunction with larger knee flexion at BR suggests that a large knee extension till BR could lead to faster release speed.

This knowledge will be useful for coaches to better train their fast bowlers and in talent identification.

P409 - HIGH INTENSITY FATIGUE PROTOCOL INFLUENCES ON DOMINANT AND NON-DOMINANT KNEE KINEMATICS DURING LANDING TASK

INTRODUCTION

Anterior cruciate ligament (ACL) injury commonly occurs among soccer player due to non-contact movement such as jumping, landing, sudden change of direction combined with deceleration, and pivoting with knee near full extension and planted foot [1]. Greater knee extension and knee abduction angles during landing may alter knee kinematic and lead to ACL injuries[2,3].Fatigue has been speculate as an important factor that further contributes to ACL injury, as it has been lead to altered lower limb mechanics during landing task, especially late in game [4].

This study aimed to investigate the effect of high intensity fatigue protocol (HIFP) on dominant and non-dominant limb knee kinematics during landing task.

METHODS

In a single group repeated measures design, fifteen (n=15) male recreational soccer players were participate in this study (age: 20.93 ± 1.53 yrs; body mass: 64.47 ± 9.69 kg; height: 169.27 ± 5.71cm). Players were required to complete a 5 min HIFP. The simulation was adopted from Bossuyt *et al*. [2] which consisted of multidirectional and utility movements, and repeated acceleration and deceleration as observed in soccer matches. Athletes were assessed prior to the simulation (time 0 min), at immediately after HIFP (time 5min), and immediately after recovery phase (time 15 min), with five (5) drop vertical jump (DVJ). Two dimensional kinematic data were recorded using three digital video cameras set at 30Hz. Heart rate (HR) and rate of perceived exertion (RPE) were observed every 5 min throughout the simulation.

A two-way repeated measures ANOVA with time treated an as independent variable was utilized to identify significant differences at $\alpha = 0.05$

RESULTS AND DISCUSSIONS

Significant different in both dominant and non-dominant knee abduction angles (valgus) only at time 15 min compared to time 0 min (Dominant: time 0=183.99±2.09; time 15 min=155.22±1.69; Non-dominant: time 0= 183.81±2.07; time 20= 154± 1.60; p=0.001, figure1). In contrast, there was no significant different in knee abduction angles immediately post fatigue (time 5 min) and knee extension angles at all times.

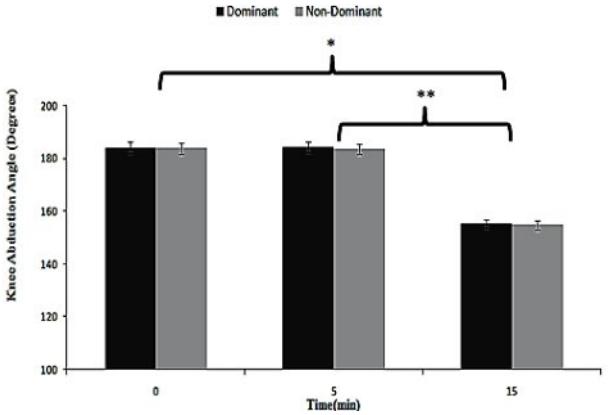

Figure 1. Effects of HIFP on knee abduction angles overtime. *Indicate significant different between time 0 min and time 15 min. ** Indicate significant different between time 5 min and time 15 min.

Although both sagittal and frontal plane knee angle were not affected immediately after fatigue, 15 min of passive rest may influence changes in knee abduction angle, that can cause the ligaments on the lateral side of the knee slack and tightens and may lead to increased risk of ACL injuries[5]. Similarly, more knee valgus lead to increased anterior tibial translation and load on the ACL [6]. Finding indicates knee abduction angles due to fatigue protocols increased over time. These may represent fatigue was main indicator that contributed to alter frontal knee kinematics angles and lead to increased ACL injury risk.

CONCLUSIONS

This study demonstrated that passive half time during rest interval may likelihood to increase the risk of injury especially during the initial stage of the second half. Using a two-dimensional DVJ task assessment with the inclusion of a fatigue protocol is an inexpensive, feasible and reliable injury screening tool to identifying ACL injury risk and return to play assessment among soccer players.

P410 - BETWEEN DAY RELIABILITY OF THE RSSCAN INTERNATIONAL FOOTSCAN®

[1]**Robert G Crowther,** [2]Malindu Fernando, [2]Anthony S. Leicht, [1]Nathan Jones and [1]Jessica M. Pohlmann
[1]University of Southern Queensland

INTRODUCTION

There exists many publications that have used the RSscan International footscan® products for plantar pressure research (1,2,3) and there is some research that has examined the validity and reliability of pressure platforms (4,5). However, the reliability of the RSscan platforms hasn't been thoroughly investigated to date. Given that human movement includes a degree of inherent biological variability, reliability analysis of pressure platforms is required to determine the level of technical variability present. Identification of the technical variability of pressure platforms can ensure high quality research and reduced reporting of Type I errors. Therefore, the aim of the research project was to examine the between-day reliability of the RSscan International footscan® 2m pressure platform.

METHODS

One participant, free of any musculoskeletal injury, performed a three-step strategy (two steps before the platform and a third step on the platform) at a self-selected speed. Initiation of gait was achieved using the dominant foot (right) and 10 trials were performed. The participant attended the laboratory at the same time of day for nine consecutive days. The participant was instructed to walk barefoot across the RSscan International footscan® 2m platform to a target 2 meters beyond the end of the plate.

The footscan® 7 gait 2nd generation software (RSscan International, Belgium) was used to determine mean peak plantar pressure (mpp) and pressure time integral (pti) for the following sites; toes, metatarsals, mid-foot, medial and lateral heel. Additionally, stance period centre of pressure (COP) was calculated and normalized to 100 points (Figure 1).

Reliability was analysed by calculating Intraclass Correlation Coefficients (ICC) with lower and upper limits (90% confidence intervals). Additionally, coefficient of variation (CV) was also calculated for all sites.

RESULTS AND DISCUSSION

There were moderate to high ICC exhibited for mpp for the metatarsals and heel (0.44 – 0.90), with the mid-foot showing very low ICC for both feet (left -0.03 & right 0.13). The pti displayed very low ICC (<0.25) for all sites except the left foot mid-foot (0.42), medial (0.60) and lateral (0.45) heel, metatarsal 3-5 (>0.79) for the left foot and low ICC for all sites on the right foot except for metatarsal 1 (0.54). COP results displayed a small variance between mean and confidence intervals (Figure 1).

The CV for mpp ranged from 16.15% at the medial heel on the left foot to 52.94% for the metatarsal 5 of the left foot. The CV for pti ranged from 19.44% at the left toe 1 to 140% at the left toes 2-5.

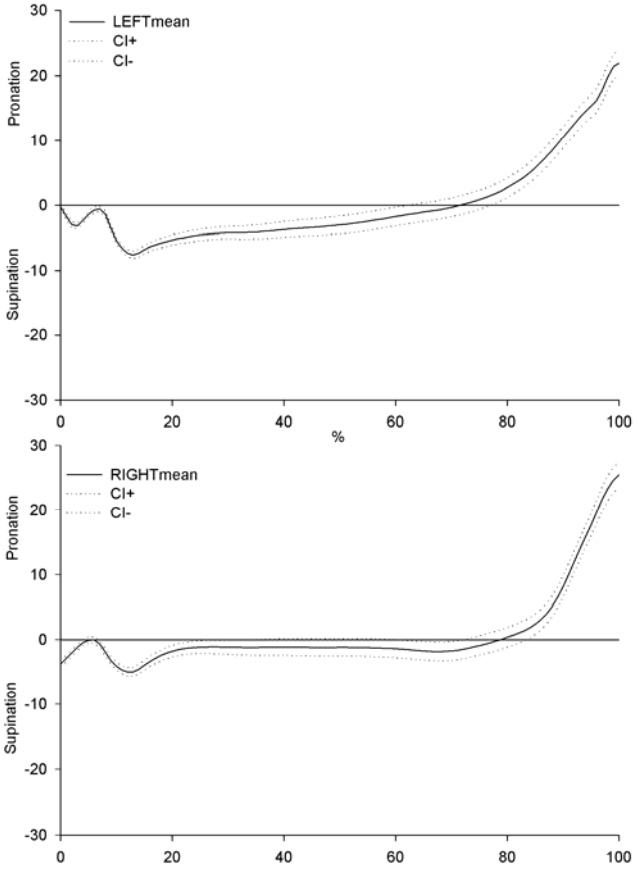

Figure 1: Centre of Pressure mean and 95% confidence intervals for left and right stance phase, plantar pressure.

These results indicated that the mpp was a reliable measure for metatarsals and heel pressures sites however, the pti exhibited poor reliability for most sites, particularly for the right foot. The CV and ICC appears to be comparable with previous research using five trials (5). Future research examining the reliability and validity of data from pressure platforms is urgently needed. Similar to studies of motion analysis systems, identification of 'typical' variability data will assist future studies of plantar pressure platforms to reduce the likelihood of Type I errors.

P411 - THE EFFECT OF AN ELASTICISED HARNESS ON GPS ACCELEROMETER VALIDITY AND RELIABILITY

[1] **Samuel White**, [2] Seaton Humphreys, [2,3] Nicholas O'Dwyer, [3] Robert Robergs, [1,2]Suzi Edwards

INTRODUCTION

To ensure the validity and reliability of variables to quantify sporting movements derived via accelerometers housed within a global positioning system (GPS), both the attachment method and location of the GPS device is of critical importance and specific to each measured outcome variable. Thoracic-mounted triaxial accelerometers embedded within GPS devices have been shown to overestimate acceleration magnitudes [1]. It has previously been postulated that the elasticised harness that fastens the GPS device to the wearer is a major contributor to extraneous acceleration magnitudes recorded by the GPS accelerometer [1,2]. It is unknown whether device moves within the small pocket in the harness and/or the harness moves relative to the skin that cause these extraneous accelerations.

The attachment location of the inertial measurement units are dependent upon the outcome variable it remains unknown if the for its location [3]. With the GPS superior location on the thoracic relative to the locations of the shank or centre of gravity used to estimate ground reaction force and energy expenditure, respectively via accelerometry, it remains unknown if GPS accelerometry is valid to estimate thoracic segment acceleration.

METHODS

Amateur rugby union players (n=17) twice performed five successful linear running tasks per lower limb at three speeds (slow=3.3 m·s^{-1}, medium=5.0 m·s^{-1}, fast=6.7 m·s^{-1}), wearing a SPI HPU device (GPSports). Three dimensional kinetic (1200 Hz, Kistler) and kinematic (300 Hz, Qualysis) data was recorded to estimate the COG (3D-Model-COG), thoracic (3D-Thoracic) and GPS (3D-GPS) peak vertical accelerations during the weight acceptance and propulsion phases. Two Delsys Trigno triaxial accelerometers were attached laterally to the GPS device on the harness (Accel-Harness) and skin (Accel-Skin). Validity was assessed with a repeated measures analysis of variance (p<0.05). Reliability was measured by the change in mean (Δmean; % and g), typical error of measurement (TEM; g), coefficient of variation expressed as a percentage (CV%) and intraclass correlation (ICC).

RESULTS AND DISCUSSION

A significant main effect for type ($F_{2,18}$=73.64, p<0.001) was observed, with interactions between phase*type ($F_{2,18}$=35.36, p<0.001), phase*speed ($F_{2,18}$=13.31, p<0.001;), and type*speed ($F_{4,36}$=8.89, p<0.001; Figure 1). *Post hoc* analysis for phase*type showed that GPSports was significantly increased compared to 3D-Thoracic and 3D-GPS throughout the stance phase (p<0.001) and showed poor reliability to estimate both peak vertical thoracic and COG acceleration when speeds were pooled (0.02 ICC, 19.11 CV%, 71.7% Δmean; 0.22 ICC, 12.68 CV%, 11.9% Δmean, repectively). Analysis of the phase*speed interaction showed that during weight acceptance the slow speed peak vertical acceleration was decreased compared to medium and fast speeds. During propulsion there was no significant differences between variables. The type*speed interaction showed GPSports had a significant increase in peak vertical accelerations across all speeds compared to 3D-Thoracic and 3D-GPS (p<0.001), and that slow speeds were significantly decreased compared to medium and fast for 3D-Thoracic. These findings indicate that vertical acceleration derived via GPS accelerometry is not indicative of vertical thoracic acceleration, and is therefore not representative of its attachment location.

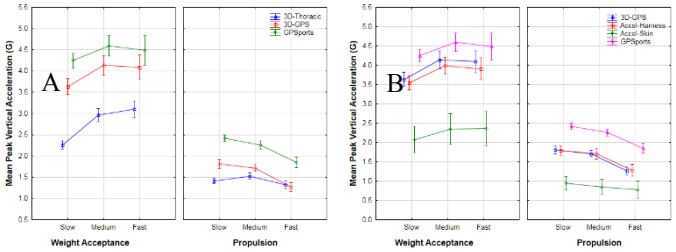

Figure 1: Means ± SD peak acceleration for (A) thoracic and (B) harness movement during stance phase in running.

For the investigation of the effect of the harness on GPS accelerometry a significant main effect for type ($F_{3,27}$=14.21, p<0.001) was observed, with interactions between phase*type ($F_{3,27}$=6.43, p=0.002) and phase*speed ($F_{2,18}$=14.62, p<0.001; Figure 2). *Post hoc* analysis of the phase*type interaction determined that GPSports was significantly higher than all other measured variables at all speeds throughout the stance phase (p<0.05), showing poor reliability when speeds were pooled (0.22 ICC, 12.68 CV%, 11.9% Δmean). Furthermore, Accel-Harness was significantly higher than Accel-Skin throughout the entire stance phase (p<0.001), whereas the 3D-GPS segment was not significantly different to Accel-Harness throughout the stance phase. This suggests that the GPS device does not move within the harness pocket, rather, the elastic properties of the harness causes a movement artefact throughout weight acceptance, leading to extraneous accelerations derived via GPS accelerometry and is major contributor to its poor validity and reliability.

CONCLUSIONS

Caution is advised when utilising GPS triaxial accelerometer data as it is not a valid nor reliable means to estimate peak vertical thoracic acceleration for its thorax location during running. To improve its validity and reliability, development of new attachment method and/or material(s) of the harness is urgently warranted.

P412 - COMPARISON OF THE MOVEMENT AT THE HIP JOINT DURING MAXIMAL INDOOR AND OUTDOOR CYCLING

[1] **Jon Iriberri**, [2]Amar Kumar and [3]Naroa Etxebarria
[1]Custon4us – Basque Country
[2]LNIPE (Lakshmibai National Institute of Physical Education) - India

INTRODUCTION

As wearable technology evolves, lighter and more practical devices are helping understand human kinematics during both clinical[1] and real-world sports performance applications. Advancements in technology has also yielded devices that allow cyclists to exercise without leaving their homes, closely mimicking the physical effort they would endure cycling outdoors on the road. However, it is unclear how the kinematic motion of stationary cycling might differ from cycling on the road and whether the demands places on key joints such as the sacroiliac joint are substantially different.

The aim of the study, therefore, was to quantify differences in the cycling technique adopted by cyclists during maximal effort stationary cycling (indoors) and road cycling (outdoors).

METHODS

Well-trained male cyclists participated in the study (n=16; age 38.0 ± 3.3 y, body mass 74.0 ± 3.6 kg; mean ± SD). The participants had a minimum training history of 5 years and were healthy and injury-free at the time of the study.

Participants were required to complete two 20 min maximal effort time trials (TT) with a wearable Inertial Measurement Unit (IMU) device. One trial was performance indoors and one outdoors using (on both occasions) the participant's own road cycle and after a 2 x 15 min warm up at 50-75% of their maximal 5 min power output. Their maximal 5 min power output was derived from their best 5 min effort during competition in the 90 days leading up to the study. Each individual bike was fitted according to the measurements each cyclist was using during training and these measurements were replicated in both trials. Participants were also asked to wear the same shoes and clothing for both TT.

The indoors 20 min maximal effort was performed on rollers using a validated Racermate computrainer to replicate the same effort completed outdoors. Participants were instructed to give their maximal effort during a 20 min Time Trial (TT). Each participant was fitted with an IMU unit (Letsense, Bologna, Italy) on their sacrum according to the ISIS reference point. Using an IMU, the following movements (°) at the sacroiliac joint were recorded continuously: obliquity (frontal plane), rotation (transverse plane) and tilt (sagittal plane), and rotation (transverse plane).

Descriptive data are shown as mean ± standard deviation (SD) and differences between conditions are reflected as Cohen's standardised effect size with 90% confidence limits (CL).

RESULTS AND DISCUSSION

The relative power output during the maximal 20 min TT for the group was similar; 3.69 ± 0.47 W/Kg (outdoors) and 3.71 ± 0.48 W/Kg (indoors). There was a higher degree of movement while cycling on the road (outdoors) compared to indoors stationary cycling (Figure 1). There was a large difference in obliquity (1.22, ±0.37; standardised difference, ±90% CL) and tilt (1.92 ±0.63) between cycling indoors and outdoors with a moderate difference in rotation (1.12 ±0.37).

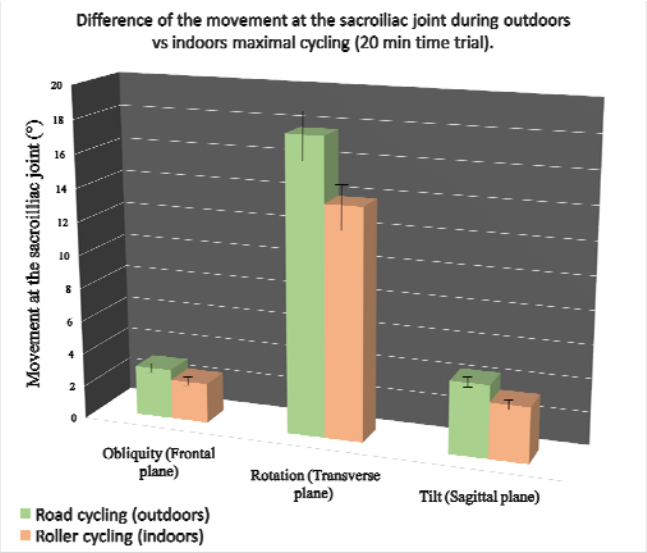

Figure 1: Differences of the movement at the sacroiliac joint during the indoors and outdoors 20 min maximal cycling time trial (TT).

The difference between cycling on the road vs cycling indoors is likely attributable to environmental and topographical factors associated with cycling on the road vs simulating a course indoors. While the physiological effort during both cycling trials is comparable, it seems cycling indoors is unable to mimic all biomechanical aspects involved in road cycling during training or competition. Core strength training might help decrease this difference by improving an athlete's cycling efficiency on the road and avoiding unnecessary and inefficient displacements on the saddle.

CONCLUSIONS

There is a greater movement at the sacroiliac joint when road cycling than cycling on rollers at an equivalent workload, adding to the inefficiency of cycling. Cyclists should consider core strength training to maintain better efficiency when riding outdoors.

P413 - EFFECT OF DYNAMIC LOADING AND UNLOADING PRECEDING STEP INITIATION ON SUBSEQUENT SIDE-STEPPING PERFORMANCE

Masahiro Fujimoto, Eri Uchida, Akinori Nagano and Tadao Isaka
Ritsumeikan University
Corresponding author email: mfujimo@fc.ritsumei.ac.jp

INTRODUCTION

Since movement initiation requires unloading of the stepping leg, the loading condition of the leg would be important for effective movement initiation. Reduced or increased loading of the stepping leg may facilitate or impede faster movement initiation, respectively [1]. Continuous bilateral knee flexion-extension movements as a preparatory motion preceding side-stepping can be utilized to control such loading conditions, where the unloading state has been reported to shorten side-stepping initiation [2]. However, it is still unclear if the loading state would impede faster movement initiation. This study investigated how dynamic loading and unloading of the legs preceding step initiation would affect subsequent side-stepping performance.

METHODS

Sixteen male collegiate basketball players performed a two-choice (left and right) side-stepping reaction task in response to the visual cue (LED) with and without a preparatory movement: prep (P) and no-prep (NP) conditions, respectively. Before the visual cue presentation, the subjects performed continuous bilateral knee flexion-extension movements in the P condition, while they stood still in the NP condition. Ground reaction forces (GRFs) were recorded at 1000Hz by a separate force platform located under each foot (Tech Gihan Co., Ltd., Kyoto, Japan), and kinematic data were obtained with a 16-camera motion capture system (Motion Analysis Corp., Santa Rosa, CA) at 200Hz.

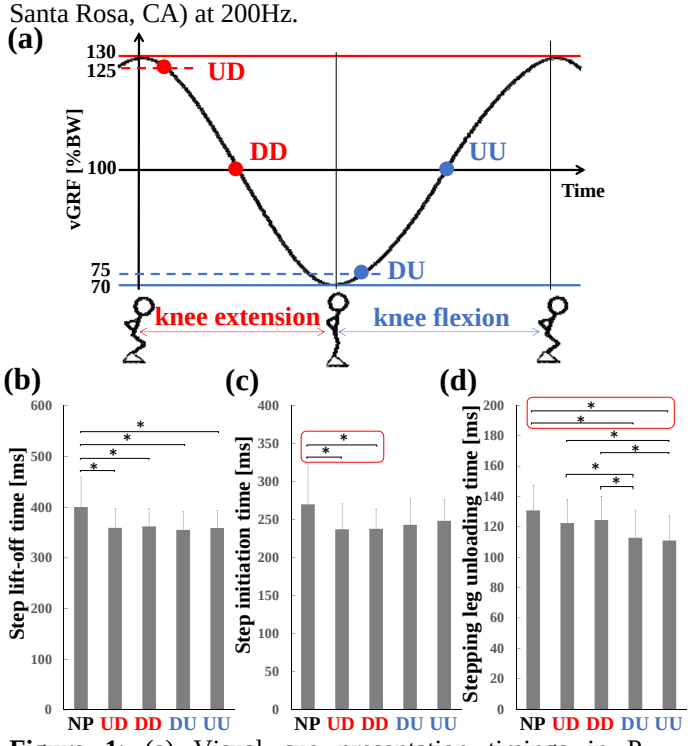

Figure 1: (a) Visual cue presentation timings in P condition, (b) step lift-off time, (c) step initiation time, and (d) stepping leg unloading time. *p<.05.

Real-time visual feedback of the vertical GRF (vGRF) was provided with a monitor behind the LEDs, and the subjects were asked to maintain the vGRF from 70 to 130% of their body weight (BW) in the P condition, while side-stepping task was performed in response to the visual cue provided at the following four timings: when the vGRF first fell below 125% and 100%BW during the knee extension phase (from Up to Down: UD, and Down to Down: DD), and when the vGRF first exceeded 75% and 100%BW during the knee flexion phase (from Down to Up: DU, and Up to Up: UU) (Fig.1a). Step lift-off time, step initiation time, stepping leg unloading time, and step velocity were calculated. One-way repeated measures ANOVA with post-hoc Bonferroni analysis was performed to examine differences between NP, UD, DD, DU, and UU conditions.

RESULTS AND DISCUSSION

Step velocity was significantly greater in all the P conditions than in the NP condition (p<.001). Step lift-off time was significantly shorter in all the P conditions than in the NP condition (p<.05, Fig.1b). These results indicate that the preparatory movement facilitated faster side-stepping regardless of the visual cue presentation timings.

Step initiation time was significantly shorter in the UD and DD than in the NP condition (p<.03, Fig.1c), while stepping leg unloading time was significantly reduced in the DU and UU as compared to the NP condition (p<.01, Fig.1d). These results imply that the significant reduction in the step lift-off time resulted from shortened step initiation in the UD and DD, and from shortened stepping leg unloading time in the DU and UU conditions. Considering that the legs were loaded during the knee extension phase in the UD and DD, while they were unloaded during the knee flexion phase in the DU and UU conditions at the instant of visual cue presentation (Fig.1a), loading and unloading states may facilitate faster step initiation and stepping leg unloading, respectively.

CONCLUSIONS

Both loading and unloading states at the instant of visual cue presentation shortened subsequent step lift-off time, which was respectively attributable to shortened step initiation and shortened stepping leg unloading time. Dynamic loading and unloading of the legs preceding step initiation could facilitate faster step lift-off, resulting from either faster step initiation or faster stepping leg unloading.

P414 - VALIDITY AND RELIABILITY OF A 2D KINEMATICS METHOD FOR MEASURING ATHLETE SYMMETRY DURING THE BMX GATE START

[1] **Josephine Grigg**, [2,3]Eric Haakonssen, [1]Evelyne Rathbone, [1]Robin Orr and [1]Justin Keogh
[1]Bond University
[2]Australian Institute of Sport
[3] Cycling Australia
Corresponding author email: jgrigg@bond.edu.au

INTRODUCTION

BMX Supercross (SX) racing technique has developed from the experiential knowledge of coaches and athletes. Quantitative analysis has been difficult due to the environment in which these races occur. Ecological validity in quantitative biomechanics has been has been shown to be important with field results differing from laboratory results in cycling activities [1].

This study quantifies the validity and intra-tester reliability of a 2D method for calculating sagittal plane kinematics during the BMX SX gate start action that utilises GoPro Hero® 4 Black 120 fps cameras and Kinovea software. This technique was used to analyze the symmetry of the sagittal kinematics of the upper body of elite BMX athletes.

METHODS

All video data were collected during standard training sessions of the BMX Australia High Performance Unit and Development Academy. All athletes were aged 18-25 years and had competed in World Cup events in the 12 months prior to testing. A markerless motion capture technique was employed. Cameras were fixed to the start ramp as shown in Figure 1. Each camera was aligned so that the athlete start position was in the centre third of the frame and the start lights at the base of the ramp were visible. Ten participants each performed 5 maximum effort gate starts. The fastest trial for each participant was analyzed.

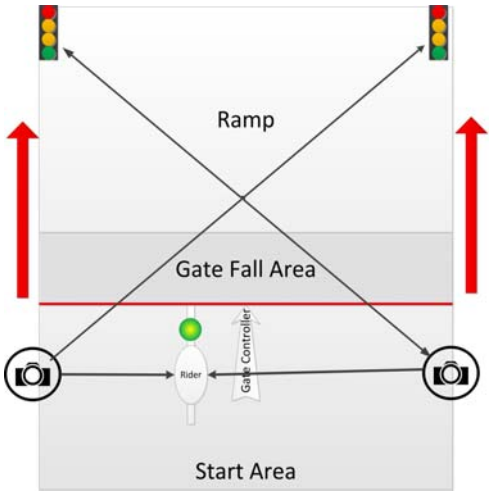

Figure 1: Top view of start ramp and gate with camera and rider.

Kinovea 0.8.15 (Kinovea.org, France) was used to track joint movement through the first 150 frames after the red start light activation. The trajectories were imported into Matlab 2014a (Mathworks, USA) where joint angles were calculated for ankle, knee, hip, shoulder, and elbow and segment angles calculated for the head, trunk and the crank.

To assess validity, the angle of a bike was measured off the track, then calculated using the same markerless motion capture technique. Intra-tester reliability for all measures was performed with 54.8 ± 30.8 (range: 28-106) days between repeated analysis of the same video files.

For two athletes (both at Olympic level), the symmetry between the right and left shoulder, elbow and trunk data were compared.

RESULTS AND DISCUSSION

The method was shown to be valid to within 1.56 ± 0.92°. for all frames. The intra-tester reliability varied across the joints with the absolute error remaining less than 4.8 ± 0.5°. This was considered acceptable given the variation of movement between trials and between riders can be up to 50° (unpublished data) and in consideration of published literature [2, 3].

For both athletes, symmetry of the trunk and shoulder was within bounds of error. For one athlete, the elbow showed significant mean difference between left and right of 7.8 ± 1.1° ($p = 0.01$) across 5 trials. It is suggested that the movement of the torso from side to side of the centre of the bike for each pedal stroke is reflected in asymmetrical elbow angles. The asymmetry pattern observed would support this hypothesis.

CONCLUSIONS

Go Pro Hero 4 Silver cameras can be used to analyse sagittal kinematics for the first ~1.2 s of the BMX gate start action. Upper body sagittal kinematics cannot be assumed to be symmetrical, even in top level athletes.

ACKNOWLEDGEMENTS

The authors wish to acknowledge BMX Australia High Performance Unit Coach Wade Bootes and the BMX Australia High Performance Unit and Development Academy riders for their input and participation.

P415 - THE RELATIONSHIP BETWEEN CORE RELATED MEASUREMENTS AND COUNTERMOVEMENT JUMP WITH AND WITHOU ARM SWING

[1,2]**Liang Guo**, [3]Li Li, and [1]Liangchou Zou
[1]Guang Zhou Sport University
[2]Shanghai University of Sports
[3]Georgia Southern University
Corresponding author email: guoliang0330@163.com

INTRODUCTION

Countermovement jump (CMJ) is a fundamental and frequent skill in many physical activities. Arm swing (AS) is mostly combined with CMJ and can improve CMJ performance significantly. Three theories, including "transmission of force" [1], "pull" [2], and "joint torque augmentation" [3], have been suggested in the literature to explain the effects of AS on CMJ. All three theories claimed that trunk played an important role in transferring energy or maintaining stability for AS to benefit CMJ.

Previous studies have indicated that core stability (CS) is very important during transferring energy and maintaining stability [4]. CS is the ability to control the position and motion of the trunk over the pelvis and leg to allow optimum power production [6]. CS is an important part of elite athletes' training programs.

Therefore, CS plays a crucial role in CMJ with AS. However, inconsistent observation were reported in previous research on the relationship between CS and CMJ performance. Some studies observed the positive results [5], but others disagree. Based on the confounded observations, some researchers suggested that the "specificity" of CS to sport event should be considered [6].

Therefore, we designed 5 core related measures (CRM) based on the previous research [7, 8, 9], which can represent different aspects of CS comprehensively, and aimed to investigate the precise relationship between CS and CMJ height with / without AS.

METHODS

20 active college students were recruited (age: 22.1±0.3 year, body mass: 75.2±3.5 kg, height: 1.72±0.02 m, 7 males and 11 females) from local university. All participants were free from any lower back and lower extremity injuries or disease within the previous year.

Each participant signed informed consent form first, then age, weight, and height were recorded before tests started. CMJ height with AS (H_{AS}) and without AS (H_{NAS}) were calculated from vertical ground reaction force data collected using a force platform (AMTI Corporation, Watertown, MA, USA). CRM included 5 tests: trunk flexion (TF) and extension (TE), where total range of motion (TFE) can be calculated; dominant limb single leg stance time test (DLS); dominant limb single leg hop distance test (DLH); timed sit-up test (SU); and trunk extensor endurance test (EE).

RESULTS AND DISCUSSION

3 CRM (TF, TFE and DLH) were correlated with H_{NAS} significantly ($p < .05$), and 3 CRM (TE, TFE and DLH) were correlated with H_{AS} significantly ($p < .05$), only one CRM (TFE) was correlated with the height differences (D_{AN}) between H_{AS} and H_{NAS} significantly ($p < .05$).

DLH correlated with H_{NAS} significantly, the two variables shared 45.3% variance. DLH correlated with H_{AS} significantly, they shared 46.5% variance. The difference (D_{FE}) between TF and TE correlated significantly with the difference (D_{AN}) between H_{NAS} and H_{AS}, where D_{FE} can predict 34.0% of D_{AN} (Figure 1).

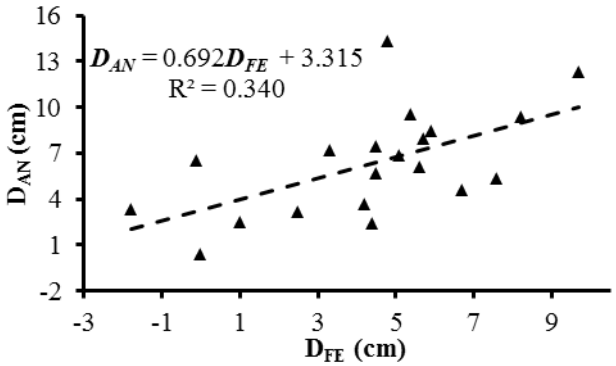

Figure 1: Regression analysis of D_{AN} and D_{FE} (n=20)

CONCLUSIONS

TFE and DLH are specific CS parameters for CMJ. DLH is a good predictor for both H_{NAS} and H_{AS}. D_{FE} is a good predictor for D_{AN}. Greater trunk flexion range of motion, combined with less trunk extension range of motion could be the key to understand how arm swing helps improve counter movement jump height.

P416 - THE EFFECTS OF 45 MIN OVERGROUND SOCCER MATCH-PLAY SIMULATION ON HIP EXTENSION ANGLES DURING ANTICIPATED SIDE-CUTTING TASKS

INTRODUCTION

Anterior Cruciate Ligament (ACL) injury has been a subject of interest in clinical sports biomechanics over the recent years. Fatigue has been proposed to be a confounding risk factor that may increase the likelihood of ACL injury [1, 2, 3, 4]. Recently proposed mechanism of the ACL injury have included hip extension as a confounding factor to the injury [5], suggesting that a more erect landing posture or a more extended hip during landing may increase the chances of the injury to occur.

This study aimed to investigate the effects of simulated soccer match-play on the kinematics of the hip extension angle using two-dimensional biomechanical assessment setting in an attempt to maximize cost-efficiency of a field-based, injury risk assessment procedure.

METHODS

In a single group repeated measures design, eleven (n=11) male recreational soccer players were consented for participation in this study (age: 22.7 ± 4.4 yrs; body mass: 66.5 ± 9.5 kg; height: 1.7 ± .08 m). Players completed a 45 min overground soccer match-play simulation adopted from Raja Azidin *et al*. [4] which consisted of multidirectional and utility movements, and repeated acceleration and deceleration as observed in soccer matches. players were assessed prior to the simulation (time 0 min), at half time (time 45 min), and immediately after half time (time 60 min), with five trials of 45˚ dominant limb side cutting tasks.

Each side-cutting task consisted of an anticipated rapid change in direction at 45˚ with the tested foot on a designated landing area. To reduce inter-trial variability, a trial was only included if the approach speed was between 4-5.0 $m \cdot s^{-1}$ with the foot landing in the designated area. Players had markers positioned at selected bony landmarks to allow angular measurements of the hip form the sagittal plane. Two dimensional kinematic data were recorded using a high-speed video camera recorder sampling at 240Hz.

Heart rate (HR) and rate of perceived exertion (RPE) were observed every 5 min throughout the simulation. A one-way repeated measures ANOVA with time treated an as independent variable was utilized to identify significant differences at $\alpha = 0.05$

RESULTS AND DISCUSSION

Significant differences in hip extension angles was observed over time ($F_{1.9,18.8} = 39.809$; $p = .011$). Pairwise comparisons indicated that hip extension angles increased at time 60 min when compared to pre-exertion (time 0 min). A more extended hip landing posture observed may have implications towards ACL injury risk.

A more extended hip angle may represent dysynchrony in hip and knee flexion which would result in tibial anterior translation, and ultimately ACL failure due to high tension [4, 5]. Similarly, a more erect trunk at initial contact would shift the center of mass (COM) backwards, positioning itself posterior the knee thus causing more knee flexion than hip flexion following the increase of ground reaction force, possibly even promoting greater hip extension. Such combination may contribute to increased anterior shear forces during landing thus increasing load on the ACL [5].

Fatigue from high exertions may have its influence on hip extension angles during initial contact of a landing phase (e. g. side cutting tasks) by altering the movement mechanics [4, 5] thus placing significant load on the ACL [6].

Passive rest during half time might also contribute to the impairment in knee and hip co-flexion harmony. This may be explained as the inefficiency of the joint mechanics to perform optimally, which is possibly a result of reduced muscle temperature due to inactivity during rest period [4].

CONCLUSIONS

Although significant changes have been observed over time in hip extension angles throughout this study, further investigation is still required for more conclusive interpretation as whether or not prolonged exertions induced by simulated soccer match-play may induce greater changes in the hip extension angles is yet to be revealed.

This study may also suggest that a two dimensional ACL injury risk assessment with the inclusion of simulated soccer match-play may be a cost effective and reliable field-based tool in identifying increased ACL injury risk among soccer players.

P417 - INTRA-STROKE ACCELERATION PROFILE OF AN ELITE MID-POINT WHEELCHAIR RUGBY PLAYER

INTRODUCTION

Propulsion techniques in wheelchair rugby (WCR) have received few detailed analyses, particularly the intra-stroke acceleration profiles, with previous investigations focusing on the effect of changing wheelchair design [1]. Inertial measurement units (IMUs) have previously been used to monitor acceleration during the initial stages of propulsion to identify when a stroke had occurred [2]. Further work is warranted for intra-stroke profiling to understand the impact of individual strokes on overall acceleration, and identify crucial variables for improving performance in WCR. Due to the variability in an individual's physical impairment in WCR, propulsion approaches are expected to be highly dependent on their capabilities. Mid-point players (those with a classification score of 1.5–2.5 points), have impaired trunk and arm function. These players perform blocking and ball-handling roles, and hence regular acceleration from standstill and optimisation of initial strokes are crucial to performance [3].

METHOD

An elite, experienced 2.0-point WCR athlete completed six 5m sprints, after providing written informed consent. Synchronised high-speed digital video (120Hz, GoPro Hero 3+) was recorded for left, right and rear views. IMUs (IMeasureU, New Zealand) were secured to the front centre of the chair frame, as well as at each wheel axle to monitor acceleration at 500Hz throughout the sprint. A sharp strike to the front of the frame was performed prior to each trial, preceded and followed by the athlete sitting stationary for 10 seconds. This allowed a clearly visible peak in the acceleration data for all IMUs for calibration and synchronisation with video footage. IMU data was down-sampled to match the video frequency and filtered at 25Hz, well above the recommended 6Hz for daily propulsion [4]. A custom MATLAB (R2016a) script was used to investigate the intra-stroke acceleration based on contact and release points. Key points were identified using the acceleration traces from the IMUs, where spikes in the trace were visible due to the change in acceleration and vibrations evident. Contact and release points were confirmed using the corresponding video frame.

RESULTS AND DISCUSSION

Figure 1 presents an example acceleration trace in the sagittal plane for the first three strokes of the sprint. Vertical lines highlight key points throughout each of the first three strokes, including contact (grey) and release (red) points. For strokes two and three, there is a large acceleration peak in the second half of the stroke. Video analysis confirmed that this corresponds to the region of the stroke after the hand has passed top dead centre (TDC) of the wheel, when the elbow is being extended. This peak occurs as the athlete uses their triceps and is aided by gravity in the direction of the push. This peak is not evident in the first stroke, likely due to the decreased release angle (mean 54°) compared with the second (68°) and third (71°) strokes.

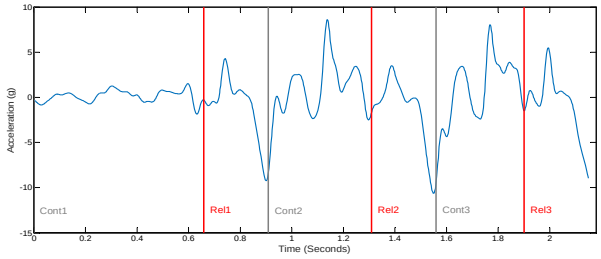

Figure 1: IMU acceleration traces for the first 3 seconds of a sprint for the frame.

During the recovery time (RT – from release to the next contact) the major acting force is the rolling resistance of the chair, evident by the large decelerations during recovery times. Figure 1 also highlights that two key regions of reduced acceleration are evident throughout the stroke (while hand is in contact). The first occurs slightly after contact, corresponding to the player attempting to 'grab' the wheel and causing a momentary reduction in acceleration. The second occurs before the large (primary) acceleration peak that corresponds to elbow extension. This trough occurs as the hand is passing TDC of the wheel, where the elbow flexion is likely to be at a maximum; the amount of force applied at this point is limited and hence the reduced acceleration observed. Reducing these troughs and RT will aid performance.

CONCLUSION

Intra-stroke profiling of an elite mid-point WCR player can be assessed using IMUs and combined digital video analysis. This approach improves on current research standards and develops a greater understanding of the stroke and the corresponding wheelchair behaviour, allowing for improved analysis of propulsion approaches.

P418 - FACTOR STRUCTURE OF ISOKINETIC LOWER EXREMITY TESTS AND SPRINT, JUMP EVENTS IN ATHLETIC

[1] Ian Heazlewood
[1]Charles Darwin University
Corresponding author email: ian.heazlewood@cdu.edu.au

INTRODUCTION

Factor analysis is a multivariate statistical approach that attempts to identify underlying constructs or factors that explain the correlations among set of variables which represent factors and these can be performance and motor fitness factors that underpin specific sports events. Factor analysis tests hypotheses concerning the structure of measured variables representing more global constructs such as multiple measures of strength represent some underpinning construct of strength. The method can summarise a large number of variables with a reduced set of derived variables or factors, such as reducing the ten events in the decathlon into five underpinning factors [1]. Finally, can determine the number of dimensions factors required to represent a set of directly measures variables.

Surprisingly few studies have applied factor analysis to understand the conceptual structure between athletic/track and field events and laboratory measures of strength, torque, work, power that are thought to be correlated with different athletic events. An important question as do laboratory derived scores that measure torque, work, power and torque acceleration energy (TAE) interact with the factor structure of track and field events, such as the sprints and jumps or stretch shortening cycle-power events can be answered by utlising this multivariate statistical methodology? The research aim was to evaluate the factor structure of sprint (100m and 400m) and jump (long jump and high jump) events with isokinetic testing of lower extremity isokinetic performance in generating torque, work, power, torque acceleration energy across three isokinetic speeds of $60^{o}s^{-1}$, $180^{o}s^{-1}$, and $300^{o}s^{-1}$.

METHODS

The research was approved by a university research ethics committee. The sample consisted of 56 young adults (25 males and 31 females) who volunteered for the study. The sample was pooled and the age range was 18 to 26 years (mean 19.23 years, S.D. =1.67 years). The poled data represented a normal distribution for the measured variables and meeting this assumption for factor analysis, as well as increasing the sample size for analysis rather than analysis based on single gender. Ability levels ranged from the national to the average club competitor.

The performances in the sprint events of 100m and 400m were timed in competition at the completion of three months training to the nearest 0.01 second as were the long jump and high jump performances which were recorded to the nearest centimeter on a surveyed athletic track under IAAF competition and officiating criteria. Isokinetic dynamometry was evaluated in a university exercise and sport science laboratory to assess torque work, power and TAE and secondary derived measures of torque/weight and power/weight were derived. The CYBEX-HUMAC NORM extremity testing and rehabilitation system was used for isokinetic testing and calibrated according to manufacture criteria. All participants performed extension/flexion movements of the preferred lower leg and were instructed to perform maximally following a warm-up sequence with each isokinetic speed. The settings for each participant complied with manufacturer guidelines for testing leg extension/flexion. The sequence is as follows for leg extension/flexion. Gravity correction was selected during the isokinetic testing.

Warm up X 4 reps at $60^{o}s^{-1}$ then test X 4 reps at $60^{o}s^{-1}$
Warm up X 4 reps at $180^{o}s^{-1}$ then test X 4 reps at $180^{o}s^{-1}$
Warm up X 4 reps at $300^{o}s^{-1}$ then test X 30 reps at $300^{o}s^{-}$

RESULTS AND DISCUSSION

The initial correlation matrix evaluating the bivariate correlations between all measured variables and the initial starting point to assess if factor analysis is applicable indicated significant correlations between all variables, as well as the correlation matrix is used to derive the factor solutions. Many correlations were r = 0.70 to 0.98. The factor analysis conducted was a principle component with different rotation solutions generated such as varimax, promax and direct oblimin. The total variance explained was 84.22% and derived a four factor solution where factor 1 was 40.5%, factor 2 was 30.3%, factor 3 was 6.98% and factor 4 was 6.37%.

The simplest factor structure was the initial principle component solution with no rotations. All the athletic events of 100m (-.725), 400m (-.734), long jump (.860) and high jump (.853) loaded on factor one with peak torque extension/flexion $60^{o}s^{-1}$, $180^{o}s^{-1}$ and $300^{o}s^{-}1$ where factor loadings ranged from .731 to .946; work extension/flexion at $60^{o}s^{-1}$, $180^{o}s^{-1}$ and $300^{o}s^{-1}$ where factor loadings ranged from .868 to .950; power/weight ratio for extension/flexion $60^{o}s^{-1}$, $180^{o}s^{-1}$ and $300^{o}s^{-1}$. TAE displayed some interesting loadings where TAE for extension/flexion $300^{o}s^{-1}$ factor loadings .832 and .800 respectively, whereas TAE for $60^{o}s^{-1}$, $180^{o}s^{-1}$ loaded across factor 2 and factor 3. Variables loadings on factor 4 were negligible.

CONCLUSIONS

Based on the results factor 4 did not represent any variables and the factor model was reduced to a three factor model by the research which accounted for 80% of the variance and the original factor loadings on factors 1, 2 and 3. The implication of these results are maximal effort performance to generate torque, work and power as well as relative torque and power on isokinetic testing of leg extension/flexion in male and female athletes (pooled data model) at $60^{o}s^{-1}$, $180^{o}s^{-1}$ and $300^{o}s^{-1}$ is measuring a similar underpinning factor that enable athletes to perform in the 100m, 400m lung, jump and high jump.

P419 - MULTIPLE MOTOR FITNESS PREDICTORS OF KARATE PUNCH POWER, PUNCH SPEED AND PUNCH RESPONSE TIME

[1] **Hovik Keshishian** and [1]Ian Heazlewood
[1]Charles Darwin University
Corresponding author email: ian.heazlewood@cdu.edu.au

INTRODUCTION

Karate punching is an integral component of successful karate completion performance in terms of reverse punch power, punch speed and punch response time [1] comparison of male elite and sub-elite karate athletes indicated punch power and punch speed that were important discriminators between these ability levels [2] and elite athletes showing significantly higher levels of reverse punch power, punch speed when compared with sub-elite athletes and no significant difference in punch response time between these groups following fatigue induced by sparring in male karate athletes [3]. Straight punch force of impact was evaluated in adult non-martial arts participants and was predicted using multiple regression analysis to be predicted by hand speed and one repetition maximum (1RM) on a cable push exercise with dominant arm which indicated a significant predictive explained variance of 63.4% [4]. however, the number of research studies attempting to predict punch power, punch speed and punch response time at this point in time from other motor fitness factors is minimal. The aim of this research was to include a larger number of explanatory variables based on general motor and karate specific variables to predict factors associated with punch, power punch speed and punch response time utlising multiple linear regression modelling.

METHODS

Research ethics approval was granted by a university research ethics committee compliant with National Statement on Ethical Conduct in Human Research (2007) Participants were twenty four young adult male karate athletes where 12 were classified as high performance athletes with black belt or higher (n = 12; age, 33.0 ± 3.5 y; stature, 179 ± 8 cm; body mass, 76.3 ± 8.7 kg) and 12 were classified as non-high performance athletes practicing karate for less than one year and held a green belt black belt (n = 12; age, 30.0 ± 12.6 y; stature, 176 ± 10 cm; body mass, 76.6 ± 19.5 kg). The data were collected in a university exercise physiology laboratory with constant temperature.

The general motor ability tests were selected to represent a cross-section of recognised human motor abilities and were height, weight, age; motor fitness variables of Margaria-Kalamen power test, standing long jump, isometric grip strength, sit-reach flexibility, arm crank, peak aerobic power, anaerobic Wingate power test for peak power, time to peak power, mean power and power/weight. Karate specific motor fitness tests were selected based on consultation with expert karate instructors that reflect karate motor ability and were karate agility, reverse power punch, reverse speed punch, reverse punch response time, balance and lower limb bilateral flexibility. Correlation matrices were derived to initially identify significant bivariate relationships between all variables and assess the relevance of multiple linear regression. Based on initial significant correlations identified multiple linear regression was applied to derive a series of predictive equations for the dependent variables of punch power, punch speed and punch response time. The other general motor fitness and karate specific variables served as the independent or predictor variables in the derived regression equation. Two multiple linear regression methods were applied, which were, enter method where user defined variables are entered in the model and stepwise method where statistical decisions are made at each step of entry to assess if a variable contributes significant explained variance to the explanatory equation.

RESULTS AND DISCUSSION

Punch power was significantly correlated with Margaria-Kalamen test (r=.498; p=.013), balance (r=.415; p=.044), arm crank (r=.494; p=.014) and mean power Wingate anaerobic cycle ergometer (r=.593; p=.003). Punch speed was significantly correlated with Margaria-Kalamen test (r=-.565; p=.004), balance (r=-.424; p=.039), arm crank (r=-.530; p=.014), peak power Wingate anaerobic cycle ergometer (r=-.577; p=.007) and mean power Wingate anaerobic cycle ergometer (r=.599; p=.003). Punch response time was significantly correlated with Margaria-Kalamen (r=-.523; p=.009), karate agility (r=.548. p=.006) and strength (r=-.413; p=.045).

Stepwise regression equations were:

1. Punch Power = .067(mean power) + 2.45(balance) + 22.54, R^2=.486.
2. Punch Speed = -.002(mean power) + 1.35, R^2=.359.
3. Punch response time = .009(karate agility test) + .16, R^2=.300.

Each punch construct was predicted by a different set of motor fitness factors. Stepwise analysis indicated common variance among many predictor variables as they were excluded.

CONCLUSIONS

Both punch power and punch speed were surprisingly predicted by anaerobic leg power tests with balance added to punch power equation. Punch response time was only predicted by karate agility. These findings suggest that complimentary training in addition to the primary task as power and speed punching, as identified by regression equations should be considered as these previously non-identified fitness factors influence karate punching ability.

P420 - PHYSIOLOGICAL, KINEMATIC AND ELECTROMYOGRAPHIC RESPONSES TO PATELLA TAPING IN ELITE CYCLISTS

[1,2] **Kim Hébert-Losier**, [2] Ngieng Siew Yin and [3] Jim Richards
[1] Faculty of Health, Sport and Human Performance, University of Waikato
[2] Department of Sports Science, National Sports Institute of Malaysia
[3] Allied Health Research Unit, University of Central Lancashire

INTRODUCTION

Over the last decade, the use of Kinesiology-Type Tape (KTT) has become increasingly popular in sports for injury prevention, injury management and performance enhancement. Many cyclists use patella KTT; however, the benefits of such interventions remain unclear, especially in uninjured elite cyclists. We aimed to determine the acute physiological, kinematic and electromyographic (EMG) responses to applying patella KTT in elite cyclists.

METHODS

Twelve elite male cyclists with no current or recent (< 1 month) injury completed the experimental protocol. All cyclists had at least four years of training experience and competed nationally. Cyclists performed 4-min submaximal cycling trials at 100 and 200 W on a Lode ergometer set-up to mimic their individual road cycling positions. Trials were carried out in a randomized order with and without patella KTT separated by 5-min passive recovery.

Physiological measurements were monitored using the K5 wearable metabolic technology wireless system (COSMED, Rome, Italy) and Polar® heart rate monitor (Polar Electro, Kempele, Finland). Cycling economy, energy cost, oxygen cost, and heart rate measures were taken over the last minute when steady state was assumed. Kinematics and EMG signals were also collected over the last minute using an infrared camera system (Qualisys AB, Gothenburg, Sweden) and wireless EMG sensors (Noraxon USA Inc., Scottsdale, AZ). Following all trials, each cyclist rated their perceived comfort levels and change in knee stability and cycling performance with KTT.

RESULTS AND DISCUSSION

Patella KTT had non-significant trivial effects on all collected physiological parameters. The effects of KTT on range of motion values of the ankle, knee, hip, pelvis, and trunk were non-significant and mostly trivial; except for a subset of small non-significant effects observed at the ankle and knee at 100 W, and at the knee, pelvis and trunk at 200 W (see **Table 1**).

Patella KTT significantly and meaningfully increased peak, mean, and integrated EMG signals from *vastus medialis*, and altered the *vastus medialis* to *vastus lateralis* activation ratio. Peak, mean, and integrated EMG signals from *biceps femoris* and *rectus femoris* also generally decreased; with changes indicating an increased *biceps femoris* to *rectus femoris* ratio. Changes in EMG signals with patella KTT were more pronounced at the lower power.

Most cyclists perceived KTT as comfortable (n = 7, 58%), providing additional knee stability (n = 10, 83%), and improving cycling performance (n = 11, 92%). Perceptions were not always well matched with individual responses.

CONCLUSIONS

Despite most cyclists perceiving an increased performance and knee stability with patella KTT; the intervention had no significant or meaningful impact on the physiological parameters and knee kinematic measures investigated. However, patella KTT did appear to stabilize the proximal segments and impact EMG signals, notably decreasing pelvis and trunk range of motion, increasing *vastus medialis* signals and recruitment in relation to *vastus lateralis*, and increasing *biceps femoris* recruitment in relation to *rectus femoris*. Hence, KTT has the potential to alter the neuromuscular recruitment patterns of elite cyclists, which could have implications for injury prevention, especially the development of patella femoral pain. The persistence of the neuromuscular changes seen has not yet been established, and the ability of patella KTT to directly enhance elite cycling performance is most likely trivial. The range of responses to KTT seen here implies the presence of positive responders, negative responders, and non-responders; however, perceptions were not able to clearly delineate cyclists into these subgroups.

ACKNOWLEDGEMENTS

We thank Dr Christopher Martyn Beaven, Dr Yeo Wee Kian, Mohd Izham Bin Mohamad, Chris Tee, all participating cyclists, Qualisys AB, and the National Sports Institute of Malaysia for their support.

P421 - RELATIONSHIP BETWEEN TRUNK ANGULAR KINEMATICS AND CLUB HEAD SPEED IN GOLFERS USING DIFFERENT WEIGHT TRANSFER STRATEGIES

[1] **Youka Izumoto**, [1] Toshiyuki Kurihara, and [1] Tadao Isaka
[1] Ritsumeikan University
Corresponding author email: sh0025sh@ed. ritsumei.ac.jp

INTRODUCTION

Golfers need a faster club head speed (CHS) to increase driving distance [1]. It is well known that the weight transfer strategies during golf swing can be categorized into two types in professional golfers, defined as "Front foot style" (Ff) and "Reverse style" (Rv) [2]. In the Ff, the center of pressure (COP) is positioned at the front foot side relative to the whole body center of mass (COM) at the ball impact. In the Rv, the COP is positioned at the rear foot side relative to the COM at the ball impact. Since trunk motion during golf swing is related to CHS [3], the Ff and Rv golfers would use different trunk motion strategies to get higher CHS. However, it is unclear whether there are differences in the trunk kinematics between the Ff and Rv golfers. The purpose of this study was to investigate the relationship between the trunk motion and CHS in golfers using two different weight transfer strategies.

METHODS

Thirty-eight collegiate skilled golfers participated in this study. There were 19 golfers with the Ff strategy (Ff group), and 19 golfers with the Rv strategy (Reverse group). The subjects completed 10 driver shots with maximum effort. Whole body and club head kinematics were obtained using three-dimensional motion capture system at 250 Hz. Maximum angular velocity of the thorax and pelvis, maximum angular velocity in the axial rotation of the thorax relative to the pelvis, and CHS were calculated. Pearson's product-moment correlation coefficients were calculated to examine the relationship between the trunk angular velocity and CHS. The significant level was set at 0.05 %.

RESULTS AND DISCUSSION

There was no significant difference in the CHS between the Ff and Rv group golfers. Significant differences were not found in all the trunk kinematic parameters between two subject groups (Table 1a). These results suggest that there were no differences in both trunk motion and the CHS between the Ff and Rv golfers.

For the Ff group, maximum angular velocity of the thorax and pelvis were significantly correlated with the CHS except maximum angular velocity in anterior-posterior tilt and axial rotation of the pelvis (Table 1b). These results were in agreement with the previous studies [3, 4]. Horan et al. [3] and Joyce et al. [4] reported that the higher CHS was achieved by an increase in the angular velocity of the thorax and pelvis. Therefore, the Ff golfers use thorax and pelvis motion in order to promote greater CHS.

In contrast, for the Rv group, Significant correlations were not found in each the trunk kinematic parameter and the CHS. These results suggest that there is no relationship between the trunk motion and the CHS in Rv golfers. Kwon et al. [5] suggested that some trunk kinematic parameters were not directly related to the CHS. Therefore, the Rv golfers use swing strategies in which a different from the Ff golfers to promote greater CHS.

Table 1;
a) Summary of club head speed and maximum trunk angular velocity of the Front foot style and Reverse style group at the ball impact (Mean ± SD).

		Front foot style	Reverse style	*p*
Club head speed [m/s]		41.9 ± 4.7	42.4 ± 4.4	n.s.
Lateral tilt [deg/s]	Thorax	33.5 ± 29.4	18.3 ± 25.4	n.s.
	Pelvis	50.6 ± 74.7	60.8 ± 52.1	n.s.
Anterior-posterior tilt [deg/s]	Thorax	108.7 ± 64.9	94.8 ± 49.7	n.s.
	Pelvis	142.8 ± 35.9	153.5 ± 40.4	n.s.
Axial rotation [deg/s]	Thorax	676.8 ± 59.3	695.8 ± 53.8	n.s.
	Pelvis	501.9 ± 66.4	531.6 ± 77.5	n.s.
	Thorax-Pelvis	303.8 ± 78.7	304.4 ± 57.9	n.s.

b) Correlation coefficient between maximum trunk angular velocity and club head speed of the Front foot style and Reverse style group (*: $p < 0.05$, **: $p < 0.01$).

		Front foot style	Reverse style
Lateral tilt	Thorax	**0.65****	- 0.14
	Pelvis	**0.48***	0.25
Anterior-posterior tilt	Thorax	**0.59****	0.04
	Pelvis	- 0.04	0.04
Axial rotation	Thorax	**0.54***	- 0.06
	Pelvis	0.29	0.04
	Thorax-Pelvis	**0.53***	0.03

CONCLUSIONS

The absolute values of CHS and the maximum trunk angular velocity did not differ between the Ff and Rv group. There were significant correlations between trunk angular velocity and the CHS in the Ff group, while no significant correlation was found in each trunk kinematic parameters and the CHS in the Rv group. These results suggest that the Ff golfers use the thorax and pelvis motion to promote greater CHS, and the Rv golfers would use other body segment motion to promote greater CHS.

P422 - RELIABILITY OF KINETIC MEASURES FROM LUNGE MOVEMENTS – COMPARISON OF DOMINANT AND NON-DOMINANT SIDE FORWARD LUNGES

[1,2]Morten H. Nielsen, [2]Wing-Kai Lam, [1,2]Jan N. Lund, [1]Uwe G. Kersting
[1]SMI, Aalborg University, [2]LiNing Sports Science Center, [3]Shenyang Sports Institute

INTRODUCTION

Badminton is played by more than 200 million people worldwide. Players have to perform various jumps, directional changes, and lunges. The lunge is one of the most frequently executed footwork skills in badminton as it accounts for approximately 15% of the total number of movements in a single match (Kuntze et al., 2010). Biomechanical investigations of the lunge movement in a badminton context are sparse, indicating that the establishment of reliability measures should be pursued.

The primary objective of this study was to determine the number of trials required to represent performance regarding ground reaction forces and joint moments by extracting intra-class correlations (ICC) and sequential averaging analysis (SAA) for dominant and non-dominant forward lunges, respectively. The secondary objective was to examine if the players would experience higher ground reaction forces and lower extremity loading on their non-dominant side.

METHODS

Fourteen male university badminton players (26.4 +/- 5.5 years, 69.8 +/- 9.2 kg, 1.75 +/- 0.05 m, experience = 5.5 +/- 3.7 years) were recruited for the study. All participants were right-dominant and free of any lower extremity injuries. Participants signed informed consent prior to data acquisition.

All lunge trials were conducted on a standard badminton court surface (Li-Ning, CP55 Premium Court Mat, Beijing, China), with two embedded force platforms (0.9 x 0.9 m, Advanced Mechanical Technology Inc., Watertown, USA) with sampling at 1,000 Hz. Reflective markers were firmly placed over the left and right legs and pelvis. Six triad markers were attached to the shoe heel counter, tibia and femur to define shoe, shank, and thigh segments. Marker trajectories were recorded using a twelve-camera motion analysis system (Vicon, Oxford Metrics, UK) sampling at 200 Hz. A shuttlecock was suspended 0.60 m above the ground, at a distance of 0.60 m from the center of the force platform. Twenty successful trials to either side were recorded following preparation and standard warm-up.

Data were low-pass filtered at 10 Hz, spline interpolated and inverse dynamics were obtained through processing in the AnyBody Modeling System (AnyBody Technology A/S, Aalborg, Denmark). Five GRF variables and nine joint moment variables were extracted. For GRF variables, initial impact peak (G_A), secondary impact peak (G_B), amortization (G_C) and weight acceptance (G_D) were selected (Kuntze et al., 2010). Additionally, the total impulse during the lunge contact period (G_{IMP}) was calculated. Peak sagittal, coronal and transverse hip, knee and ankle moments were extracted.
ICC and SAA were used to estimate the number of trials required to obtain good reliability (ICC>0.75; SAA: subsequent moving average within 0.25 * SD of the mean of all trials; Hamill & McNiven, 1990) for all variables extracted. A paired *t*-test was employed to assess differences between the dominant and non-dominant sides (P<0.05).

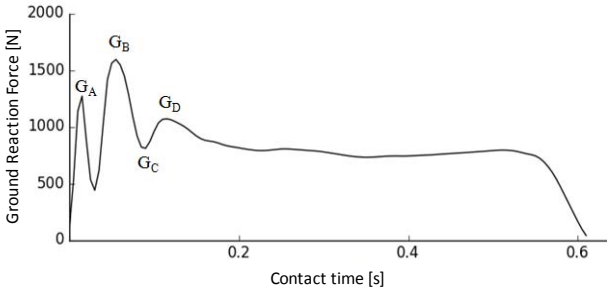

Figure 1: Variables extracted from ground reaction force.

RESULTS AND DISCUSSION

Based on the ICC analysis, the averaged minimum number of trials for all 14 kinetic variables varied between 7.9 and 8.0, for the dominant and non-dominant sides, respectively. Using the SAA approach, the averaged minimum number of trials was slightly higher, i.e., 10.3 and 9.5, indicating that dominant and non-dominant side lunge tests are comparable in regard to requirements for reliable testing. However, the range of scores across the difference variables was substantially larger for the ICC-based estimation. These results may imply concerns in regard to the results from previous studies where only five trials were used (Hong et al., 2013; Kuntze et al., 2010; Lam et al., 2016) while this information will be important for future studies to assess the effect of interventions, such as footwear or training on lunge biomechanics.

In comparison of the dominant side, lunging to the non-dominant side lead to increased transverse plane moments and G_{IMP} but reduced frontal plane moments which may indicate a more controlled and therefore safer execution on the dominant side.

CONCLUSIONS

The minimum number of trials needed to provide reliable results for the assessment of lunge biomechanics was 8 – 10. The information provided in this study will serve researchers and coaches as a basis for future studies on equipment interventions and training programmes. The data may serve as a reference for studies on injury prevention in badminton.

P423 - FEASIBILITY OF A TRAINING EXERCISE PROTOCOL FOR THE FOOT AND ANKLE OF LONG DISTANCE RUNNERS

[1]**Alessandra B. Matias**, [1]Ulisses T. Taddei, [1]Rafael Inoue, [1]Fernanda Iacovanduano, [1]Isabel C. N. Sacco

INTRODUCTION

The foot and ankle complex is long known for its capability of shock absorbance, terrain adaptation, bodyweight support, and contribution on propulsion during walking and running in healthy conditions. Evidences shows that when the intrinsic foot muscles are weak or dysfunctional, all roles previously described might be compromised increasing loads carried by other passive structures, such as the plantar fascia, promoting excessive pronation and compromising several activities performance and increasing incidence of foot deformities [1,2]. Our main goal was to examine the feasibility of a randomized controlled trial for injury prevention of long-distance runners using therapeutic exercises focused on the foot-ankle complex. The secondary outcomes were to verify the foot health and functionality status and the biomechanical changes during running that denoted an improvement in the mechanical efficiency of absorbing loads and propelling the body while running after the exercises.

METHODS

Four healthy long-distance runners (31,8 ± 2,5 years) with at least one year of running experience and weekly running distance more than 20 km and less than 100km were randomized to one of two groups: the Intervention group (IG) participated in an 8-weeks foot muscles training program while the control group (CG) performed a placebo stretching protocol. Runners also had to practice 8-exercises remotely-supervised at their home 3-times/wk for the whole duration of the follow-up (16-weeks) by accessing a web-software developed. Among the secondary outcomes of the RCT, this feasibility study assessed the foot health status by the Foot Health Status Questionnaire [3], foot-ankle kinematics (IOR foot model) [4] and ground reaction force during running. The runners were assessed at baseline, after 8-wks of intervention and after 16-wks of baseline. All participants had to enter their weekly training volume, exercise protocol performance data and injury occurrence once a week in a web-software developed. Comparisons among T0, T8 and T16 was done by 2-way ANOVA(2x3).

RESULTS AND DISCUSSION

There was no significant difference between T0, T8 and T16 in both groups for the angle of the second metatarsal bone to the ground nor the angle of the fifth metatarsal bone to the ground during mid-stance phase ($p>0.05$). The angle of the first metatarsal to the ground was lower in T8 than T16 ($p<0.05$) only for the IG. Angle between the first and the second metatarsal did not change in the IG while for the CG it was higher in T0 than T8 ($p<0.05$). The angle between the second and fifth metatarsal was significantly lower in T16 than in T0 ($p<0.05$) for IG, while in the CG, T8 was lower than T0 ($p<0.05$) and T16 ($p<0.05$). Angle of the ankle at first contact showed no differences between T0, T8 or T16 for IG ($p>0.05$) while for CG, this variable was significantly lower between T16 and both T0 and T8 ($p<0.05$). There was no difference in maximum ankle flexion between T0, T8 or T16 for IG ($p<0.05$) while for CG, this variable in T16 was significantly lower than in T0 and T8 ($p<0.05$). Maximum calcaneal eversion was significantly lower in T16 than in T0 for the IG ($p<0.05$). No differences were observed in the CG for this last variable ($p>0.05$). Medial longitudinal arch angle was significantly higher in T0 than in T8 ($p<0.05$) and T16 ($p<0.05$) for IG while for the CG, T0 was significantly lower than T16 ($p<0.05$). Ankle extensor peak power, ankle extensor moment, first and second peak of vertical ground reaction force, push off rate, loading rate between 20 to 80% and between 0 to 100% of the stance phase did not show significant differences between T0, T8 and T16 ($p>0.05$). Maximum ankle extension in T8 was significantly higher than in T0 for the IG ($p<0.05$). No differences were observed in the CG for this variable ($p>0.05$).Ankle range of motion in T16 was significantly lower than T0 ($p<0.05$) and T8 ($p<0.05$) for the IG. For the CG, T16 was significantly lower than both T0 ($p<0.05$) and T8 ($p<0.05$). The foot health status at T0, T8 and T16 did not changed among periods for Foot Function ($p=0.368$), Footwear ($p=0,778$), General Foot Health ($p=0.761$), General Health ($p=0.368$), Physical Activity ($p=0.716$), Sociability ($p=0.135$) nor Vigor ($p=0.165$) (Friedman ANOVA test). The primary outcome is running-related injury incidence in one-year follow up, which could not be verified during the short time of this feasibility study (16 weeks). None of the runners reported any injury during the 16-weeks of study.

CONCLUSIONS

We conclude that the exercises can improve the biomechanics during running since important variables like the maximum calcaneal eversion has decreased and the medial longitudinal arch has also decreased reducing the dynamic strain in the IG. In addition, that the full study is feasible; runners that matched the eligibility criteria are willing to participate and to be randomly allocated in either IG or CG. There was good acceptability to the protocol verified by the web-software reports and the superior results in strength gain by the IG. Adherence to the exercises dropped after eight weeks by a mean of 37.4%. The protocol had good acceptability after all participants in the IG had answered an anonymous questionnaire of satisfaction. Researchers were successful on teaching and assessing participant's performance on each exercise through the score entered on the web-software and through an inquiry during locally supervised training.

INTRODUCTION

Due to the force development and the high-speed contacts performed during a rugby match, executive technique is essential both for task effectiveness and injury prevention.
The tackle has been recognized as the task leading to the higher number of injuries, and thus to the higher recovery time needed from the athletes. [1, 2] Moreover, since young age, the players have been reported to place more interest on the effectiveness of the tackle, rather than on their own safety or on a good technique [3]. Although injury rate has been correlated with athletes' age [4], no information can be found in literature about technique comparison between young and experienced players. Acceleration at contact, along with high impact speed and correct body posture are expected to deliver a great force on the opponent, to perform a dominant and safe tackle. Finally, to regain a quick standing posture after grounding is essential to strive for the ball possession. The aim of the present study is to assess, directly on-field, the tackling technique both in senior and young élite athletes, to investigate experience-correlated differences.

METHODS

Two groups of subjects participated in the study: 5 athletes belonging to the Benetton Rugby Treviso 1st XV (mean ± standard deviation (SD) BMI: 29.26±4.41, age: 24.20±4.49 years), and 5 athletes from the U18 XV of the Italian Rugby Federation (FIR) Academy (mean ± SD BMI: 28.32±2.96, age: 17.13±0.64 years). All the athletes take regularly part in international fixtures. Subjects, after signing informed consent, performed 4 repeating side-on tackles in the rugby field at 2 different heights between: the knee and the hip (KH) and the hip and the pelvis (HP). Video sequences and plantar pressure (PP) distribution were acquired by means of a Novel Pedar system and 4 synchronized cameras (GoPro Hero3+); hence peak PP (PPP), peak vertical ground reaction force (PV), hip, knee and ankle joints kinematics were determined [5,6] and their position with respect to the tackle task evaluated with a purposely developed Matlab code. Specific features were tracked bilaterally directly on the motion sequences [5]: acromion, C7, L5, anterior iliac spine, posterior iliac spine, greater trochanter, lateral femoral epicondyle, calcaneus, two points on the shoe matching 1st and 5th metatarsal head. Key instants were recognized as: left foot PV, right foot PV, contact instant.
Tackler's center of mass (CM) acceleration have been calculated basing on 2D trajectory reconstruction; positive and negative CM acceleration peaks have been recognized in three phases of the task: start-contact (PC), contact-grounding (CT), and grounding-ball retrieve (TR). Finally, an independent T-Test or Kruskalwallis based on normal distribution of the data in SPSS has been performed between the variables to highlight differences between the two groups.

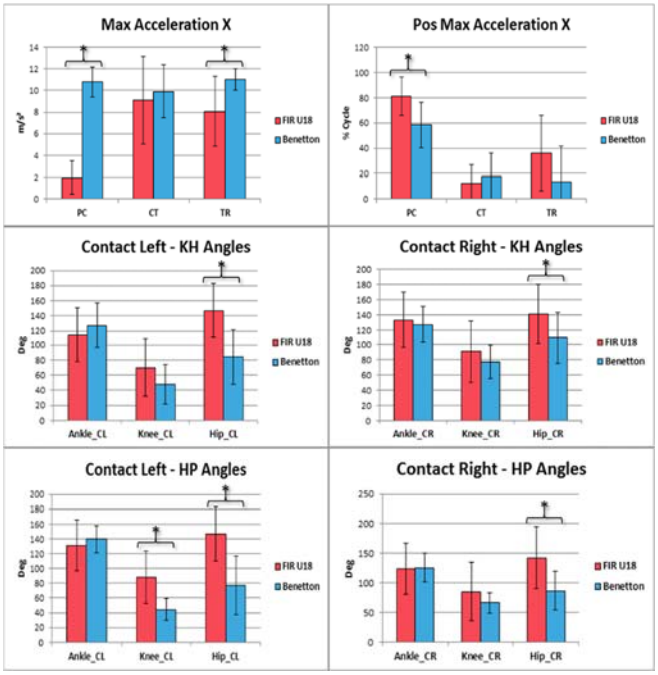

Figure 1: Acceleration peaks, their position in the three tackle parts, and joint angles at contact (* = p<0.05).

RESULTS AND DISCUSSION

Results highlighted differences between the two groups, concerning acceleration and body posture while approaching the tackle: the noticed differences might be related to the experience disparity between young and senior athletes. Benetton displayed lower flexion angles at all lower limb joints on the tackle dominant leg, with higher acceleration.

CONCLUSIONS

The present experimental setup allowed to distinguish different tackling strategies between young and experienced players. Results could be taken in consideration from coaching staffs, to improve the tackle technique developing.

INTRODUCTION

The high force development during contacts and the high-speed execution of tasks performed during a rugby match makes executive technique essential both for effectiveness and injury prevention purposes. The tackle has been recognized as the contact, high-speed task leading to the higher number of injuries, and thus to the higher recovery time needed from the athletes. [1,2]. Acceleration at contact, along with high impact speed and correct body posture are expected to deliver a great force on the opponent, to achieve an effective and safe tackle. Although speed and moments of players have been already investigated in the tackle, little information is available in literature on body posture. Moreover, since young age, the players have been reported to place more interest on the effectiveness of the tackle, rather than on their own safety or on a good technique [3].
The aim of the present study is to assess, directly on-field, the tackling technique both in senior élite University team and young international élite athletes, to investigate experience and technique correlated differences.

METHODS

Two groups of subjects participated in the study: 10 athletes belonging to the University of Padua team (CUS), competing in the 2nd category national championship (mean ± standard deviation (SD) BMI: 27.3±2.16, age: 21.4±3.22 years), and 8 athletes from the U18 XV of the Italian Rugby Federation (FIR) Academy (mean ± SD BMI: 28.32±2.96, age: 17.13±0.64 years), taking regularly part in international fixtures. Subjects, after having signed informed consent, performed 6 repeating side-on tackles in the rugby field at 2 different heights: between the knee and the hip (KH), and between the hip and the pelvis (HP). Video sequences and plantar pressure (PP) distribution were acquired by means of 4 synchronized cameras (GoPro Hero3+) and a Novel Pedar system. Peak PP (PPP), peak vertical ground reaction force (PV) along with hip, knee and ankle joints kinematics were determined [4,5] and their position was extrapolated with respect to the tackle task evaluated with a purposely developed Matlab code. Specific features were tracked bilaterally directly on the motion sequences [4]: acromion, C7, L5, anterior iliac spine, posterior iliac spine, greater trochanter, lateral femoral epicondyle, calcaneus, and a point on the shoe corresponding to the 5th metatarsal head. The key instant considered was the contact between the two players. Tackler's center of mass (CM) acceleration has been calculated based on 2D trajectory reconstruction, hence CM acceleration at contact has been extrapolated.
Finally, an independent T-Test or Kruskalwallis (depending on normal distribution) has been performed to highlight differences between the two groups.

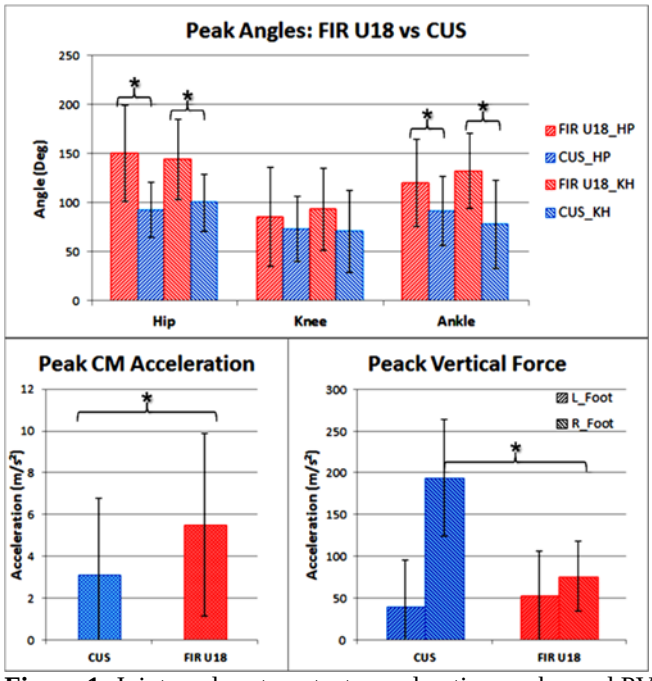

Figure 1: Joint angles at contact, acceleration peaks, and PV at contact (* = $p<0.05$).

RESULTS AND DISCUSSION

Results (Figure 1) highlighted differences between the two techniques, mostly concerning body posture at contact: the noticed differences may be due to the experience disparity and the different coaching technique between players. On one side the higher acceleration, along with the higher joint's range of movement made possible a winning tackle, in spite of the lower PV reported, on the other lower range of motion and acceleration were displayed with higher PV.

CONCLUSIONS

The present study highlighted differences in tacking technique, probably due to different coaching strategies and on-field experience that may indicate a more effective tackling posture.

P426 - EFFECTIVENESS AND INJURY PREVENTION DURING RUGBY TACKLE: AN ON-FIELD, BIOMECHANICAL BASED ASSESSMENT

[1] **Pavan Davide**, [1] Cibin Federica, [1] Guiotto Annamaria, [1] Colangelo Alessandra, [1] Spolaor Fabiola

INTRODUCTION

Due to the hits and high forces developed during a rugby match, injury rate has been found to be higher than other non-contact sports. The scrum has been recognized as the task that is more likely to injure athletes tacking part in it. The tackle leads to a higher number of injured players and to the higher recovery time spent off-field. [1, 2] Tackler injuries have been recognized to mostly affect the shoulder and lower limb, especially the anterior cruciate ligament (ACL) [3]. An adequate training and executing technique is therefore mandatory [4]. High impact speed, acceleration at contact, correct body posture and great force delivery are expected to perform a dominant and safe tackle. Finally, regaining a quick standing posture after grounding is required to retrieve the ball. The aim of the present study is to develop a biomechanical based tool to assess tackling technique, directly on field, as a means for injury prevention and performance optimization.

METHODS

10 subjects participated in the study (mean ± standard deviation (SD) BMI: 29.26±4.41, age: 24.20±4.49 years). However, only the results from half the sample will be presented here. All the athletes were members of the Benetton Rugby Treviso team; one of the two Italian clubs permanently tacking part in the Guinness PRO12 international championship. Subjects, after signing informed consent, performed 4 repeating tackles in the rugby field at 2 different heights: between the knee and the hip (KH) and between the hip and the pelvis (HP). Video sequences and plantar pressure (PP) distribution were acquired by means of a Novel Pedar system and 4 synchronized cameras (GoPro Hero3+); hence peak PP (PPP), peak vertical ground reaction force (PV), hip, knee and ankle joints kinematics were determined [5,6] and their position with respect to the tackle evaluated with purposely developed Matlab code. Specific features were tracked bilaterally, directly on the motion sequences [5]: acromion, C7, L5, anterior iliac spine, posterior iliac spine, greater trochanter, lateral femoral epicondyle, calcaneus, two points on the shoe corresponding to the 1st and the 5th metatarsal head, lateral humerus epicondyle. Key instants were recognized as: left foot PV, right foot PV, contact. A further Matlab code was developed to calculate the knee torque evolution during the performed task, both in flexion/extension (FET) and varus/valgus (VVT). Tackler's center of mass (CM) acceleration was calculated based on a 2D trajectory reconstruction; positive and negative CM acceleration peaks were identified in three phases of the task: start-contact (PC), contact-grounding (CT), and grounding-ball retrieve (TR).

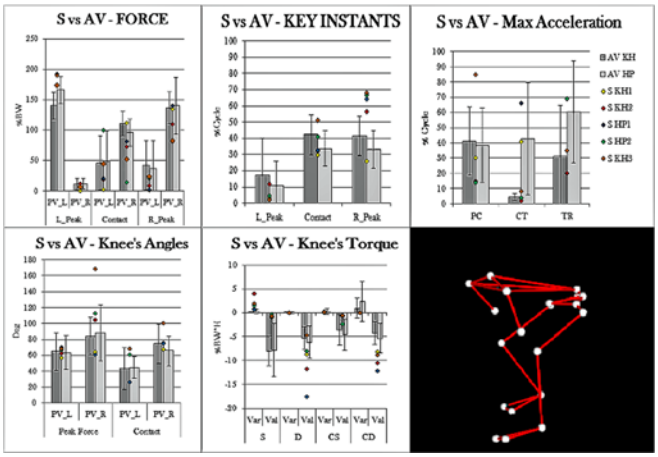

Figure 1: Subject single tasks and means ± SD comparison for PV, key instants, acceleration peaks, knees angles and VVT, 3D reconstruction.

RESULTS AND DISCUSSION

Results (example in Figure1) highlighted different behaviors of athletes while approaching the tackle: effective and dominant tackle attitude has been underlined in single players, as discussed with the coaching staff, and potentially injuring knee behaviors have been reported to elaborate specific training protocols.

CONCLUSIONS

The present experimental setup and elaboration flow has allowed us to effectively assess executive quality and safety of the tackle, directly on-field. Results have been supported from the coaching staff. Further development of the study will include enhancing the sample size and to develop a complete screening tool for coaches and video analysts, while determining a complete biomechanical model for the tackle.

ACKNOWLEDGEMENTS

The authors acknowledge the Benetton Rugby Treviso club for athletes and rugby field availability.

P427 - PREDICTING GROUND REACTIONS DURING SINGLE-LEG LANDINGS USING ZERO-MOMENT POINT

[1]**Jeffrey A. Reinbolt** and [2]Cyril J. Donnelly
[1]University of Tennessee, Knoxville and [2]University of Western Australia

INTRODUCTION

Anterior cruciate ligament (ACL) injuries affect approximately 1 in 3,000 individuals each year [1] and most occur during non-contact sport movements, such as sidestepping or single-leg landing [2]. Injury prevention aims to modify body position to minimize knee loads during weight-acceptance phase of these movements [3, 4].

To determine optimal whole-body kinematics for minimizing ACL injury risk, accurate ground reactions are necessary to calculate muscle and joint loads. Directly measuring ground reaction forces is not practical when investigating emergent behaviors modifying neuromuscular control or joint-level movement for reducing loads. Several computational approaches can predict ground reactions from body kinematics [5]. One approach deserving further exploration is predicting ground reactions by locating the ***Zero-Moment Point*** (**ZMP**) [5, 6], a well-known notion within the robotics field. For biomechanists, the ZMP is conceptually similar to the Center of Pressure (CoP), but the ZMP uses gravity and inertia forces rather than contact (reaction) forces and moments. The ZMP and CoP positions coincide when the model is dynamically balanced (gravity and inertia forces are equal and opposite to contact forces).

In this study, we used OpenSim [7] modeling and simulation to examine ZMP-predicted ground reactions during single-leg landings and determine how sensitive predictions are to different kinematics. We hypothesized that: **H1**) the ZMP approach predicts ground reactions during single-leg landings and **H2**) predictions using dynamically-inconsistent kinematics produce larger root-mean-square errors (RMSE) from measured ground reactions compared with using more dynamically-consistent kinematics.

METHODS

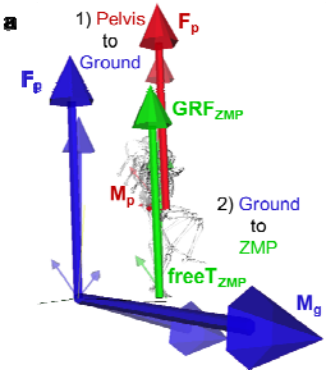
Eight male Western Australian Amateur Football players (20.5±1.77 yrs, 87.8±4.76 kg, 1.86±0.08 m) were randomly selected from a cohort participating in a single-leg jump landing protocol [3]. A 12-camera Vicon MX system recorded 3D marker trajectories at 250 Hz and an AMTI force platform recorded ground reactions at 2,000 Hz.

A 3D, full-body model with 37 actuated degrees of freedom was used in each simulation (Figure 1a) created with a 3-step process. First, the model was scaled to participant-specific anthropometry. Second, ***inverse kinematics*** (**IK**) determined model kinematics matching measured kinematic marker data. Third, a ***residual reduction algorithm*** (**RRA**) determined optimal actuator controls producing kinematics from a forward dynamic simulation, where optimization [4] minimized inconsistencies (residual forces and moments) between model dynamics and measured ground reactions.

The IK and RRA kinematics were separately used with the ZMP approach to predict ground reactions and compared with measured values. Inverse dynamics, without external contact loads applied, determined pelvis residuals. These residuals were transformed to an equivalent set of forces and moments about the inertial (ground) reference frame origin. Similar to the CoP, the ZMP approach further transformed these quantities to ZMP-predicted ground reactions, a set of forces and a single, free vertical torque (horizontal moments are 0), and located the ZMP in the ground reference frame.

RESULTS AND DISCUSSION

Confirming H1, ground reactions were accurately predicted during single-leg landings when the model used the RRA motion adjusted for dynamic inconsistencies (Figure 1b). The largest RMSE's were in the anterior reaction force (1.25 %BW) and lateral ZMP position (1.24 cm), likely due to minimized, but not eliminated, dynamic inconsistences. Confirming H2, predicted ground reactions were not accurate when the model used the dynamically-inconsistent IK motion. The largest RMSE's were in the vertical reaction force (73 %BW) and anterior ZMP position (154 cm), due to dynamically-inconsistent inverse kinematics, as the same skeletal model and any inherent modeling errors were used with both sets of kinematics for each participant.



b

ZMP Predictions	RMSE for 2 Kinematics	
	IK	RRA
GRF (%BW)	51.2	1.05
freeT (%BW*HT)	9.29	1.12
CoP (cm)	111	1.04

Figure 1: (a) Participant-specific model during landing and pelvis residuals (*red*) transformed to equivalent forces and moments about the ground origin (*blue*) to ground reactions from the Zero-Moment Point (ZMP) approach (*green*); (b) root-mean-square errors (RMSE) for all 8 participants.

CONCLUSIONS

The ZMP approach was able to predict ground reactions during single-leg landings; however, due to large accelerations and forces during this sport movement, dynamically-consistent kinematics are needed to make accurate predictions with the ZMP approach. Future work to determine whole-body kinematics minimizing lower-limb, knee, and ACL injury risk should constrain the ZMP position to remain under the landing foot.

INTRODUCTION

Movement screening tests, such as the Functional Movement Screen™ (FMS), are used to screen for movement abnormalities that may be predictive of performance potential or injury risk in athletes and/or workers [1]. However, these screens are scored subjectively and scores can change based on the rater or the performer's knowledge of the grading criteria [2]. Quantitative methods can help us understand how underlying attributes (e.g. height, sex, ability, or injury history) contribute to movement patterns. This information can then be used to identify ideal movement patterns for a specific class, faciliating customized movement screening. Using motion capture and principal component analysis (PCA) of whole-body motion may provide an objective, data-driven method to identify unique and statistically important movement patterns. Therefore, the overarching goals of this research are to: 1) examine athletes' movement variability when performing standardized functional movements using PCA; and 2) to determine if whole-body movement patterns can be differentiated based on classifiers such as skill level, sport played, injury history, sex, and anthropometry.

METHODS

This study is based on motion capture data collected by Motus Global from 542 athletes representing eight different sports (soccer, baseball, tennis, basketball, lacrosse, track and field, golf, and football) ranging in ability from recreational (i.e. do not play on competitive teams) to professional (e.g. NFL, MLB, FIFA). Each athlete performed 14 range of motion tasks and 7 stability tasks, where the tasks were designed to challenge athletes' balance, stability, and power. In this abstract, we will only examine the bird-dog and drop-jump tasks and only classify differences between novices and elites. Whole-body motion data were collected using an 8-camera Raptor-E motion capture system (Motion Analysis, CA, USA). PCA was applied to time-series position data for each athlete to reduce the dimensionality of the dataset for further analysis. The x, y, and z position data for joint centres and landmarks were used for the analysis so that whole-body motion patterns could be examined and videos could be created depicting the results for each movement with robust models.

The PCA calculated principal components (PC) and the corresponding PC scores explaining individuals' variance from the mean. Based on pilot data, 10 PCs and scores were retained for both the bird-dog and drop-jump task. A linear discriminant function (LDF) differentiating between skill levels (novice vs. elite) was applied to the reconstructed motion data [3]. Data were reconstructed for each group (i.e. novice vs. elite) by adding and subtracting the LDF multiplied by 1SD to the mean movement across all athletes [3]. To further study differences between athlete groups, an ANCOVA (controlling for sex, sport, injury, height, weight) was used to determine significant differences in PC scores between novice and elite athletes, where each PC was interpreted using single component reconstruction [4] (not reported in the abstract but to be presented in person).

RESULTS AND DISCUSSION

For the bird-dog task, the first 10 PCs explained 98.8% of the movement variability and the LDF accurately classified 77.7% of the cases as either a novice or elite athlete. Elite athletes had greater flexion and extension throughout the task and more trunk rotation compared to novice athletes. These findings suggest that elite athletes have better balance and neuromuscular control of their trunk compared to novice athletes. For the drop-jump task, the first 10 PCs explained 97.9% of the movement variability and the LDF accurately classified 61.3% of the cases. Elite athletes squatted lower during the pre-phase of the jump and reached a greater maximal vertical height compared to the novice athletes (Fig. 1). In addition, there were differences between the timing of the arm swing between the two groups. The application of PCA combined with LDF analyses provided a data-driven objective method to identify differences in whole-body movement patterns between novice and elite athletes performing a bird-dog and drop jump task.

Figure 1. 0%, 25%, 50%, 75% and 100% of the drop-jump task for ±1 SD from the mean along the discriminant function that separates novice (red) and elite (black) athletes.

CONCLUSIONS

Novice and elite athletes were differentiated using PCA and LDF while performing a bird-dog and drop-jump task. These analytical techniques could provide an objective, data-driven method for future movement screening. Currently, we are analyzing the remaining 19 movement tasks and differentiating athletes using additional classifiers (i.e. sport, injury history, sex and anthropometry).

P429 - DIFFERENCES IN PERFORMANCE OF SPRINTING IN A SIDEWAYS DIRECTION BETWEEN THE USES OF FORWARD AND COUNTER STEP TECHNIQUES

[1] **Takahiko Sato**, [1]Yusuke Fukuhara and [1]Tadao Isaka
[1]Ritsumeikan University

INTRODUCTION

In field sports, an effective sprint start from a stationary standing position is important in developing speed as much as possible in a short period of time. Forward step (FS) and counter step (CS) are the two common sprint start techniques. CS has typically been considered as an inferior technique compared to FS because it includes an unnecessary step in a direction opposite to the movement. However, Kraan et al. [1] suggested that using CS to accelerate forwards could be advantageous because of additional benefit from the stretch shortening cycle. In addition, there is mounting evidence that CS could generate faster sprint start time from the stationary standing position compared with FS [2-4]. While athletes start sprinting in various directions in the field sports, all of previous studies focused on the sprint start in the forward direction. It remains unclear which technique is superior when athletes start sprinting in a sideways direction. Therefore, the purpose of this study was to determine differences in sprint performance following FS and CS in a sideways direction.

METHODS

Ten male lacrosse players performed 5m forward sprint following FS and CS in a right direction from the stationary standing position. For FS, subjects initiated a first step to the right side with their right foot, while turning the body to right, followed by forward sprint. For CS, subjects initiated an additional side step to left with their left foot, while turning the body to the right, before the first forward step in the right direction. 3-D kinematic data were recorded by a passive retroflective marker motion capture system at a sampling rate of 200Hz, and the whole-body center of mass (COM) was calculated. Ground reaction forces (GRFs) were also recorded by force plates at a sampling rate of 1000Hz. Movement initiation was defined as the first frame meeting a requirement that the vertical or sprint-direction components of GRF exceeds mean GRF plus or minus three times the SD of these components in the last 50 frames. The following five step events commonly observed during FS and CS were identified based on GRFs: initial lift-off of the right foot from the starting position, as well as contact and lift-off of two forward steps. Five components of COM velocity in the sprint-direction at the lift-off of second forward step were calculated, including an initial velocity at the movement initiation based on the kinematic data and four variables of the velocity generated by GRFs acting on the following four contacting feet: (1) the right foot in the initial contact phase; (2) the left foot in the initial contact phase (and the contact phase of additional step in CS); (3) the right foot in the contact phase of first forward step; and (4) the left foot in the contact phase of second forward step. Five components of COM displacement in the sprint-direction at the lift-off of second forward step were also calculated as displacements generated by the initial velocity and GRFs acting on the four contacting feet. Times from the movement initiation to each step event were compared using two-way repeated measures ANOVA (two step techniques x five step events). Each COM velocity and COM displacement variables were compared by using six separate paired t-tests between the FS and CS conditions. Significance level was set at 0.05.

RESULTS AND DISCUSSION

A significant main effect for step event were found in the times from the movement initiation to each step event (P<0.001), and there is no interaction and main effect for step technique. The sums of all COM velocity and displacement components were significantly larger in FS than CS (P<0.05, P<0.001) (Table1). These results indicate that FS allowed athletes to travel longer distance and accelerate greater compared to CS, while the time period of two forward steps were not different between the two techniques.

Table 1: COM velocity and COM displacement

	COM velocity [m/s]		COM displacement [m]	
	FS	CS	FS	CS
Initial velocity	0.02±0.01	0.01±0.01	0.02±0.01	0.01±0.01
Right foot in initial contact phase	-0.23±0.11*	-0.39±0.25*	-0.26±0.12*	-0.40±0.28*
Left foot in initial contact phase	2.68±0.26	2.54±0.36	1.91±0.21*	1.69±0.29*
Right foot in 1st step contact phase	1.30±0.12*	1.38±0.14*	0.45±0.05*	0.49±0.06*
Left foot in 2nd step contact phase	0.73±0.13	0.70±0.15	0. 05±0.01	0. 05±0.01
Sum of all components	4.50±0.28*	4.24±0.36*	2.17±0.11†	1.83±0.16†

* Significant difference between two groups (P < 0.05)
† Significant difference between two groups (P < 0.001)

While the component of the left foot in initial contact phase included the additional side step in CS, this COM velocity and displacement components in CS were similar to or smaller than FS (P<0.05) (Table1). In both of COM velocity and COM displacement, the components of the right foot in initial contact phase in CS generated larger negative effects on sprint performance than FS (P<0.05) (Table1). These results indicate that counter step in the direction opposite to movement does not provide an additional benefit but disadvantage to the sprint performance in CS.

CONCLUSIONS

The carrent study demonstrated that FS may be a better sprint start technique than CS even when the athletes are intended to sprint in a sideways direction. Athletes in the field sports may be considered to use a forward step technique to initiate sprinting in a sideway direction as well as in a forward direction.

P430 - TECHNIQUE DIFFERENCES BETWEEN ELITE AND SUB-ELITE CRICKET FAST BOWLERS

[1] Anees Sayed, [1]Sai Aditya, [1]MB Gnanavel, [1]KA Thiagarajan, [1]S Arumugam
[1]Sri Ramachandra University
Corresponding author email: sanees@srassc.in

INTRODUCTION

Cricket biomechanical studies have focused on the link between the fast bowling technique and injury risk in fast bowlers [1] and the contribution of fast bowling technique to the ball release speed [2], as ball release speed can be considered to be an indicator for performance in fast bowlers.

Technique parameters such as straighter front knee during front foot contact (FFC) phase [1], larger front foot braking force [1], rapid front foot loading rate [1], shoulder angle at ball release (BR) [2], Run-up speed [2], knee angle at BR [2] and trunk flexion between FFC and BR [2] have been identified as technique parameters unique to faster bowlers during previous studies. Additionally, straighter front knee, larger front foot braking force and larger vertical loading rate are parameters which potentially increase the risk of lower back injury [1].

Biomechanical studies in fast bowlers have focused on elite fast bowlers or junior level fast bowlers. Technical differences between elite and sub elite fast bowlers have not been adequately studied. The aim of this study was to compare the biomechanical parameters between elite and subelite fast bowlers, to see whether the bowlers from the elite group bowl faster, have significant differences in the technique parameters and have higher injury risk.

METHODS

Twenty eight fast bowlers were selected for this study, with the bowlers divided into groups based on their playing level. The elite group consisted of 14 bowlers (Age = 23.7 ± 3.4 years; height = 1.79 ± 0.05 m; body mass = 75.8 ± 8.2 kgs) who were playing in the state's (Tamil Nadu, India) 1st Division cricket league. Ten bowlers from the elite group had also played first class cricket as the first division is the league preceding the First class level. The subelite group (Age = 18.6 ± 2.3 years; height = 1.79 ± 0.07 m; body mass = 70.1 ± 8 kgs) consisted of fast bowlers playing in 2nd and 3rd division of the same State. 14 technique parameters which have been linked to either fast bowling speeds or linked to higher injury risk, were identified from various studies.

The bowlers were required to ball 6 deliveries at a good length while their bowling action was being captured with 16 Vicon (MX-T20s) 3D cameras and the ground reaction force was measured using an AMTI force plate. The fastest delivery from each bowler was selected for this study. Independent t-test were performed using SPSS software to identify the technique parameters which showes a significant difference between the two groups.

RESULTS AND DISCUSSION

Out of the 14 parameters selected, Run up speed and Ball release speed were found to be significantly higher in the elite group of bowlers. All the remaining technique parameters did not show a significant difference. Table 1 describes the means, standard deviation and the range of selected parameters.

Table 1: Description of selected kinematic parameters measured

Technique Variable	Group	Mean	Std. Deviation	Range
Front foot peak V_{GRF} (BW)	Subelite	6.43	1.61	3.11 - 8.38
	Elite	6.31	1.63	3.33 - 10.2
Rear foot loading rate (BW/s)	Subelite	46.9	27.45	16.8 - 95.1
	Elite	40.4	23.30	9.06 - 98.3
Knee flexion at FFC (°)	Subelite	19.3	10.03	4.7 - 41.3
	Elite	13.3	8.78	-6.1 - 27.7
Maximum knee flexion (°)	Subelite	44.4	16.03	18.2 - 67.3
	Elite	40.3	22.80	-2.4 - 81.8
Maximum Trunk lateral flexion (°)	Subelite	42.7	7.05	34.9 - 55.8
	Elite	42.3	7.24	30.2 - 52.9
Shoulder angle at ball release (°)	Subelite	196	10.70	184 - 221
	Elite	194	11.81	178 - 223
Run-up speed (m/s)*	Subelite	5.74	0.70	4.4 - 6.7
	Elite	6.33	0.45	5.6 - 7
Ball speed (m/s)*	Subelite	31.3	2.07	27.8 - 33.9
	Elite	34.0	1.47	30.8 - 35.8

Note: * Significant correlation, $P < 0.05$

CONCLUSIONS

The elite group bowled faster and this could be attributed to the faster run-up speed as previous research has correlated run-up speed with faster ball release speed. Other parameters which correlated with faster ball release speed in previous studies, did not vary significantly between the 2 groups in this study. Parameters, such as anthropometry and fitness levels, need to be studied between the two groups to further explain the difference in bowling speed between the 2 groups. Parameters such as high trunk lateral flexion and straighter knee during front foot contact phase have been associate with high load on the lower back, but in this study there was no significant difference in these parameters between the groups, suggesting that the injury risk in similar between the groups.

P431 - INERTIAL MEASUREMENT UNIT BASED ACTIVITY SEGMENTATION DURING FAST BOWLING IN CRICKET

[1] **Jayamini Ranaweera**, [2]Pujitha Silva [3]Siva Gawsalyan and [4]AMS Deshapriya
[1]University of Moratuwa, Sri Lanka
Corresponding author email: jayarolf10@gmail.com

INTRODUCTION

Fast bowling is one of the main activities in cricket. Being injury free and enhancing bowling speed are few of the key aspects fast bowlers concentrate on in the modern era. Vision based motion analysis systems providing biomechanical analysis tend to assist scientists improve the above parameters in fast bowling. However due to greater cost and operational complexity of vision based systems the demand for development of low cost [2] motion analysis systems with greater operational environment flexibility has increased in recent times. At present, Inertial Measurement Unit (IMU) based motion analysis systems have gained the potential of supporting such demands.

However, IMU based motion analysis data alone will not assist a sports scientist to carry out a biomechanical analysis of a fast bowler. The motion analysis data will need to be segmented into various phases (seven key activities) occurring in fast bowling. This paper attempts to solve this problem by using pattern recognition techniques to IMU data and segment key phases in fast bowling for a specific type of fast bowling action.

METHODS

6 Fast bowlers with side-on action type were selected for the study. The bowlers were selected such that all their heights deviated with +-3 inch deviation and weight with +-10kg deviation.

3 IMU sensors were placed on the body at forearm, trunk, thigh and 1 accelerometer was placed on the foot. Each subject was made to bowl 10 deliveries with repetitive bowling actions allowing limited variations. The subjects were asked to exert similar effort into each delivery. The accelerometer operating at 150 Hz was specifically used to detect foot contact. The 9 axis IMU's were sampled at 350 Hz with a time stamp for each data set. The data was initially stored in quaternion form and plotted in Microsoft Excel followed by MATLAB.

Preprocessing was carried out by observing the data from each activity isolated from the total delivery. The subject carried out the specific activity ex: run-up, delivery stride and follow through independently. Event detection is proposed to be achieved by segmenting the data into windows. Start and end of each delivery can be detected by allowing the bowlers to do the same trigger movement at starting and ending moments in delivery.

Feature extraction was carried out by developing feature vectors with statistical parameters like mean, variance, skewness and kurtosis. This was carried out for all quaternions in the data set.

Feature selection and classification was carried out by selecting the best performing features from the set. For classification four classifiers were tested: Naïve Bayes (NB), Support Vector Machines (SVM), Partial Decision Tree (PART) and k-nearest neighbor (kNN) [1].

RESULTS AND DISCUSSION

The initial results plotted in Microsoft Excel depicts an observable pattern in the quaternion data. The data from sensor on trunk shows maximum variation due to slight variations in trunk rotation during each delivery. The 10 sets of data for each subject when plotted depicted a similar pattern in most cases however, slight offsets in the graphs were visible due small variations in starting and ending movements during bowling. Quaternion data plot of sensor on forearm used for segmentation is shown in Figure 1.

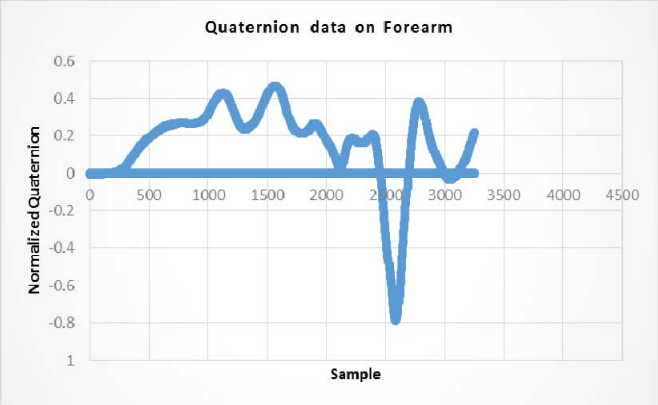

Figure 1: Quaternion data pattern from IMU on forearm during fast bowling.

The segmentation algorithm was compared and evaluated against the video recordings for validation. By this the segmentation accuracy of the algorithm was validated. The computational accuracy and complexity of each classifier was examined to select the best suited classifier for the current application.

Complications in segmentation were highlighted when the algorithm was repeated against different individuals due to slight variations in bowling actions.

CONCLUSIONS

It is seen that pattern recognition techniques can be applied to IMU data for segmentation of side-on fast bowling actions. Further, multiple IMU's are required to be placed on different part of the body for an accurate and complete segmentation of the side on fast bowling action.

ACKNOWLEDGEMENTS

Kairos 3D motion analysis system provided accurate quaternion data which were used for segmentation.

P432 - NOVEL BODY SENSOR NETWORK ARCHITECTURE FOR HIGH PERFORMANCE BADMINTON MOTION ANALYSIS

Pujitha Silva, **Kawsihen Elankumaran**, Pradeep Kathirgamaraja, Sabareesan Easwaramoorthy, Nirothipan Megalingam
University of Moratuwa, Sri Lanka
Corresponding author email: kawsihen15@gmail.com

INTRODUCTION

Badminton is definitely one of the most competitive sport played today that requires great amounts of speed, strength, precision and agility. Winning a game necessitates mastery over sophisticated racket movements in different types of techniques and strategies. We present a high performing wireless inertial sensor network architecture with high data rate, range and a backend software tool chain for visualizing, analyzing the collected data. This will not only help players monitor, analyze and improve their gameplay performance but also help them refrain from shots that could potentially lead to injuries. For validating the performance of the design we have considered the mid-racket velocity and smash time during forehand smash as the test parameters in the game.

Video based analysis traditionally used in such settings are expensive and resource demanding. They require massive computational power and are often inaccurate due to video occlusions encountered during gameplay. As for the inertial tracking setups, sports like Tennis and Swimming have dedicated tools which Badminton is lacking. The more generic motion tracking devices such as Opal by ADPM technologies are adaptable to a lot of motion tacking tasks but lack game specific optimizations such as data rate and analysis algorithms [1].

METHODS

Our system consists of 15 wearable wireless sensor nodes that record kinematic data at key locations in the body during gameplay. The micromechanical sensor node that we designed and developed is shown in Figure 1. The sensor node had inertial sensor modules, controller, Wi-Fi transceiver and power supply onboard. We used InvenSense MPU 9250 as the main inertial module along with InvenSense ITG-3701 gyroscope and STMicroelectronics H3LIS331DL accelerometer for extended range sensing. The sensor node includes the Espressif ESP8266-03 Wi-Fi transceiver for wireless communications. Tensilica 32 bit RISC processor in the Wi-Fi transceiver serves as the master in the sensor node. The sensor node was developed as a wearable module with the electronics fabricated on a two layer printed circuit board and the enclosure 3D printed. The recorded inertial data from all the nodes are sent to a host computer in real time. Madgwick's algorithm is used in the controller for sensor fusion of measured accelerometer, gyroscope and magnetometer data to yield orientation values in quaternion format [2]. This data is transmitted along with a timestamp to the host.

A variety of visualization and analysis software are run in the host. A server running in the host receives the transmitted data from all the nodes and maintains a pipeline that feeds data to different applications. For visualization of motion we use Blender which is an open source modeling, animation and game engine software. OpenSim is used for biomechanical modeling, simulation and analysis in learning about the muscular forces associated with the motion. We also run our own algorithms to retrieve parameters of interest pertaining to the game such as mid-racket speed and smash time.

Figure 1: The high performance sensor node developed and tested.

RESULTS AND DISCUSSION

The system was tested on professional Badminton players. The subjects were served the shuttlecock from the service end and asked to perform different forehand smashes. This was repeated several times with each player performing the smash and the recorded data was logged.

Results from the test indicated that the developed sensor node was able to operate at the target data update rate of 500 Hz. The software were also able to accurately model the kinematic and biomechanical motion of the subject. The retrieved game parameter values from the algorithms revealed that they were in close consensus with the values from previous literature and experimentation.

CONCLUSIONS

An inertial motion tracking method is a cost effective and efficient way to monitor, analyze and provide feedback on Badminton gameplay. Experiments showed that our wireless inertial sensor network architecture was able to achieve higher data rates and model fast smashing action with sufficient accuracy. This will help Badminton players improve their sport performance and abstain from postures that could lead to injuries. Further research along this line could investigate on efficient algorithms for the spatial tracking of the motion of the player in the game arena.

P433 - CHARACTERISTICS OF 3-D HUMAN BODY SHAPE IN JAPANESE SWIMMERS BY USING HOMOLOGOUS BODY MODEL

[1]**Mari Soma**, [1] Yu Kashiwagi, [2]Noriko Hakamada and [1]Kazuo Funato

[1]Nippon Sport Science University
[2]Japan institute of sports sciences, Tokyo
Corresponding author email:marikichi.19901110@gmail.com

INTRODUCTION

Conventional methods such as the Martin-type or Tape measures have been used for human body anthropometry such as length and circumference of each body segment. There is few studies for quantifing the segment shape, i.e. foot shape analysis by using principal component analysis [1].

3-D body shape is important especially for swimmers because drag yielded by different body shape largely affects athletic performance [2].

The purpose of this study was to draw the morphological characteristics between Japanese elite swimmers and non-athletes. Using a Principal Component Analysis (PCA) of Homologous Body Model (HBM), quantification on of 3-D body shape was established.

METHODS

Subjects including male swimmers (MS; Age; 20.8 ±1.8yrs, BH;173.1±5.8cm, BW;69.8±6.1kg,), female swimmers (FS; Age; 20.5 ±1.9yrs, BH;162.6±5.0cm, BW;59.3±6.0kg,), male non-athletes (MN; Age; 18.8±1.5yrs, BH;170.9±5.2cm, BW;59.4±8.2kg) and female non-athletes (FN; Age; 21.5 ±2.5yrs, BH;158.6±6.0cm, BW;54.2±6.5kg,) participated in this study.3-D whole body line scanner (BLS; Hamamatsu Photonics Ltd, Japan) was used to scan their standing whole bodies. HBM had constructed by fitting the whole body laser scan called polygon date to generic template model based on anatomical landmarks. HBM consisted of 20,000 vertex of the same topology, and each data point was calculated based on the anatomical homology. Having established the correspondence among all the models, we can perform PCA.

FINA point determined by International Swimming Federation was used for the relationship between "shape" of the body and performance.

All statistics analysis was used by paired t-test performed on selected means to detect significant differences ($p<0.05$) between MS and MN, FS and FN (SPSS; IBM SPSS Statistics Version.22). The relationship between "shape" of the body and FINA point (swimming performance) were used by Pearson's correlation coefficients ($p<0.05$).

RESULTS AND DISCUSSION

In comparison with non-athletes, both MS and FS showed significantly large lean body mass (MS; 60.4±5.6kg, MN; 51.0±6.7kg and FS; 46.8±3.8kg, MN; 41.5±4.9kg, $p<0.001$) and larger chest circumference (MS; 98.7±4.2cm, MN; 84.2±5.4cm and FS; 90.9±4.7cm, FN; 85.3±4.7cm, $p<0.001$). In normalized HBM as to body height, the larger trunk ratio was characteristics for both MS and FS.

MS was larger in trunk ratio, chest, abdominal and buttock (Figure 1a).

FINA points were associated with "shape" of the body (Figure 1b). FINA point with the "shape" of the body showed a significant correlation (MS; $r=-0.447$, $p<0.05$).

Homology model of the 3-D body shape enable to quantify the individual difference and characteristics of body shape.

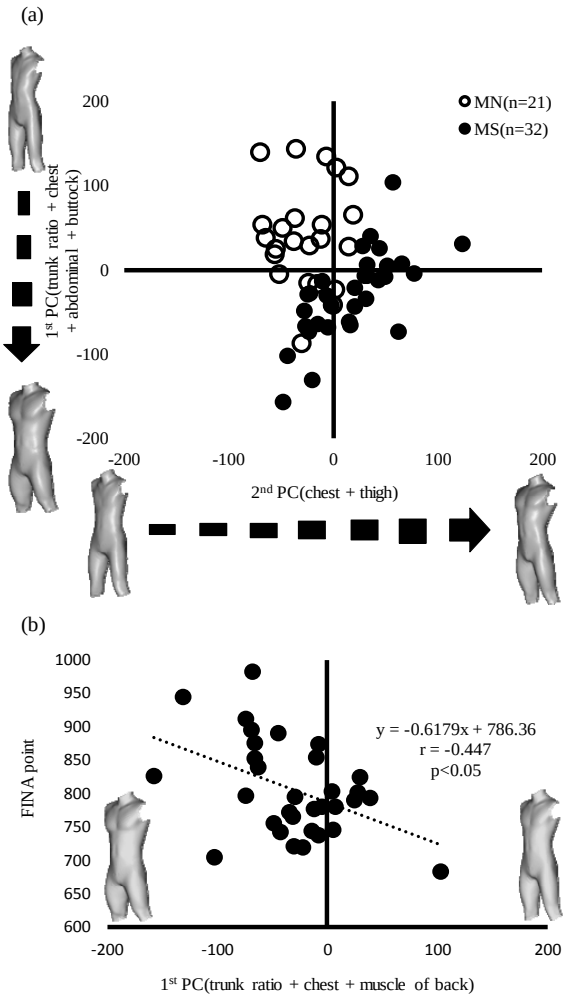

Figure 1: Plotting of PC scores on x (2nd PC) and y (1st PC) coordinates for MS and MN (a). Distribution maps using 1st PC scores (trunk ratio, chest and latissimus-dorsi muscle) and FINA point. The FINA points allows comparisons of results among different events. The FINA point scoring assigns point values to swimming performances, more points for world class performances typically 1000 or more and fewer points for slower performances (b).

CONCLUSIONS

3-D human body shape analysis by using homologous body model revealed that Japanese male swimmer and female swimmer were characteristics as larger trunk ratio as well on flatter trunk shape.

P434 - ACCELEROMETER MEASUREMENT OF UPPER LIMBS CHARACTERISTIC OF TENNIS DOUBLE HANDED BACKHAND STROKES

[1] **Mu-Lin Tai**, [2] Kai-Lung Chang, [3]Wen-Tzu Tang
[1,2,3] National Taiwan Sport University
Corresponding author email: wentzutang@gmail.com

INTRODUCTION

Sports training in response to scientific, through the instrument to monitor the athlete‘s performance is quite common. Because of the accelerometer is small size, easy to operate to provide immediate feedback, there are many studies using accelerometer to measure human activity [1]. The most common applications currently in motion are to observe swing and vibration to discuss motion behavior. Hand backhand is a closed kinetic chain, is classified in the coordination of two drive action mode [2].The purpose of this study is to use the accelerometer to discuss the two-handed behavior of tennis backhand strokes.

METHODS

The subjects are two young female players who training tennis for more than 5 years and training more than 18 hours average weekly. There are very skilled double handed backhand strokes technology. Using Accelerometer form Trigno ™ Standard Sensor (± 9g).Accelerated regulation placed in the upper arm of the wrist flexor and extensor carpal muscle, sensor direction of the arrow pointing to the distal.

Experiment on standard tennis courts. With double-handed backhand, hit three successful ball and choose one of the fastest speed and focus the phase before and after impact 0.3 seconds.

In data processing, the raw data were exported into excel file with EMGworks Analysis, The acceleration values of right and left wrist muscles were multiplied by the negative sign. The acceleration direction was opposite to that of the right wrist and left wrist. Of the acceleration in the same direction, and 0.3 seconds before and after the moment of the ball as a discussion.

RESULTS AND DISCUSSION

The results showed that ±9g in the impact can not illustrate the acceleration of the practical situation of the acceleration. In impact, the right hand to withstand more shots instant shaking. While the role of the left hand is to accelerate forward, he is the main role of hand. Especially in the X and Z axis acceleration. In one hand, the acceleration of the extensor and wrist muscles was almost similar, but the acceleration of the Y-axis in the right hand showed a significant swapping of the right hand before the shot to assist the left hand to adjust the face, Giangarra (1993) proposed because the grip of the relationship between the hands of his right hand backhand more spin, can enhance the stability of the elbow and strength, can be transmitted in the moment of impact hit the power, not by the elbow absorb. Presumably the hands backhand action can prevent tennis elbow occurred in the machine [3].

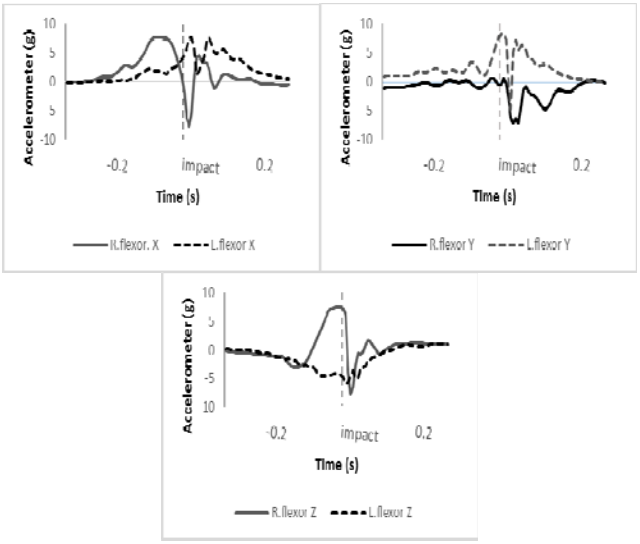

Figure 1: Typical acceleration pattern of both flexor carpal muscle

CONCLUSIONS

It's show that the ±9g sensor can’t observation of the actual behavior in impact. In future, the studies can use the new Trigno ™ Standard Sensor (± 16g), and it also increase the parameters of gyro. The acceleration in the XZ-axis of a hand is the similar as the tendency of the wrist flexor and extensor muscle, but in the Y-axis on right hand before impact can be observed in the rotation behavior. Whether the wrist flexor or extensor muscle at impact, its show the right hand to absorb more shock form the impact.

P435 - COMPARISON OF EEG DURING MOTION IN REAL SPACE AND VIDEOGAME

College of Science and Technology

Corresponding author email: kentaro@kanto-gakuin.ac.jp

INTRODUCTION

Enjoying virtual motion indoors has become possible in recent years thanks to the Nintendo Wii videogame console, which can be played using body motion controls. In fact, "Wii-habilitation" has seen the console find widespread use in physical rehabilitation. However, the difference between actual motion and motion that takes place in virtual reality in a game setting has not yet been studied in detail.

The purpose of this study is to measure and conduct a comparative analysis of brain waves upon real motion and under videogame (VR), focusing on alpha (α) waves produced during concentration and relaxation, and beta (β) waves produced under stress and the process of distributing.

METHODS

The subjects of this study were six healthy, right-handed people (male university students aged 21–22 years old).
In compliance with the international 10-20 system, electrodes were placed in positions C1, C2, C3, C4, C5, and C6. In the present research, we used the Eggo Sports Brain Wave sensor (Advanced Neuro Technology) and performed measurements at a 512 Hz sampling rate. For motion in VR, we used a Nintendo Wii. The activities considered were Wii Sport Resort Table Tennis (Nintendo) and a real table tennis game. The first person to reach 6 points was considered the winner. In order to allow brain waves to stabilize, targets were asked to take three abdominal breaths before measurement. The Wii game was played soon after the real table tennis game, in order to avoid inadvertent differences in brain wave measuring positions. Experiments were carried out sequentially five times, real game followed by VR. Subsequently, subjects were asked to relax for 5 minutes. Using MATLAB, α and β waves extracted from signals obtained with the brain wave sensor were analyzed, and a comparative study was conducted for each situation (scoring, conceding a point, rallying, and smashing). In the present research, significance tests were based on one-way analysis of variance.

RESULTS

We performed frequency analysis of brain waves obtained from the targets, calculated their power spectrum, and then plotted their average values in a graph. Observing α and β waves obtained in real space and in VR, we found that α waves had statistically significantly higher values in every situation (Figure.1). Moreover, comparing α waves between real space and VR, α waves had higher values during scoring, rallying, and upon conceding a score in real space, but VR showed higher values upon smashing (Figure.2).

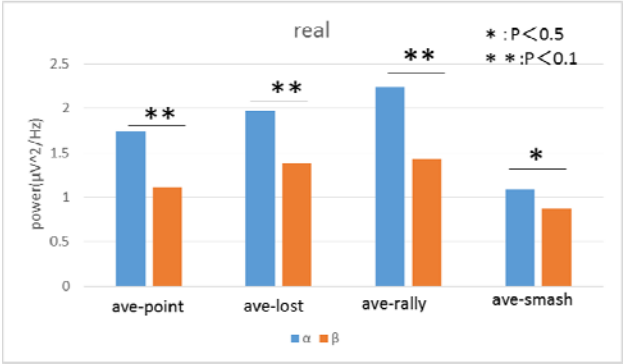

Figure 1: Conparison of α wave and β wave in real space.

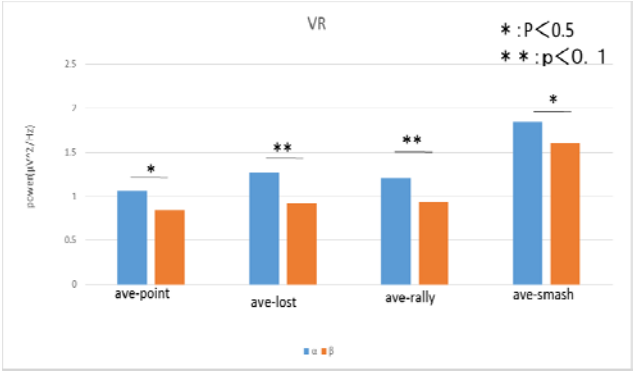

Figure 1: Conparison of α wave and β wave in videogame.

DISCUSSION

It was found that in both real space and VR, α waves had statistically significantly higher values than β waves. It is worth noting that when real space is compared with VR, whereas in VR it is possible to return a ball by simply adjusting the timing of the swing (in two dimensions), in real space a variety of information is necessary to return a ball, such as the depth, height, and force, in three dimensions. Therefore, the brain may be required to work more actively in order to process such information. Thus, we believe that moving the body in real space activates the brain in a more effective way than playing virtual sports in VR. However, α waves during smashing were higher in VR. A possible explanation is the tendency to make powerful swings despite the fact that in VR there is no need to control the amount of force, which is a factor that leads to higher concentration. These facts suggest that exercise effects can also be expected in VR, although not at the same level as in real space.

P436 - THE CHARACTERISTICS OF LOWER EXTREMITY DURING TRUNK-TWIST EXERCISES

[1] **Kazutaka Takahashi**, [1] Takeshi Asai
[1]University of Tsukuba
Corresponding author email: kaz.aventador.83090@gmail.com

INTRODUCTION

Trunk-twist movement accompanying the stretch-shortening cycle (SSC) movement is one of the factors that improve the hitting performance such as tennis [1]. The trunk-twist movement seen in hitting performances appears to be generated by pelvic rotation [2]. Therefore, the bar twisting exercise is considered an effective exercise to improve the trunk-twist movement [3]. However, no study has investigated the characteristics of pelvic rotation during this exercise. The purpose of this study was to investigate how the lower extremities act on the pelvis when it is rotated about the superior-inferior axis during the bar twisting exercise.

METHODS

Twenty-one healthy male college students participated in this study (age, 21.91 ± 3.18 years; height, 1.76 ± 0.05 m; weight, 78.67 ± 17.01 kg). All participants performed the bar twisting exercise by using a special trunk-twist training machine. On this machine, bar rotation was limited to the horizontal plane. To determine the effect of SSC, participants performed the exercise by using SSC and not using SSC (CON). In SSC, participants rotated the bar clockwise; when the right side of the bar passed the mark (located at bar angle −75°), participants immediately rotated the bar counterclockwise. In CON, the participants rotated the bar counterclockwise from the mark (not using SSC movement). Participants were required to rotate the bar with each foot on two force platforms, and keep the body steady when they stopped the bar. Three different loads (0 kg, 10 kg, and 20 kg) were used during SSC and CON. The three-dimensional coordinates of 49 retro-reflective markers fixed on the body (47 points) and outer end of bar (2 points) were recorded by the Vicon system (Vicon Motion System, Ltd., 250 Hz), using twelve cameras. The ground reaction force was measured with two force platforms (Kistler Instrumente AG, 1000 Hz). Smoothing of the coordinates was achieved by using a Butterworth digital filter with optimal cut-off frequencies of 2.5–15 Hz, which were determined using the residual method. The global coordinate system was defined as follows: The X-axis represented the mediolateral direction, Y-axis represented the anterior-posterior direction, and Z-axis represented the vertical direction. An inverse dynamics approach was used to calculate joint torques and joint forces at the ankle, knee, and hip joints. The pelvic torque, defined as the torque acting on the pelvis about its superior-inferior axis through the hip joints was determined from the hip joint torque and forces [2].

A two-way analysis of variance with Bonferroni post hoc contrasts was used to detect differences in the means. The significance was accepted at $P < 0.05$.

RESULTS AND DISCUSSION

Figure 1 shows the pattern of pelvic torque generated during the bar twisting exercise. There was a significant CON-SSC × loads interaction in the peak pelvic torque. There was no statistical difference in the torque generated with different loads in SSC and CON. However, peak pelvic torque at SSC-10 kg and SSC-20 kg was significantly greater than that at CON-10 kg and CON-20 kg. Thus, SSC movement during the bar twisting exercise using heavy loads is important to generate the pelvic torque.

There was a significant difference in the pelvic torque generated at the point when the bar started to rotate counterclockwise. This torque in SSC was significantly greater than CON and significantly greater with increasing loads. Because of the momentary inertia of the bar, the lower extremities generated force and power to cause pelvic rotation at the initial phase of counterclockwise rotation with the heavier loads.

According these results, the lower extremity exerted a greater force and power during the SSC movement and developed pelvic torque with heavier loads.

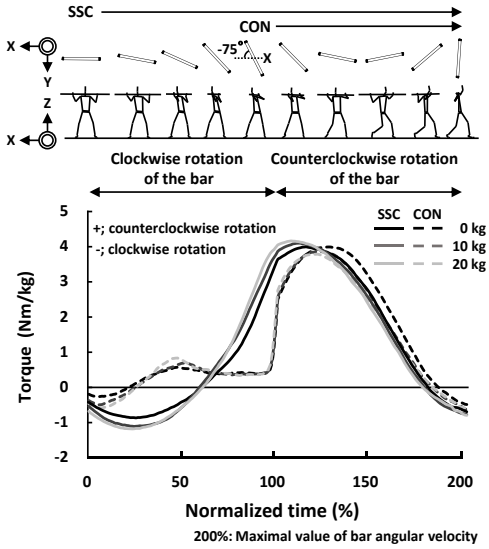

Figure 1: The pattern of pelvic torque generated during bar twisting exercises.

CONCLUSIONS

In the bar twisting exercise, the exertion of force by the lower extremities on the pelvis was no statistical difference at different loads. However, with heavy loads, the SSC movement generated larger pelvic torque. Moreover, with heavy loads, the pelvic torque was greater when the bar started to rotate counterclockwise. These results suggest that the lower extremities generated force and power to cause pelvic rotation, especially with the heavy loads accompanying the SSC movement.

P437 - EFFECT OF FRONT LEG EXTENSION TIMING DURING KICK-START ON SWIMMING START PERFORMANCE

[1] **Takahiro Tanaka**, [2]Kazumasa Ozeki, [3]Tatsuya Urata, [4]Toyoyuki Honjo, [1]Masahiro Fujimoto,

INTRODUCTION

The kick-start is one of the commonly used block start techniques in competitive swimming, in which one foot is placed on the front surface of the starting block, while the other foot is placed on the back plate (Fig.1 A). A fast start with a greater horizontal velocity at take-off is important for competitive success [1], and it has been reported that different kick-start positions affect such take-off velocity [2]. Since swimmers push off first with the rear leg and then with the front leg during the kick-start, front leg extension timings relative to the rear leg push-off would also affect take-off velocity. The objective of this study was to investigate the effects of different front leg extension timings during the kick-start on swimming start performance.

METHODS

Five Japanese male collegiate swimmers (height: 1.77 ± 0.08 m, body mass: 73.16 ± 7.37 kg, age: 20.4 ± 1.62 years) performed kick-start from a starting block with a back plate with their maximum effort. Whole-body kinematic data in the sagittal plane were obtained using a high-speed camera at a frame rate of 100Hz.

Based on the empirically obtained whole-body kinematic data during kick-start, the whole-body was modeled as linked nine rigid-body segments to simulate the kick-start performance with different front leg extension timings (Fig.1A). Front leg extension timings were adjusted by shifting the time-series data of the ankle and knee joint angles, and foot segment angle for the front leg, 0.01 to 0.04s earlier ($T_{0.01}$ to $T_{0.04}$) from the original data (T_0) (Fig.1B). The kick-start motion was simulated using both forward and inverse kinematics under some simplifying assumptions with geometric constraints. The horizontal and vertical velocities of the whole-body center of mass (COM) at take-off were analyzed to assess swimming start performance.

RESULTS AND DISCUSSION

The horizontal take-off velocity increased for the subject A, B, and C, whereas it decreased for the subject D and E as the front leg extension timing became earlier (Fig.1C). The vertical take-off velocity increased as the front leg extension timing became earlier for all the subjects (Fig1. D).

The vertical take-off velocity reached toward zero for the subject A, B, and C, while it increased away from zero in a positive direction for the subject D as the timing became earlier. This could explain why the horizontal take-off velocity became larger for the subject A, B, and C, but smaller for D with the earlier front leg extension timings. Positive and negative values in the vertical take-off velocity indicate upward and downward velocity, respectively. The COM velocity would be more horizontally directed as its vertical component reaches zero, while it would be directed upward as its vertical component becomes larger than zero. It appears that the earlier front leg extension timing allowed the subject A, B, and C more horizontally-directed take-off, while leading to more upward-directed take-off for the subject D, resulting in the larger and smaller horizontal take-off velocity, respectively. These results indicate that front leg extension timings would either positively or negatively affect horizontal take-off velocity, depending on the vertical take-off velocity.

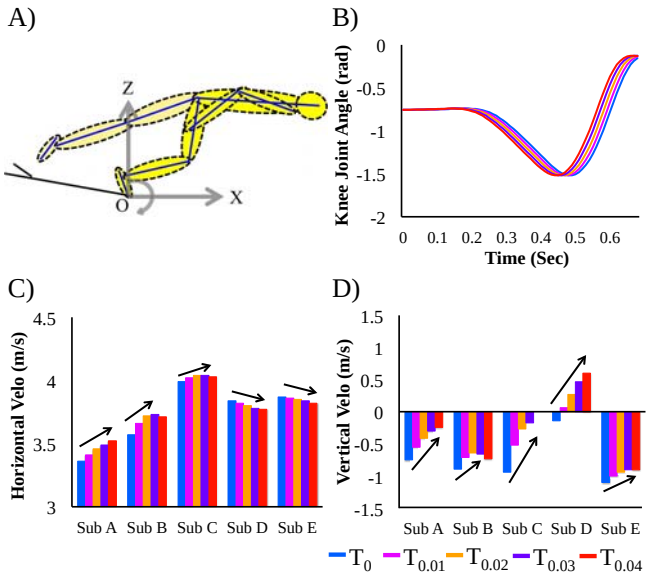

Figure 1: A) Rigid-body segment model during the kick-start, B) Front knee joint angles for different front leg extension timings, C) Horizontal take-off velocity, and D) Vertical take-off velocity for different leg extension timings.

CONCLUSIONS

The vertical take-off velocity increased as front leg extension timing became earlier. Front leg extension timings either positively or negatively affected horizontal take-off velocity, depending on the vertical take-off velocity. For the swimmers generating downward COM velocity at take-off, earlier front leg extension timing would allow them to generate a greater horizontal velocity, whereas it would decrease horizontal velocity for the swimmers generating upward COM velocity at take-off.

P438 - EFFECTS OF SWING CONSISTENCY ON OUTCOME ESTIMATIONS IN GOLF PUTTING

[1] **Hideyuki Tanaka** and [1] Masato Iwami
[1] Tokyo University of Agriculture and Technology
Corresponding author email: tanahide@cc.tuat.ac.jp

INTRODUCTION

Putting on the green in golf imposes heavy demands on the accurate driving of a ball to an intended distance. To improve putting skills throughout repeated strokes in practice, therefore, golfers must acquire representations of the relationship between the impact force and putting outcome. Experts can predict more accurately the error of ball location than novices in impact motor actions such as baseball batting [1] and soccer place-kicking [2]. While experts can achieve high accuracy of outcome estimation, how it interacts with motor control abilities is still ambiguous. The present study aims to determine 1) how accurately novices and expert golfers can estimate outcome of putts and 2) how consistently they can execute putting swings. We analyzed the relationships between putting swing consistency and outcome estimation accuracy.

METHODS

Six elite amateur golfers (19-21 years old with their golf score handicaps of lower than 3.0) and six novices (20-23 years old) participated in the experiment after providing written informed consent. This experiment was performed with the approval of a local ethics board.

A 7.0 m long and 0.9 m wide synthetic textile material simulated a golf green. All participants used a commercially available, standard PING type putter (Anser 2, PING, USA). A photomicrosensor was installed on the green at 60 mm ahead from the starting ball position. It signalled the passage of a ball to operate the closure of an electric shutter-spectacles (PLATO, Translucent Technologies, Canada). A spherical infrared-reflective marker was attached behind the centre of blade on the putter wing. Three high-speed cameras (OptiTrack Prime13, NaturalPoint, USA) recorded 3D positions of the reflective marker at 240 fps.

The participants performed an outcome estimation task while wearing the shutter-spectacles. They were asked to drive a golf ball to a target at 1.2, 2.4 and 3.6 m from the starting ball position as close as possible. Once a ball was hit, the shutter-spectacles occluded participant's vision. In the absence of vision, the stopped ball was removed from the green. After the recovery of vision, the participants were asked to indicate their estimations of the stopped ball position using a laser-pointer as accurately as possible. They performed five successful trials for each target distance.

The 3D position data of the reflective marker were analyzed to compute three kinematic measurements of the downswing on the 2D plane along the longitudinal side of putting green: (1) the amplitude (total length of swing arc) (Amp [m]), (2) maximum velocity (Vel [m/s]) and (3) maximum acceleration (Acc [m/s^2]). The putting swing consistency was evaluated by calculating the coefficient of variance (CV) of the three kinematic measurements. The outcome estimation accuracy was assessed by calculating the absolute error (AE [mm]), i.e., the absolute difference between the stopped ball position and the estimated ball position along the longitudinal side of putting green.

RESULTS AND DISCUSSION

A mixed-design two-way repeated measures ANOVA test detected significant effects of the target distance ($F(2, 20) = 12.2$, $p < 0.001$, $\eta_p^2 = 0.55$) and skill level (expert vs. novice) ($F(1, 10) = 11.5$, $p < 0.005$, $\eta_p^2 = 0.53$) for the AE. There was no significant interaction between the two factors ($p > 0.05$). The outcome estimation errors significantly increased as the target distance increased. The experts achieved higher accuracy of the outcome estimation than the novices (Figure 1, left).

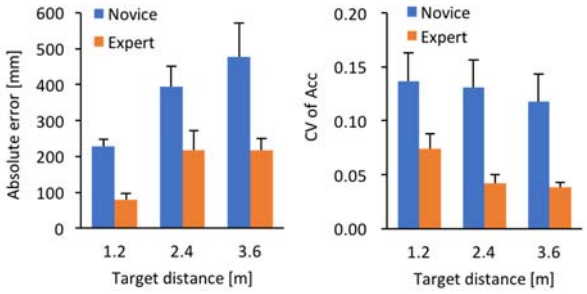

Figure 1: Means and standard errors for the AE of the stopped ball position estimation (left) and CV of the maximum acceleration of downswing (right)

For the CV of Acc, a significant effect of the skill level ($F(1, 10) = 17.8$, $p < 0.005$, $\eta_p^2 = 0.64$) was identified, but neither a significant effect of the target distance nor two-way interaction were found (ps > 0.05). Tendencies of the statistical results for the CV of Amp and CV of Vel were same as for the CV of Acc. The experts executed the downswing movements with higher consistency than the novices (Figure 1, right). The consistency of the downswing was not affected by the target distance.

There were no significant correlations between the AE and CVs of the three kinematic measurements for the experts and novices (rs < 0.3, ps > 0.05). This suggests that the expertise of outcome estimation in golf putting is independent of the swing control abilities.

CONCLUSIONS

Elite golfers have higher abilities not only to execute golf swing actions, but also to estimate the outcome of their own actions. Our investigations showed that there is no strong effect of the swing consistency on the outcome estimation in golf putting.

P439 - A VIDEO-BASED METHOD TO QUANTIFY STROKE SYNCHRONISATION IN CREW-BOAT SPRINT KAYAKING

Cheryl S Tay and Pui W Kong
Nanyang Technological University
Corresponding author email: cheryltsh@gmail.com

INTRODUCTION

Individual and crew boats are raced in Olympic Kayak Sprint, where the smallest unit of a crew-boat is the two-seater sprint kayak (K2). There are complexities associated with competitive performance in the crew-boats that are not found in the single boats, such as a need for paddling stroke synchronisation. However, little has been documented about crew-boat sprint kayaking.

The purpose of the study was to introduce a video-based method to quantify stroke synchronisation in crew-boat sprint kayaking. It was hypothesised that stroke synchronisation profiles would vary across sub-elite sprint kayak K2 crews.

METHODS

The study received ethical approval from the Nanyang Technological University Institutional Review Board (IRB-2014-12-022). Written consent was obtained from all participants. Twelve sub-elite sprint kayakers (6 males and 6 females) were paired into 6 single-gender K2 crews for 200-m time trials. The crews were recorded using a 120 Hz video camera from a sagittal view. Video analysis was used to identify timing differences (offset) within each crew at four meaningful positions of the stroke, namely the catch, immersion, extraction and release [1]. Offset was also calculated as a percentage of the mean water phase duration for each crew.

RESULTS AND DISCUSSION

A summary of performance outcomes for the 200-m trial and stroke synchronisation offset for each of the six K2 crews is provided in Table 1. The best performing male and female crews were M1/M2 and W1/W2 respectively. The magnitude and direction of offset varied considerably among the six crews, and also across the four stroke positions of the catch, immersion, extraction and release.

The mean offset was 17 milliseconds (ms) out of a water duration phase of 291 ms, or 5.7%. All six crews were more synchronised at the catch (11 ms, 3.8% offset) compared to the release (21 ms, 7.2% offset), but the pattern was unclear for the immersion and extraction positions. The absolute offset values were very similar to what was reported in rowing pairs, which were 11 ms (catch) and 22 ms (release) [2]. However the percentage offsets were much larger than the values of 1.6% (catch) and 3.1% (release), since the water phase duration in sprint kayaking was less than half of that in rowing (313 ms versus 698 ms).

CONCLUSIONS

This study introduced a video-based method to quantify stroke synchronisation in crew-boat sprint kayaking. The best performing male and female crews have higher offsets than the group mean. At present, it is not clear whether these crews were fast because of the slight asynchronicity, or in spite of it. Future studies may investigate the relationship between synchronisation and performance in crew-boat sprint kayaking.

ACKNOWLEDGEMENTS

We thank Coach Balazs Babella and the Singapore National Kayak Sprint team for participating in the study. This study was supported by the Nanyang President's Graduate Scholarship, Nanyang Technological University.

Mean			313	11	3.8	9	3.1	25	8.7	21	7.2	5.7

Note: ms – millisecond. Offset was the timing difference of the back paddler with reference to the front paddler in a K2, and was calculated for each position as Offset (ms) = Timing of back paddler - Timing of front paddler.

P440 - CAN THE NOVEL MOTION CONTROL FOOTWEAR REDUCE REARFOOT EVERVSION ANGLE DURING WALKING?

[1] Yen-Chen Tseng, [1] Yun-Ju Lee [1] Po-Tsun Chen [2] Cheng-Feng Lin [1] Chich-Haung Yang
[1] Department of Physical Therapy, College of Medicine, Tzu-Chi University, Hualien, Taiwan
[2] Department of Physical Therapy, College of Medicine, National Cheng Kung University, Tainan, Taiwan
Corresponding author email: r.chyang@mail.tcu.edu.tw

INTRODUCTION

Lower extremity injury, such as knee pain, patellar tendinitis and plantar fasciitis, has been associated with excessive rearfoot eversion during running [1]. Hence, the motion control footwear has been considered as an intervention to alter rearfoot motion, which is defined as a kind of sports footwear to limit excessive rearfoot eversion. However, the mechanism of the motion control footwear on controlling rearfoot motion remains unclear. The novelty of motion control footwear used in the current study is plastic plate (PP) insertion corresponding to individual rearfoot posture.

Meanwhile, the measurement of rearfoot motion is used a video camera to record and calculate angles from markers on the dorsal side of shank and the heel part of the shoes. This method has been implied that it might not represent rearfoot motion properly. A calcaneal mold has been evaluated in walking and has been considered as a better and accurate approach to measure the rearfoot motion [2]. The aim of this study was to investigate effects of this novel motion control footwear on changes in rearfoot eversion by using the calcaneal mold in walking.

METHODS

Six health collegiate students (male /female =1:1; age: 22.3 ± 1.2 years; height: 165.1 ± 4.4 cm; weight: 57.5 ± 3.0 kg) were participated in this pilot study. All participants were recruited to meet the inclusion and exclusion criteria. A calcaneal mold was customized individually and placed on their calcaneal with an extend mold out of footwear to be represented the calcaneal motion during walking based on the previous study [2]. Furthermore, two points over the segments (leg and the calcaneal mold respectively) were defined as bisection line on each segment. The rearfoot eversion angle was calculated as acute angle between the leg and calcaneal bisection lines [2]. A video camera (GoPro Hero 4, American technology, USA) was positioned 100 cm behind the participant at height of 6 cm from the floor and perpendicular to the measurement plane. In addition, the camera was used to collect two-dimensional rearfoot motion at sampling rate as 60 Hz. All participants wore the novel motion control footwear with and without insert PP and performed five over-ground walking trials by self-selected speed. The rearfoot angles during walking were calculated by the ImageJ software (NIH, USA), and 60% stance phase from initial stance was analyzed [3]. Rearfoot angles at heel strike and the maximal rearfoot eversion angle within 60% stance phase were evaluated. The Wilcoxon signed rank sum test was used to examine any difference in two rearfoot angles between with and without inserting PP. Statistical difference was set at $p<0.05$.

RESULTS AND DISCUSSION

Figure 1 illustrated that 60% stance phase of a gait cycle from one participant performed walking with (blue) and without (red) inserting PP. The Wilcoxon signed rank sum test was revealed a statistically significant difference in rearfoot eversion angle at heel strike (mean difference = 1.07°, p=0.028) and maximum rearfoot eversion angle during 60% of stance phase (mean difference = 2.45°, p=0.028) between with and without insert PP.

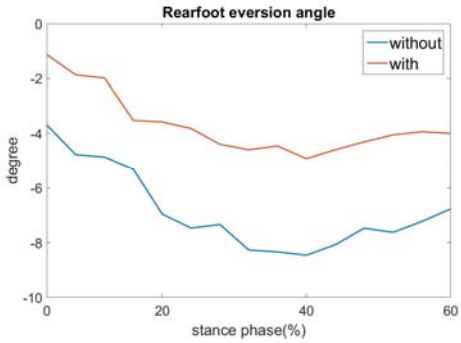

Figure 1: One participant performed walking with (red) and without (blue) PP

In the without PP condition, the rearfoot eversion angle was 2.8° at heel strike and the maximum rearfoot eversion angle was 6.1°, which are similar with the previous study (around to 2.2° and 6.3°) [4]. This indicates that the calcaneal mold and the function of motion control footwear without PP were comparable with the previous research [4]. The significant differences between with and without PP conditions could reflect the adjustment effects of inserting PP on rearfoot eversion angle during walking. Thus, we confirm that the dynamic rearfoot angle can be altered by this novel motion control footwear.

CONCLUSIONS

The results of this pilot study show that there is immediate effect of motion control footwear with PP and decrease dynamic rearfoot angle during walking.

ACKNOWLEDGEMENTS

We would like to thank the contribution of all participants and financial support from Buddhist Tzu-Chi Foundation, Taiwan (TCMRC-P-103006).

P441 - COMPARISON OF BODY SEGMENT MODELS FOR FEMALE HIGH JUMPERS

Mikko Virmavirta, Juha Isolehto
University of Jyväskylä
Corresponding author email: mikko.virmavirta@jyu.fi

INTRODUCTION

Determining the human body segment inertial parameters (BSIP) has a long history including many scientific studies, starting from simple reaction board methods and resulting in more advanced scanning technologies (brief review available by Virmavirta and Isolehto 2014). Selection of the proper segment model for motion analysis of different type of athletes needs a good understanding of prior work on body segment parameters and body structure of the subjects in question. The purpose of the present study was to determine the location of the body center of mass **(CoM)** of female high jumpers by using a high accuracy reaction board and two different segment parameter models. The study was part of the more comprehensive project focusing on body composition of female athletes while reducing body mass.

METHODS

Nine Finnish national level female high jumpers participated in this study (PB 181.9 ± 4.0 cm, age 22.4 ± 2.9, height 176.5 ± 5.6 cm, weight 62.5 ± 2.4 kg, and fat % 17.1 ± 2.6). The true location of subjects' (CoM) was determined by using a high accuracy balance board with knife edge pivot in the mid region, and a very sensitive force transducer at one end. Calibration of the reaction board was done by moving a homogenous steel bar (35 kg, 1590 mm) with a known CoM location along the board (8 measurements) covering the range of force values used in measurements with subjects. The difference between the true position of CoM and the position estimated by the reaction board was 0.7 ± 0.4 mm, thus providing a reliable method for determining the CoM reference values.

Subjects' reaction board results were compared to the CoM locations obtained by segment models commonly used in motion analysis studies (Dempster 1955 adjusted by Clauser 1969 and Zatsiorsky et al. 1990 adjusted by de Leva 1996). For the 2D analysis, the images of dual energy x-ray absorptiometry (DEXA) were used to accurately locate the bony landmarks which the segment models are based to. Overhead camera was used to photograph the subjects for later comparison of digitizing accuracy.

RESULTS AND DISCUSSION

The location of the CoM determined by a reaction board was 55.92 ± 0.53 % of subjects' body height. This is exactly same value what Virmavirta & Isolehto (2014) measured earlier for female students of physical activity (55.91 ± 0.88 %). The results for the segment model of Dempster and deLeva were 57.51 ± 0.61 and 56.77 ± 0.92 %, respectively. Both values differed significantly from the reference values of reaction board (p = 0.001 and 0.044, respectively).

It is known that the Dempster model, which was based on male cadavers of older age, does not work with physically active, younger people. The present results confirm that the use of Dempster's model, emphasizing upper body mass and underestimating leg mass, is likely to cause large errors when generalized to female athletes. The model of de Leva adjusted for female subjects differed only slightly from the reaction board reference, thus, providing appropriate model for female high jumpers. Different results for two segment models can be explained by examining the mass distribution of trunk (49.70 and 42.57 % of the total body mass for the model of Dempster and de Leva, respectively) and thigh (10.00 and 14.78 %) segments in the models. Slightly too high location of CoM for de Leva's model may be caused by the trunk segment CoM position in the model (37.82 % as referenced to origin of the segment).

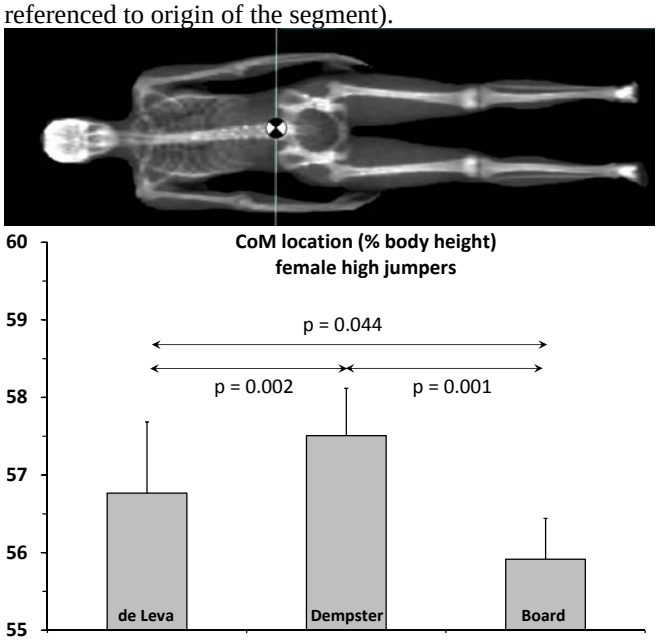

Figure 1: Upper: Example of DEXA image used to digitize landmarks for CoM determination. Lower: Comparison of segment models with balance board.

CONCLUSIONS

DEXA scans, which are used primarily to evaluate bone mineral density and total body composition and fat content, provide also a good tool to evaluate the different segment models based on bony landmarks. Although the present results show that the segment model of de Leva can be successfully used for female high jumpers, they also give a justification for slight changes in the model. It can be concluded that careful attention should be paid while selecting the proper model for motion analysis of different type of female athletes.

P442 - THE INFLUENCE OF GEARING FOOTWEAR ON PERFORMANCE AND BIOMECHANICAL INJURY RISK

John W Wannop, Anthony Killick, Ryan Madden and Darren J Stefanyshyn
University of Calgary
Corresponding author email: b.wannop@ucalgary.ca

INTRODUCTION

The gearing of footwear, which alters the metatarsalphalangeal (MTP) joint bending as a function of forefoot bending stiffness, has been postulated as a method of improving athletic performance and reducing the risk of injury during many sports. As the shoe moves through greater amounts of bending, forefoot stiffness should increase non-linearly, to shift the centre of pressure forward (improving performance), while restricting forefoot bending in regions where turf-toe injury may result. Recently, materials which allow for stiffness modifications as a function of forefoot flexion angle have been developed, however, the efficacy of this technology is unknown. Therefore, the purpose of this project was to evaluate the influence of gearing technology (a variable bending stiffness shoe) on biomechanics during running and sprinting.

METHODS

Ten male recreational athletes performed in two footwear conditions consisting of an altered US 10 adidas 16.4 FXG cleat. The footwear was altered by placing carbon fibre insoles made with AFX technology manufactured by Carbitex, Inc. into the shoes creating two different conditions: Control (no insole) and the variable stiffness (varStiff) shoe (gearing insoles). The stiffness of all footwear was measured using the FAST tester [1].

The experiment consisted of athletes performing liner locomotion while running at 5.0 m/s and during a maximum effort sprint acceleration. Five successful trials were obtained for each movement with data being collected on the left foot and lower leg. For the sprint acceleration, the athletes could start from any position and landed with their second footfall in the center of the force platform, with five-meter performance being measured with timing lights. Kinetic and kinematic data were collected for the left foot/leg using a Kistler force platform (2400 Hz) and an eight-camera motion analysis system (240 Hz). Spherical retro-reflective markers were attached to the shank and shoe for kinematic data collection. The MTP, ankle and knee joint center were determined using a standing neutral trial prior to dynamic data collection. The internal resultant joint moments were calculated using an inverse dynamics approach and compared using a paired t-test (α=0.10).

RESULTS AND DISCUSSION

No performance differences were observed during maximal sprint acceleration (Control=1.09s, varStiff=1.08s). The effectiveness of the variable stiffness insole was confirmed, as no significant differences in peak MTP bending angle were observed during running, but a significant decrease was observed during accelerating (p=0.004). However, when running in the variable stiffness shoe, the centre of pressure was shifted more anteriorly (p =0.006), while the medial-lateral movement of the centre of pressure was reduced (p=0.029)

Peak joint moments and angular impulses at the ankle and knee during running are shown in Table 1. In terms of running injury risk, it is thought that increased non-sagittal plane joint loading can lead to joint injury [2]. At the ankle joint, the peak external rotation moment was reduced by 33% (p=0.034), while the angular impulse was reduced by 30% (p=0.071) when athletes performed in the variable stiffness shoe. No significant differences were observed in the frontal plane. This data indicates that a variable stiffness shoe may reduce the risk of athletes suffering an ankle injury as it has been shown that 90% of all ligamentous injuries at the ankle are caused by internal rotation (transverse plane) and inversion of the foot [3]. At the knee joint, no significant differences were observed in the transverse plane, but the peak knee abduction moment was significantly reduced by 14% (p=0.017) while the angular impulse was reduced by 15% (p=0.077) when athletes ran in the variable stiffness shoe. Frontal plane knee joint loads have been directly linked to chronic injuries such as patellofemoral pain syndrome [2] and osteoarthritis [4], therefore, utilization of gearing insoles in athletic footwear may reduce the joint loading at the knee and may decrease the knee injury risk of athletes.

CONCLUSIONS

Variable stiffness insoles had no effect on sprint acceleration and reduced biomechanical injury risk variables at the knee and ankle joint during running.

ACKNOWLEDGEMENTS

The study was funded by Carbitex. Carbitex was not involved in data collection or in the interpretation of results.

P443 - WORKING IN SYNCHRONISATION: IDEAS ON HOW AN EFFECTIVE COACH – BIOMECHANIST RELATIONSHIP FUNCTIONS

[1,2] **Amy Waters**, [2]Elissa Phillips, [1,2]Derek Panchuk and [1]Andrew Dawson
[1] College of Sport and Exercise Science, Victoria University, Australia
[2] Movement Science, Australian Institute of Sport, Australia
Corresponding author email: amy.waters@ausport.gov.au

INTRODUCTION

In recent years there has been an increase in knowledge of and access to sport science especially biomechanics support in high performance sport coaching. It is becoming increasingly common for biomechanists to have long term interactions with coaches and their athletes. These relationships can be beneficial to both coaches and biomechanists, with coaches gaining valuable insight and knowledge into an athletes' performance and biomechanists being able to see the direct effects of their research and to better understand their area of interest. However, it has been indicated that the relationships between coaches and biomechanists are not as effective as they could be [1].

The aim of this research was to explore the interactions biomechanists have with elite athletics coaches to establish how an effective coach – biomechanist relationship functions in high performance sport.

METHODS

Eleven biomechanists from six different countries with at least an undergraduate degree in sport science (or similar), experience working high performance sport and published research in sprinting biomechanics participated in this research.

A semi-structured, in-depth interview was conducted with each participant lasting from approximately 30 to 60 minutes. Each interview covered the participant's biomechanics background, knowledge of sprinting biomechanics research, experiences working with high performance coaches and views on what a functional coach – scientist relationship should look like.

Each interview was analysed inductively, then transcribed and coded into higher and lower order terms, with major and minor themes extrapolated [2, 3].

RESULTS AND DISCUSSION

All of the participants were asked, as part of establishing their biomechanics background, who the desired audience for their research is. Most expressed a wish to have their work reaching and benefiting coaches, however, they expected that this was not the case in reality. For example: *"…ideally sprint coaches. Whether or not they get it kind of thing, in the form that they need it, I don't know if that's quite the case."* The method in which biomechanics research is published (i.e. academic journals) was often cited as a reason for this disconnect between the two groups. It was thought that, in reality coaches sought knowledge from other sources.

The relationship between the coach and biomechanist outside of the dissemination of research was explored with the participants. Responses on the role a biomechanist could play in the daily training environment ranged from assisting the coach day to day, *"…if a coach identifies something and the athlete won't buy in to it…from that perspective having actual data…a type of visual representation of what the coach is trying to overlay,"* to long term tracking and measuring of technique changes.

Other participants saw their role as a biomechanist as bringing a unique knowledge and skill set to a multidisciplinary team that included the coach and other sports science professionals (e.g. physiotherapist and strength and conditioning coach) that allowed problems to be solved that couldn't be solved with a holistic approach. Whether this be having technical knowledge of the athletic event or providing the team with the relevant data, allowing interpretations to be made by the group.

Coach education was another common theme established by the participants. For some participants educating coaches was seen as part of their relationship, *"I think it would be more important… to be able to disseminate and educate, and there's a definite education piece to communicate in a way that the coach will understand."* Many of the participants suggested they had worked with coaches who did not have high levels of biomechanics knowledge, but, that it was the job of the biomechanist to inform and educate the coach. By either communicating their information in a coach-friendly way or, by becoming involved in the coach accreditation process, ensuring coaches acquire the desired levels of biomechanics knowledge.

CONCLUSIONS

This research explored the role the biomechanist has in the high performance environment specifically their interactions with athletics coaches. Biomechanists expressed a desire for their research to affect coaching practice but thought that this was not the case. Educating coaches was a common theme in coach – biomechanist relationship. An effective coach – biomechanist relationship involved the combination of a unique set of knowledge and skills, and experience that is mutually beneficial in solving problems.

ACKNOWLEDGEMENTS

The Authors would like to thank the biomechanists who made the time to contribute to this project.

P444 - SINGLE INERTIAL SENSOR DETECTS ASYMMETRY NEAR THE CENTRE OF MASS IN HEALTHY COMPETITIVE RUNNERS

[1]Sara Winter, [2]Susan Gordon
[1]James Cook University
[2]Flinders University
Corresponding author email: sara.winter@jcu.edu.au

INTRODUCTION

To date studies assessing asymmetries in running gait have been limited to treadmills [1,2] or short over ground runs [3]. Wireless inertial sensors now provide a method to assess running kinematics continuously during prolonged over ground running. This study used a single inertial sensor placed on the low back (LB) near the centre of mass to detect and measure differences in contact time (CT), flight time (FT) and peak acceleration in three planes
(vertical (VT), mediolateral (ML) and anteroposterior (AP)) during the stance phase of gait between the lower limbs (LL) of runners during a prolonged outdoor over ground run.

METHODS

Twenty two healthy competitive long distance runners (15 male, 7 female) completed an eight km (20 laps) run on an all-weather athletics track at a self-selected time-trial pace. A single wireless inertial sensor (tri-axial accelerometer, 250Hz) was attached to the runner's LB. The time when participants had completed 730m (lap two on straight of the track) and were comfortably in stride was synchronised with the acceleration data provided by the sensor. Gait variables (CT, FT, VT, ML, AP) were analysed for the following 16 steps and averaged for statistical analysis. Wilcoxon Signed Rank Tests were used to compare acceleration variables between left and right LL for non-parametric data. Significance level was $\alpha = 0.05$. Asymmetry was calculated using the absolute symmetry index (ASI) (%) [2], where a value of zero% indicates perfect symmetry and 10-15% used as an acceptable difference between LL [5,6].

RESULTS AND DISCUSSION

Participant characteristics were: (Median, Interquartile Range (IRQ): Age, 36 years (30.50-50.25); Years running, 8.00 (6.00-21.50); Weekly km 60.00 (40.00-75.00); Lap two point time, 2.59.50 min (2.49.50-3.19.25) and final time, 33.19.50 min (31.28.00-34.51.25). Peak ML and AP acceleration were significantly greater during left LL stance than right LL stance. However, the ASI values were in the acceptable range between LL. No significant differences in CT, FT and peak VT were found. The ASI revealed the least variation between LL for CT and FT (highest symmetry). High inter-subject variability (IRQs) in ASI for peak VT, ML and AP was observed, with lower variability for CT and FT (Table 1). .

Table 1. Comparison of acceleration measures between right and left LL and ASI (%) at 730m: Median (IQR).

Acc. Variables	Right Limb	Left Limb	P value	ASI (%)
CT (sec)	0.23 (0.20-0.25)	0.22 (0.20-0.24)	0.709	0.026 (-3.29-5.44)
FT (sec)	0.11 (0.09-0.14)	0.13 (0.10-0.15)	0.051	1.45 (-4.14-10.26)
Peak VT	-4.98 (-6.03—4.01)	-5.17 (-6.80- -4.07)	0.123	9.59 (-12.66-29.06)
Peak ML	1.64 (1.25-2.42)	-1.75 (-2.18- -1.37)	0.001*	12.58 (-1.58-28.65)
Peak AP	-1.64 (-1.25- -2.42)	-1.75 (-2.18- -1.37)	0.001*	12.00 (-1.87-19.51)

* Values are significant at $p \leq 0.05$ level.

This is the first study to assess gait symmetry using a single inertial sensor placed on the LB during a prolonged over ground run. The significant differences and highest ASI values found in horizontal plane gait variables (peak ML and AP acceleration) have been reported in previous running analysis studies during short overground runs [3,7]. The non-significant difference for peak VT between LL and lower VT ASI values than horizontal plane gait variables has also been observed during treadmill [1] and short over ground runs [3]. However, high inter-subject variability in acceleration variables must be taken into account.

Low CT ASI and inter-subject variability found in this study has also been reported during short duration treadmill runs [2,8]. In contrast the low ASI values and moderately low inter-subject variability for FT has not been reported during treadmill running [2,8]. However, stride time (combination of CT and FT) has been reported to differ between treadmill and over ground running [9], and the findings from this study provide data to explain the difference.

This main findings from this study found significant asymmetry in peak acceleration measures are present in healthy long distance runners. It has been suggested that natural and minor asymmetry in runners are acceptable [1,10], and all variables in this current study were within the acceptable differences between LL.

CONCLUSION

This study demonstrated that a single wireless inertial sensor placed on the LB was able to detect asymmetry between LL in runners during a prolonged outdoor over ground run. This method allows for accurate measurement of running gait in a runner's natural environment.

P445 - RELATIONSHIP BETWEEN VERTICAL JUMP AND FRONT- OR REAR-WEIGHTED TRACK START IN SWIMMING

[1]Kazusa Tanida and [2]**Tetsu Yamada**
[1]Yonemaru Elementary School
[2]Kanazawa University
Corresponding author email: te2yamada@staff.kanazawa-u.ac.jp

INTRODUCTION

Start is one of the important phase in the race of swimming, especially short distance swimming events [1]. Weighted position of track start was varied by preference of each swimmer. Welcher et al. [1] showed that time to 7.5m was not significant difference between front- and rear-weighted track start. Consequently, no criteria to select front- or rear-weighted position for track start. The purpose of this study was to investigate the relationships between vertical jump and front- or rear weighted track start in swimming.

METHODS

Ten varsity club swimmers (age, 20.2±1.0yrs; height, 166.7±6.6cm; body mass, 60.4±7.3kg) were selected as subjects. They were given verbal instructions on each of the starts, and then performed each two trials of the front-weighted track start and rear-weighted track start. All the trials in the sagittal plane were videotaped from right lateral of the starting block with a digital camcorder (120Hz) (HDR-CX900, Sony) and from right lateral at the 10m form the starting end of the pool with a digital high speed camcorder (300Hz) (EX-F1, Casio) at the same time. LED light simultaneously with starting beep was used to synchronize camcorders. In another day, the subjects performed vertical jump with hands held at their side. All the jumps were videotaped from right lateral with digital camcorder (120Hz) (HDR-CX900, Sony). Thirteen body landmarks (right hand, wrist, elbow, and shoulder and both toes, heels, ankles, and knees and right greater trochanter, vertex, tragion, suprasternale, and lower end of thorax) were digitaized from starting signal to water entry in track start trial, from the lowest position of the greater trochanter to landing in vertical jump trial. The coordinates were smoothed with a fourth order Butterworth digital filter with cut-off frequencies ranging from 6 to 15 Hz which were determined automatically [2]. Paired t-test was examined for differences between parameters. Relationships between parameters was assessed using Pearson's correlation coefficient. All the statistical analysis were run with SPSS (IBM).

RESULTS AND DISCUSSION

Time to 10m (front, 4.34±0.27s; rear, 4.31±0.28s), block time (start signal to take-off) (front, 0.70±0.06s; rear, 0.75±0.07s), flight time (take-off to water entry) (front, 0.40±0.06s; rear, 0.40±0.06s), and underwater time (water entry to 10m) (front, 3.24±0.32s; rear, 3.16±0.30s) were not significant difference between the front-weighted track start and the rear-weighted track start. Horizontal velocity at take-off of the rear-weighted track start was greater than the front-weighted track start (front, 4.11±0.23m/s; rear, 4.29±0.19m/s; $p<0.05$). The vertical jump height was related to the time to 10m and the underwater time of the front-weighted track start (10m: $r=-0.92$, $p<0.05$; underwater: $r=-0.85$, $p<0.05$) and the rear-weighted track start (10m: $r=-0.91$, $p<0.05$; underwater: $r=-0.82$, $p<0.05$), but other times were not significant related to the vertical jump height. Figure 1 showed relationships between time difference of front- and rear-weighted track start and minimal joint angles of hip and knee of the vertical jump (above: time difference in block time, below: time difference in underwater time).

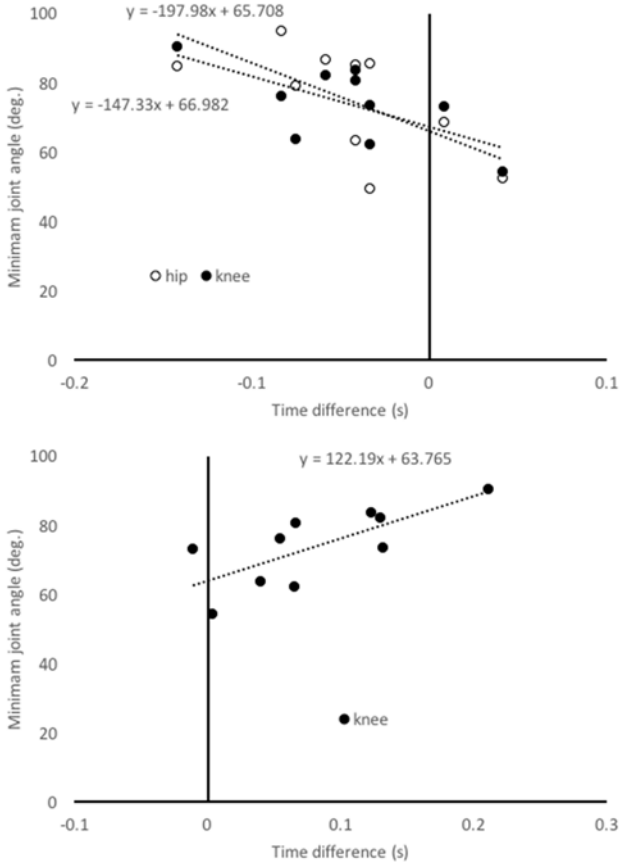

Figure 1: Rerationships between time difference of front- and rear-weighted track start and minimal joint angles of hip and knee of the vertical jump.

The time difference of block time between front- and rear-weighted track start was related with the minimal joint angles of the hip and knee of the vertical jump, and the time difference of underwater time was related to the minimal knee joint angle of the vertical jump.

CONCLUSIONS

Some minimal joint angles of the vertical jump were related to the time difference between front- and rear-weighted position, therefore the minimal joint angle might be used to criteria for the front- or rear-weighted track start.

P446 - EFFECTS OF CARTILAGE MECHANICAL PROPERTIES ON SUBCHONDRAL BONE STRESSES

[1]**Fatemeh Malekipour**, [1]Peter V.S. Lee
[1]The University of Melbourne
Corresponding author email: fmal@unimelb.edu.au

INTRODUCTION

Altered articular cartilage (AC) mechanical properties are associated with an altered load transfer to the underlying subchondral bone (SCB) which can lead to osteoarthritis (OA). In particular, cartilage lateral strain under high-rate compression may change due to a reduced water content as it degenerates [1]. The short-term mechanical response of healthy AC resembles that of an incompressible elastic material [2], leading to a large ratio of lateral/compressive strain (Poisson ratio v_{AC}=0.5). As the water content reduces in a degenerated cartilage tissue, it exhibits less fluid-like behavior [1] and smaller lateral/compressive strain. This phenomenon can be simulated using a smaller Poisson's ratio for AC [3]. In this study, we used micro-computed tomography (µCT)-based finite element (FE) modelling of cartilage-bone plugs to quantify the effects of AC lateral strain, using a reduced Poisson's ratio, on the SCB stress distribution. We hypothesized that a reduced cartilage lateral strain will lead to a reduced tensile stress in the SCB.

METHODS

Three equine cartilage-bone plugs (Ø=9 mm) were scanned (µCT, Skyscan-1076, Belgium) at 9 µm resolution to develop three high-resolution µCT-based FE models of cartilage-bone in ABAQUS (Simula, USA) [4]. SCB was represented as an isotropic elastic material (elastic modulus = 3 GPa). AC was simulated as an incompressible, neo-Hookean hyperelastic material with a shear modulus of 18 MPa [4]. To understand the effects of cartilage lateral strain on the SCB tissue stresses, AC was simulated using a Poisson's ratio of v_{AC} = 0.4999 and 0.3 (equal to its underlying SCB) to represent fully incompressible and less incompressible AC, respectively. A Poisson's ratio of 0.4999 was used instead of 0.5 to avoid convergence problems in numerical modeling. Bottom nodes of SCB were fixed. *In situ* boundary conditions were applied to SCB by constraining the side nodes in all directions except for the axial direction. In addition, to consider the effect of surrounding cartilage tissue, only the innermost 3mm diameter ring of SCB was analyzed. Axial displacement of 0.4 mm was applied to the cartilage surface. The 90th percentiles of tensile and compressive stresses were found across the SCB thickness for n=5 transverse slices. The results were compared under axial stress of 20 MPa.

RESULTS AND DISCUSSION

Reducing AC Poisson's ratio from 0.4999 to 0.3 led to a reduction of 147.6 ± 69.3% in tensile and 15.2 ± 2.9 % in compressive stress in the transverse slice just below the cartilage in SCB. The magnitude of tensile stress was smaller than the compressive one (Fig.). However, considering the fact that bone is much weaker in tension than in compression, these stresses may still lead to microcrack formation in calcified-cartilage. When the lateral strain in cartilage was reduced, stress at the interface changed to compressive stresses only. Previous FE studies that used simplified and two-dimensional FE models of cartilage-bone did not observe any tensile stress at the interface of cartilage and calcified-cartilage [5]. In this study, using a real geometry we could detect tensile stresses at the interface which was associated with the lateral expansion of the AC under high-rate compression. Future studies are required to simulate the mechanical properties of a degenerated cartilage in more detail, and also include a degenerated SCB microarchitecture to understand the distribution of the mechanical load in diseased cartilage-bone in comparison with a normal cartilage-bone.

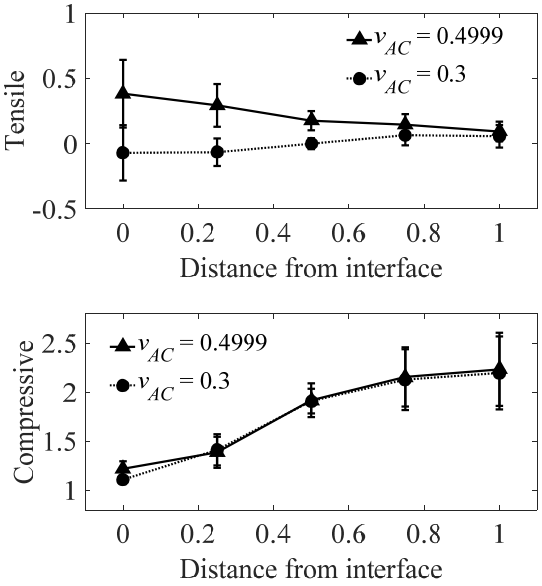

Figure: Normalized tensile and compressive stresses across SCB thickness for v_{AC}=0.4999 and 0.3. The 90th percentiles of stresses for each SCB transverse slice were divided by the axial stress for each specimen (approximately 20 MPa).

CONCLUSIONS

Under impact loading during a jump landing, when both the magnitude and the rate of the compression are high, the lateral strain of cartilage due to its incompressible behavior may lead to microdamage at the interface. However, during normal walking or running, the lateral strain of cartilage creates small tensile stresses at the interface which may play a vital role in regulating a healthy bone remodeling in SCB. Altered stresses, and in particular lack of tensile stresses transferred through the degenerated cartilage to the bone due to a reduced water content may alter the SCB remodeling process and lead to OA.

P447 - IN SITU MAPPING OF THREE-DIMENSIONAL STRAIN IN LIVE CARTILAGE

[1] **Eng Kuan Moo**, [1]Scott C. Sibole, [2]Sang Kuy Han, [1]Walter Herzog
[1]University of Calgary
[2]Korea Institute of Industrial Technology
Corresponding author email: ekmoo@ucalgary.ca

INTRODUCTION

The deformation behaviour of cartilage has been of interest as the bio-synthesis of chondrocytes is directly influenced by the mechanical micro-environment. Typically, mechanical deformation of cartilage is measured using two approaches. The first approach uses cells or cell nuclei as tissue-embedded fiducial markers. In the second approach, two dimensional user-defined grid lines are photo-bleached onto the tissue using confocal laser microscopy. These two approaches only provide a resolution of 50-200µm [1, 2]. Recent advances in non-linear multi-photon microscopy have opened new possibilities as the excitation volume of this imaging technique is highly localized [3], thereby allowing for user-defined three-dimensional (3-D) grid lines. The current study was aimed at developing a new imaging protocol that allows 3-D micro-strain analysis in live intact cartilage at high spatial resolution.

METHODS

Fresh porcine cylindrical (6-mm diameter) cartilage explants (N=2) were incubated in 5-DTAF for 45min to fluorescently label the extracellular matrix (ECM). Specimens were then embedded rigidly into dental cement. Tissue thickness was measured using dissection microscopy. The osteo-chondral specimens were compressed in a light-transmissible compression system mounted onto the stage of a multi-photon microscope. Prior to compression, 3-D evenly-spaced 1µm-wide grid lines (10µm inter-spacing in x-, y-, and z-directions) were photo-bleached onto the top 100µm-thick cartilage tissue at high laser intensity. A 12.5% nominal tissue strain was then applied in a direction perpendicular to the cartilage surface (axial or z-direction) and was held for 20 minutes. Image stacks (pixel size in xy-plane: 0.2µm) were acquired prior to and at 20-minutes of compression, using multi-photon microscopy at 1µm z-spacing. A 3-D strain analysis was performed by tracking the grid position in the tissue for the unloaded and loaded conditions.

RESULTS AND DISCUSSION

A representative example of cartilage deformation before and after mechanical compression is shown in Figure 1. Most grid points are identified in the xy-plane by image processing and indicated as overlaid red dots (Figure 1). The grid inter-spacing in the z-direction (in xz- and yz- planes) visibly decreased in the mechanically-loaded (Figure 1B) compared with the unloaded tissue (Figure 1A). The unconfined compression protocol resulted in overall axial strains of ~22.5% in the 100µm-thick tissue, which is 1.8 times higher than the applied nominal tissue strain (12.5%). This is due to the low compressive stiffness in superficial- compared to mid- and deep- zone cartilage [4]. When individual 10µm-thick-layers were analyzed, the local axial strains varied from 20- 30%. However, only small strains (<2%) occurred in the tangential directions (xy-plane).

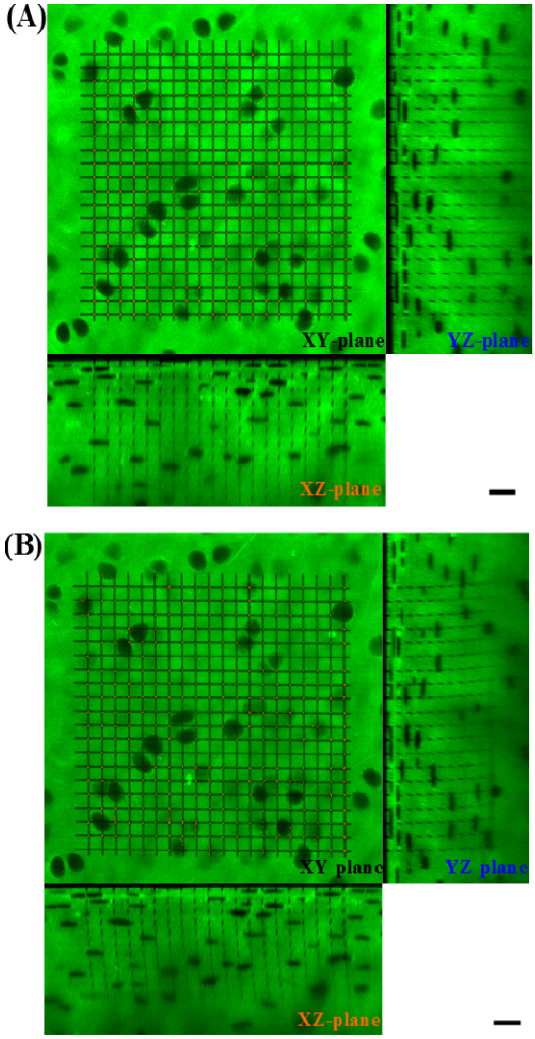

Figure 1: Orthogonal view of mechanically (A) unloaded and, (B) 12.5% nominal strain-loaded cartilage. 3-D grid lines (dark lines) of eleven 10µm-spaced layers were imprinted onto fluorescently-labeled tissue (green) by photo-bleaching. The black ellipses are cartilage cells. Scale bar represents 20µm.

CONCLUSIONS

We developed a high-resolution (10µm) imaging technique that allows for direct measurement of 3-D strain fields in intact cartilage. As chondrocytes range between 10-20µm, our imaging protocol allows for detailed analysis of the cell micro-environment. Future studies will focus on investigating the relationship between tissue deformation and cell biosynthetic response to enhance our understanding of the mechanisms underlying cell mechano-transduction.

P448 - EFFECT OF SUBSTRATE RIGIITY ON CELL MIGRATING USING MICROCHANNEL DEVICE

INTRODUCTION

Cell migration is known to play an important role in a number of physiological events in living body such as morphogenesis, wound healing, and tumor metastasis. This cellular process can be initiated and controlled by external physical cues which include a gradient of substrate rigidity [1]. Recently, many researchers have shown their interests in investigating a collective cell migration. It is because in the most cases of human cellular system, cells are moving and interacting with other cells in a group. For example on a 2D surface, epithelial cells always bound to their neighbors via cell–cell adhesion molecules such as E-cadherins [2].

MEMS techniques have been employed to measure cellular behaviors at micro-scales. In this study, we focus on the effect of substrate rigidity on cell migration behavior by using a microfabricated device. We have fabricated a PDMS-based microfluidic device which consists of microchannels with flat surface and micropillars to serve different substrate stiffness for evaluating velocity profile of collective cell migration.

METHODS

A PDMS-made microfluidic device was used to observe migration of a group of cells. Briefly, a silicon-based SU-8 mold of the device was first fabricated via photolithography process. The microfluidic device was then prepared using double casting fabrication method with a mixture of PDMS polymer. The device consists of 4 sets of 6 microchannels (200 µm wide and 50 µm in height) and a reservoir (15.5 mm x 16.8 mm) for establishing a confluent cell monolayer. Four out of the 6 microchannels were fabricated with arrays of micropillars with 2 and 3 µm in diameter (6.5 µm in height) at the bottom surface, giving a substrate stiffness of 13 kPa and 41 kPa, respectively.

Bovine aortic endothelial cells (BAECs, Cell Application Inc, San Diego, USA) were cultured in DMEM supplemented with 10% FBS and 1% penicillin and streptomycin at 37°C/5% CO_2. A suspension of BAECs at a concentration of 2.2 x 10^5 cells/ml with cell culture medium was loaded to the reservoir of the microfluidic device and the culture was incubated at 37°C/5% CO_2 until reaching a confluent monolayer.

On the day of experiment, the confluent cells were set in a CO_2 incubator on an inverted microscope stage (IX81, Olympus, Tokyo, Japan). After backfilling with the cell culture medium at the end of the microchannels, the PDMS stopper was removed from the microchannels to initiate cell migration. A time-lapse image sequence of the cell migration was obtained using a 10x objective lens and migration rate was calculated.

RESULTS AND DISCUSSION

Figure 1 shows cell migration for flat, 13 kPa and 41 kPa substrate stiffness at 0 h and 12 h. It was observed that the cells migrated faster into flat surface than other 2 microchannels with 13 kPa and 41 kPa substrate stiffness. It was also shown that the migration rate of the cells was higher in hard substrate (41 kPa) than soft substrate (13 kPa). The cells organized an interaction with each other and do not exhibit any gaps for most cases not only on the flat surface but also on the micropillar substrate. This indicates that although the area in contact of cells to substrates is different between the flat surface and the micropillar substrates this difference may not significantly affect the cell migration behavior.

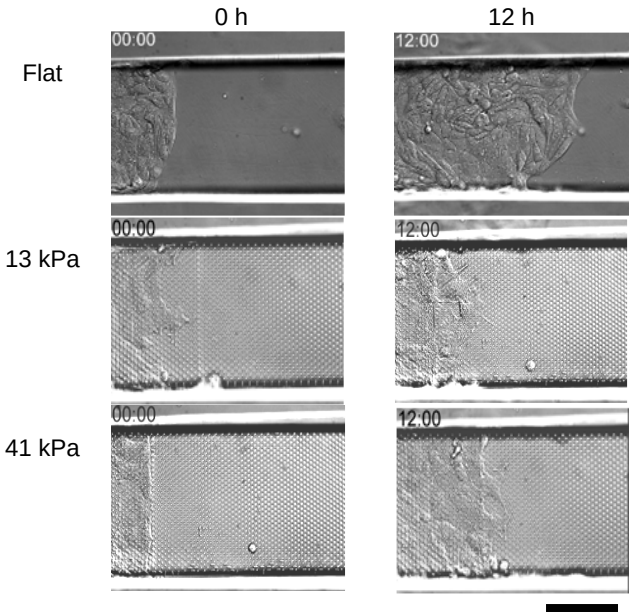

Figure 1: Cell migration on flat surface and micropillars with stiffness of 13 kPa and 41 kPa. Scale bars: 100 µm.

CONCLUSIONS

We have demonstrated collective cells migration using a microfluidic device and have found that the collective cells migrate faster with increasing the stiffness of substrate, indicating cells can monitor substrate rigidity.

INTRODUCTION

Repetitive mild traumatic brain injury (r-mTBI) has been gaining increasing attention from the researchers since several studies have reported that the cognitive dysfunctions after single mTBI become measurably long-term deficits, such as delayed speed of processing and memory dysfunction, after r-mTBI, contributing to the emerging hypothesis that r-mTBI may cause cumulative damage to the brain, and in the absence of cell death, could result in cognitive deficits which may ultimately progress to memory and learning dysfunction [1]. Studies also associated r-mTBI with "second-impact syndrome" and chronic traumatic encephalopathy (CTE) as possible consequences of r-mTBI [2]. However, the potential injury mechanisms involved in r-mTBI remain unclear and research on r-mTBI is still in early stages. The uniaxial stretching device which could give various combinations of strains and strain rates to neurons was developed to allow an in vitro model in which subsequent injuries were induced by using a uniaxial stretching device for realization of the post-injury sequelae of r-mTBI. The uniaxial stretching device mainly consists of a servo actuator, a linear sensor for measuring tensile displacement, a load cell for measuring tensile loading and a polydimethylsiloxane (PDMS) chamber which to cultured cells. A full description of the device configuration and loading mechanism has been published [3]. However, it is difficult to culture cells on PDMS for long term which to do repetitive uniaxial stretching experiment. This study focus on mechanical properties of PDMS and it was determined PDMS culture surface suitable for uniaxial chamber which has been developed to evaluate damaged neuronal cells by repeated strain.

METHODS

Tensile test was carried out using test pieces made of PDMS material. Mechanical properties of PDMS depend on the mixing ratio of the base material and curing agent, temperature, and the time of curing. The basic PDMS condition of the mixing ratio of the two liquids are 1:10, temperature is 65℃ and the time of curing is 1 hour. Compared with that condition, PDMS of new conditions were created the mixing ratio of the two liquids is 1:7.5, 1:5 and temperature is 100℃ and the time of curing is 24 hour. The tensile test was applied until the test piece break. Young's modulus was calculated from the relationship of stress strain of the test piece under each condition.

PC12 cells adhesion experiment was conducted. 3types of cell culture surface Young's modulus is 0.3, 0.6, 0.9 [MPa] (Low, Middle, High group) was employed. Phase-contrast images were obtained each 24 hour for 10 days. The medium in the PDMS chamber was changed at 4, 8 days during the experiment. The number of cells was manually measured. Cell adhesion was defined as the cell number on PDMS substrate.

3types of stretching experiments were conducted. The single loading groups were subjected to initial stretching with a strain of 0.1 at a strain rate of 5 s^{-1}, the repetitive loading groups were subjected again to the same stretching 1 h after first stretching with a strain of 0.1 at a strain rate of 5 s^{-1}. A neurite swelling was defined as a thick part in a neurite. Injured neuron was defined as the rate of neurons that have neurite swellings.

Results were expressed as the mean ± standard deviation (SD) of 3-4 independent experiments. 50–200 neurons per a PDMS substrate were analyzed totally. Means were compared by Steel's multiple comparison test. A p value of less than 0.05 was considered significant.

RESULTS AND DISCUSSION

Strength, elongation, Young's modulus of PDMS test pieces obtained from the tensile test are shown in Table 1. This result showed that the highest Young's modulus of PDMS was prepared by the mixing ratio of the two liquids are 1:10, temperature is 100℃ and the time of curing is 24 hour.

Table 1: Strength, elongation, Young's modulus of PDMS test pieces.

	Strength [Pa]	Elongation [%]	Young's modulus [MPa]
1:10, 1h, 60℃	18±0.4	55.7±4.2	0.38±0.05
1:10, 24h, 60℃	26±0.1	43.7±1.4	0.60±0.03
1:10, 1h, 100℃	23±0.2	45.2±3.9	0.52±0.01
1:10, 24h, 100℃	28±0.4	31.5±2.7	0.87±0.07
1:7.5, 1h, 60℃	22±0.4	38.9±3.2	0.58±0.01
1:5, 1h, 60℃	28±0.2	39.4±0.6	0.76±0.04

Cell adhesion on all condition of PDMS substrates were observed in PC12 cells. Although there was no significant difference in the cell number among all groups, cell adhesion tended to increase in the High group compared to low, middle group at a few days after cell seeding. Therefore, in repetitive stretching experiment cell culture surface was employed PDMS condition of High group Young's modulus.

The stretching experiment showed that even though initial insult induced some level of swelling formation, swelling formation increased by second stretching confirming that r-mTBI causes increased amounts of cellular damage when compared with single insults of the same magnitude.

P450 - EFFECTS OF HIGH HYDROSTATIC PRESSURE ON MEMBRANE FLUIDITY AND INTRACELLULAR SIGNAL TRANSDUCTION IN CHONDOCYTE PROGENITOR CELLS

INTRODUCTION

Living tissues such as blood vessel and articular cartilage are known to be loaded with hydrostatic pressure. Articular cartilage is located at the both ends of bones, and facilitates joint movements. Many elder people suffer from osteoarthritis (OA), which is of the major diseases in cartilage. Articular cartilage is composed of cell (chondrocyte) 2%, matrices (collagen, proteoglycans) 18% and water 80%. When articular cartilage is loaded with compressive stress, then chondrocytes are known to be loaded with hydrostatic pressure up to about 10 MPa. Therefore, many researches have been done for detecting how chondrocytes sense the hydrostatic pressure, how intracellular signals and gene expressions are regulated.

On the other hand, articular cartilage is focused as one of the most interest tissue to be regenerated in the field of regenerative medicine. Articular cartilages have adequate visco-elastic mechanical properties for sustaining weight and movements. We introduced static or intermittent hydrostatic pressure loading systems, which could realize physiological loading conditions. Then, we tried to adapt hydrostatic pressure to cartilage tissue engineering, for controlling differentiation of chondrocytes because cultured chondrocytes are easy to be dedifferentiated, and secondly for promoting gene expressions of matrices such as collagen, aggrecan, and cartilage tissue regeneration, resulting in improving its mechanical properties. We presented also possible pathways of signal transduction in chondrocyte by hydrostatic pressure loading in terms of ERK phosphorylation, RAS/Rap1 activation, and change of fluidity in plasma membrane.

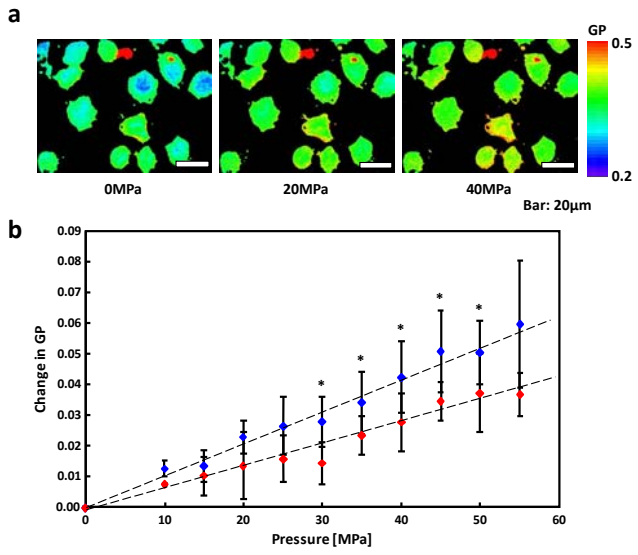

Figure 1. Changes in Plasma Membrane Fluidity by HP Loading a: representative lauedan GP images b: linear relationship between HP and changes in GP

Membrane mechanical properties are critical in modulating nutrient and metabolite exchange as well as cell signaling. The plasma membrane is predominantly composed of lipids, cholesterol and proteins, and its fluidity is tightly regulated by cholesterol and lipid desaturases. Hydrostatic pressure is known to affect membrane fluidity in microorganisms. To determine whether membrane fluidity was also altered in mammalian cells under pressure, we investigated the effects of pressure on membrane fluidity and desaturase expression in mouse chondrogenic ATDC5 cells. We describe the methods, results and conclusion on this membrane fluidity experiments under hydrostatic pressure loading, as follows.

METHODS

To measure membrane fluidity, ATDC5 cells were stained with the fluorescent probe Laurdan and pressurized from 0 to 55 MPa in a windowed culture chamber mounted on a fluorescence microscope. Laurdan was excited at 340 nm and the emitted light was collected by the blue and green channels of a CCD camera, respectively giving two intensity values IB and IG; membrane fluidity was assessed by calculating the Laurdan Generalized Polarization (GP) using the formula GP = (IB-IG) / (IB+IG). For gene expression analyses, cells were pressurized for up to 24h in another pressure chamber placed inside a 37°C water bath and PCR was performed to measure the expression of the desaturase genes Fads1, Fads2, Scd1 and Scd2.

RESULTS AND DISCUSSION

Laurdan imaging of pressurized ATDC5 cells showed a linear increase in the Laurdan GP, and hence a decrease in fluidity, under increasing pressure as shown in Figure 1. PCR analyses showed that ATDC5 cells under 10 or 20 MPa for 24h saw a significant decrease in the expression of all four desaturases under study. Cholesterol, which also decreased membrane fluidity, had a similar effect but removing cholesterol from the plasma membrane did not affect the desaturase down-regulation under pressure.

CONCLUSIONS

These results show that hydrostatic pressure affects mammalian cell membrane properties and suggest that the lipid membrane itself could play a leading role in pressure mechanotransduction.

P451 - DEVELOPMENT OF A NOVEL TISSUE-ENGINEERED MATERIAL COMPOSED OF MESENCHYMAL STEM CELLS AND COLAGEN FIBRIL

INTRODUCTION

Mesenchymal stem cells (MSCs)-based self-assembled tissue (scSAT) has great potential as a repairing material for cartilage tissue[1-2]. However, the collagen density and amounts of extracellular matrix elements contained in the scSAT are insufficient for clinical application. It is known that cultivation of MSCs in collagen gel is one of major methods for generating tissue repair material and tendon. In addition, it has been reported that fibroblasts can remodel a hydrated collagen lattice to a tissue-like structure[3]. However, the density of collagen and mechanical property of the constructs produced in collagen gel are low. To solve these problems, we focused on the result that self-assembled collagen was obtained in collagen-dissolved acidic solution neutralized at 37°C[4]. In the present study, we have developed an aggregate consisting of mesenchymal stem cells and collagen fibril as a novel tissue-engineered material. The structural properties of the aggregate were analyzed.

METHODS

Porcine dermal collagen-suspended acidic solution of 3 mg/mL (collagen solution) was neutralized by a medium (Dulbecco's modified Eagle medium (DMEM) supplemented with 10% fetal bovine serum, 100 U/mL penicillin, 100 μg/mL streptomycin, and 2 mM L-ascorbic acid 2-phosphate). The mixture was incubated for 1 day at 37°C to obtain self-assembled collagen. Meanwhile, MSCs were obtained from synovial membranes derived from human knee joints. After 4-time passage, self-assembled collagen and MSCs at a density of 4×10^5 cells/cm^2 were put on a Millicell® cell culture insert (cell insert) installed on a 6-well culture plate. They were dehydrated by centrifugation of 1,000 rpm, then the aggregate of self-assembled collagen and MSCs (fibril/MSCs) was cultured in the medium for 7 days. For comparison, a composite of collagen gel and MSCs (gel/MSCs) was also prepared as a control. A mixture of 3 mg/mL collagen solution, quintuple-concentrated DMEM, and 37 g/L $NaHCO_3$ in a ratio of 7:2:1 were mixed on ice to make collagen gel. The gel solution and MSCs at the density of 4×10^5 cells/cm^2 were put on the cell culture insert installed on a 6-well culture plate and cultured for 7 days. After cultivation, the structure of both fibril/MSCs and gel/MSCs were observed using a scanning electron microscope (SEM).

RESULTS AND DISCUSSION

Gross appearance of fibril/MSCs and gel/MSCs were shown in Figs. 1(a) and (b). The gel/MSCs composite was extremely soft due to a large amount of water. On the other hand, the fibril/MSCs exhibited a sheet-like tissue having fibrous structures. SEM images of the fibril/MSCs and gel/MSCs were shown in Figs. 1(c) and (d). The surface of gel/MSCs exhibited a gently undulated structure uniformly consisting of fine fibrils of approximately 10 μm in diameter. In contrast, the surface of fibril/MSCs had a 3-dimentionaly complex, hierarchial structure consisting of fine fibrils and thick fascicles of approximating 10-50 μm in diameter.

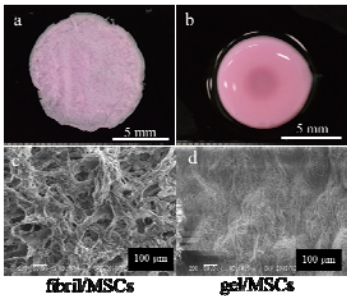

Figure 1: Gross appearance of (a) fibril/MSCs and (b) gel/MSCs. SEM images of the surfaces of (c) fibril/MSCs and (d) gel/MSCs.

It has been reported that the collagen obtained in collagen-dissolved acidic solution neutralized at 37°C was ranged from 1 μm to 5 μm in diameter[4]. It is considered that the thick, collagen fascicle-like structure observed in the specimen of fibril/MSCs was generated from MSCs. Such structure was not observed in the specimen of gel/MSCs. It is, therefore, suggested that the generation of collagen structure is more active in fibril/MSCs than in gel/MSCs, possibly due to the effect of centrifugal treatment in the production process of fibril/MSCs. This feature of fibril/MSCs is beneficial to the improvement of the structural property of scSAT.

CONCLUSION

In this study, we have developed a fibril/MSCs aggregate via culturing MSCs with a collagen fibril-suspended, neutralized medium. The aggregate has abundant MSCs and matured hierarchial fibril- and fascicle-scale collagen structure. Therefore, it is suggested this aggregate has a potential as a novel tissue-engineered material for cartilage repair.

P452 - SIMILARITY OF KNEE MUSCLE SYNERGIES BETWEEN TWO DYNAMIC TASKS

[1]Teresa E. Flaxman, [1]Mohammad S. Shourijeh, [2]Tine Alkjaer, [2]Erik B. Simonsen, [3]Michael R. Krogsgaard, [1]Daniel L. Benoit

INTRODUCTION

The central nervous system is theorized to control numerous degrees of freedom of the body by a reduced set of activation signals called *muscle synergies*. Muscle synergies are suggested to represent basic neural mechanisms that are common across different dynamic conditions [1]. This study determined if two knee extensor dominant tasks that varied in demand levels and complexity but showed similar movement profiles would recruit common muscle synergies or if synergies were task specific.

METHODS

Twenty-two healthy adults performed 10 squatting and lunging tasks at a controlled speed. Electromyography (EMG) of ten muscles, kinematics and kinetics were collected and normalized to percent cycle (squats) or time spent on the force plate (lunges). Concatenated non-negative matrix factorization (CNMF) extracted muscle synergies and corresponding activation coefficients [2]. The number of synergies that reconstructs >90% of variance accounted for (VAF) in the original EMG data was extracted. Between task similarity of synergy vectors was assessed with interclass correlation coefficients ($ICC_{(1,k)}$). Similarity was accepted at ICC≥0.75. The uniqueness of each task's synergies was evaluated with cross-reconstruction [3].

RESULTS & DISCUSSION

Two muscle synergies were extracted from the experimental squatting data and three synergies from the lunging data (Figure 1). S1 (ICC=0.99) and S2 (ICC=0.79) of both tasks were statistically similar and could reconstruct the data of the opposite task. S1 of both tasks were dominated by quadriceps muscle weightings. Corresponding C1 profiles were statistically similar to knee extensor moment patterns (ICCs>0.75). Supported by previous work [4], $S1_{lunges}$ and $S1_{squats}$ are suggested to be specific for body support and movement control.

A "general" muscle synergy was observed in S2 of both tasks. Since the knee lacks sufficient muscular contributions to support against frontal and transverse plane loads, these synergies are co-activation strategies to support the knee throughout the task cycle. Lunging required an extra synergy ($S3_{lunges}$) to be recruited for heel strike and push-off phases. Recruitment of additional task specific synergies has been observed when tasks increase in complexity [1]. Considering non-contact knee injuries occur at time of impact and gastrocnemius activity is altered in populations with unstable knees [5], this extra synergy may provide insight into strategies of knee stabilization.

CONCLUSION

The consistency in synergy structure and function suggests muscle synergies represent moment generating or joint stabilizing motor modules that can be flexibly recruited to execute a variety of movements.

P453 - INFLUENCE OF STEM PROFILES ON DISTRIBUTION OF STRESS IN HIP-FEMUR IMPLANT

INTRODUCTION

Total hip arthroplasty (THA) is the key solution to persons who desire to attain the lively lifestyle after severe hip pathology. At present, hip arthroplasty is familiar to people and surgeons, however detailed knowledge in the field of mechanics, design, loading conditions in the hip and in computational methods are far more important in the auxiliary development of hip implant design and surgery. Although several causes were identified by the researchers for the failure of hip implants, stress induced in the hip implants during daily activities holds a significant value which leads to wear and loosening of the implants. During normal walking activity, the hip loading pattern varies from person to person based on their weight and the peak hip joint load leads to hip pathology [1]. Even though THA are carried out for hip joint failure, when compared with the natural joints the mobility and load transfer ability gets altered. This kind of alteration occurring through THA may limit the daily activities and acts as a root for misalignment of the implant [2].

Denoting to the above discussions, we made an investigation to identify the influence of cross-section of the stem in the stress distribution in the hip implants. Analyses were performed in the two types of stem geometry characterized as type A (without notch) and type B (with notch), which leads to identical geometry in implant contour but altered stem cross sections. The most commonly used bio material Ti6Al4V is considered for the stem and it is evaluated for idealized condition for comparison between the considered stem types.

METHODS

The geometric modelling of the hip implant follows the model from literature [3], with a design change to improve the performance of the implant in stress distribution. Analysis of the implant along with actual femur geometry leads to more computational time and mostly to the situation of memory error in the hardware. In this investigation, analogous to the femur, a cylindrical structure was considered to house the implant for analysis. A plate like arrangement is provided with the cylinder for supplementary constraint purpose, to make an idealized analysis. Poly methyl methacrylate (PMMA) polymer is considered for bone cement and the properties of cortical bone, Ti6Al4V and PMMA were obtained from available literatures. Physiological loading environments are binding data, for the performance investigation of hip implant.

According to the type of activity performed the loading pattern on the hip varies from 180 to 279 % of body weight (BW) [4]. An adult male having body weight of 85 kg under fast walking condition is considered for this analysis and a load of 2170 N, which corresponds to maximum hip joint load during walking is applied at the tip of the stem.

RESULTS AND DISCUSSION

The profile of type A, type B stems and their idealized test conditions used in this investigation are shown along with Von Mises stress (Figure 1). Stresses were measured at four different landmark spots (LS) in both the implants for comparison.

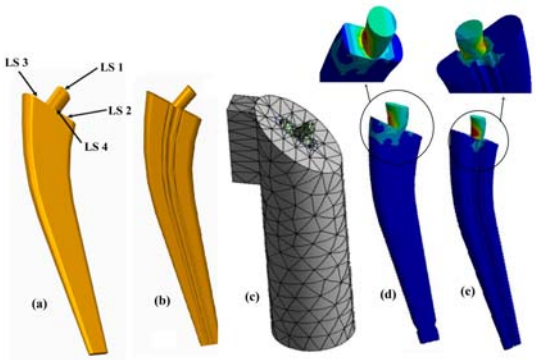

Figure 1: Stems with idealized conditions and results. (a) Type A stem, (b) Type B stem, (c) Idealized test condition, (d) Von Mises stress in stem without notch (e) Von Mises stress in stem with notch.

The Von Mises stress of 100 MPa and 95 MPa were obtained in type A and B stem at LS 1, thus a 5 % reduction in stress is observed in the stem with a notch. Stress of 49 MPa is observed at LS 2 in stem without notch, whereas 25 MPa in stem with notch, which provides a 48.97 % reduction in stress in stem with notch. Similarly, a 62.5 % stress reduction is noticed in notch profile stem at LS 3. At LS 4, stress of 58 and 45 MPa is observed in stem without and with notch respectively, which offered a 22.41 % of reduction in stress. By the execution of design and mechanics concepts in the type B stem, better stress reduction is obtained when compared with single notch stem explained in earlier literature [3].

CONCLUSIONS

In this work the influence of stem profile in stress distribution of hip implants by considering two types of stem profiles were investigated. Out of the two types of stems considered, a stress reduction of 62.5 % is achieved by the proper implementation of design criteria. Based on the results it is quantified that the stem profile has a major influence in stress developed in implants and the attained stress reduction in type B (without notch) stem promotes the life of implant by postpone the wear and loosening of implants.

P454 - THE VALIDATION OF A SWIMMING RELAY CHANGOVER-TIME MEASURMENT SYSTEM

[1] **Victoria Troster**, [1] Kevin Ball, [1] Emily Nicol and [1, 2] Elaine Tor
[1] Victoria University
[2] Victorian Institute of Sport
Corresponding author email: victoria.troster@live.vu.edu.au

INTRODUCTION

The effectiveness of the swimming relay event is highly reliant of the relay changeover-time [1,2]. This action is very short; however, those relay teams with shorter changeover-times can gain a competitive advantage ahead of those teams with an equal or shorter swim time [1,3,4]. A major challenge in executing a successful relay changeover is the ability to correctly time the movements of the incoming swimmer with those of the outgoing swimmer [4]. The "perfect" changeover is when the toes of the outgoing swimmer will leave the starting platform at the same instant as the incoming teammate's fingers touch the wall [3].

Recent research on feedback in sport has indicated that there has been a large shift towards real-time feedback during training. In addition, feedback needs to be considered from both a measurement and a relevance perspective while being task and performer specific [5]. Currently, there are no low-cost timing systems commercially available to provide real-time relay changeover feedback to athletes and coaches. This led to the development of the *Relay Test* (Superinteractive, Geelong, Australia) Apple iOS Application (App). The system connects directly into the Omega OCP5 touchpad and Omega OSB11 start block currently used at major swimming pools and competitions. Thus, the purpose of this pilot study was to determine if this *Relay Test* system is a suitable and reliable relay changeover-time measurement training tool.

METHODS

Three sub-elite athletes randomly performed the relay changeover using either the single-step or double-step start technique. A total of ten changeover-time trials were recorded for each of the two start techniques. Reliability and concurrent validity statistical analyses were undertaken using two customised spreadsheets created by Hopkins [6]. The time-validated video footage from two high-speed cameras (recording at 240 frames-per-second) were used as the criterion measurement. One camera filmed the start and the other was positioned underwater and recorded the incoming swimmer's fingers touch on the wall. Alternating athletes within the trials was considered acceptable as the aim was to assess the *Relay Test*'s ability to measure relay changeover-time compared to the criterion measurement.

RESULTS AND DISCUSSION

The reliability of the *Relay Test* system was calculated to determine its consistency and reproducibility. The overall ICC between the *Relay Test* system (practical) and the time-validated video (criterion) for both the two start techniques resulted in a very strong correlation (ICC = 0.99 with limits of agreement = 95%, respectively). Table 1 presents the relay changeover-time for both the single-start and double-leg starts.

Table 1: Relay Changeover-Times for Single and Double-Leg Starts

	Single-Leg Start		**Double-Leg Start**	
Trial No.	**Relay Test (s)**	**Video (s)**	**Relay Test (s)**	**Video (s)**
1	0.34	0.35	0.16	0.11
2	-0.08	-0.15	0.54	0.52
3	0.15	0.17	-0.01	-0.10
4	0.34	0.33	-0.22	-0.23
5	-0.07	-0.05	0.45	0.40
6	0.01	0.03	0.03	-0.06
7	0.24	0.25	0.02	0.01
8	0.03	0.04	0.41	0.41
9	0.01	0.00	-0.22	-0.21
10	0.33	0.32	-0.17	-0.17
MEAN	0.13±0.17	0.13±0.18	0.07±0.28	0.10±0.28

Concurrent validity analysis was assessed to ensure the *Relay Test* system's ability to measure relay changeover-time. For both start techniques, the regression equation returned an R^2 value of 0.98 which was interpreted as a very high correlation. Also, the standardised typical error estimate was interpreted as small according to Hopkins [6]. This indicated that the differences between the practical and criterion measurement will have small practical significance to the relay changeover-times displayed on the *Relay Test* App.

CONCLUSIONS

This study aimed to examine relay changeover-time data measured from a novel *Relay Test* App. The findings from the reliability and concurrent validity analyses indicated that the system could be suitable for practical application using one particular Omega OCP5 touchpad and Omega OSB11 start block. Coaches and athletes were given an indication of the reproducibility of the *Relay Test* system to measure relay changeover-time within the training environment (providing the adequate functionality of the Omega OCP5 touchpad and Omega OSB11 start block) and has opened further research and development opportunities.

P455 - CHANGE IN THE POSITIONAL RELATIONSHIP BETWEEN THE ACTIN CYTOSKELETON AND THE CELL NUCLEUS DURING OSTEOGENIC DIFFERENTIATION

Hiromi Miyoshi
RIKEN Center for Life Science Technologies
hiromi-miyoshi@riken.jp

INTRODUCTION

It is well known that the actin cytoskeleton provides mechanical support and endogenous force generation for cell shape determination and migration. Furthermore, it has been demonstrated that the actin cytoskeleton is related to cell fate, specifically proliferation and differentiation [1].

The actin cytoskeleton is connected with the nucleus through inner nuclear membrane proteins. The membrane proteins interact across the luminal space with other nuclear envelope proteins such as lamins, which form stable nuclear structures and can bind to chromosome DNA. Through this link, the mechanical force is assumed to be directly transmitted to the nuclear interior. This link changes nuclear morphology and intra-nuclear architecture, specifically chromatin recombination, nuclear matrix distortion, and DNA melting, which lead to alter the nuclear transportation of soluble signaling intermediate, and transcription events. Thus, it is important to clarify how actin cytoskeleton links to the cell nucleus, in order to understand the mechanism of the actin cytoskeletal control of the cell proliferation and differentiation.

In this study, the change in the positional relationship between the actin cytoskeleton and the cell nucleus during osteogenic differentiation was evaluated by a confocal microscopy.

METHODS

Bone marrow derived human mesenchymal stem cells (Lonza) were plated on a cover slip and cultured in mesenchymal stem cell growth medium (Lonza). Osteogenic differentiation medium is used for the osteogenic induction.

For the visualization of the positional relationship between the actin cytoskeleton and cell nucleus, fluorescent staining was performed by fixing cells in 4% paraformaldehyde. Cells were washed and permeabilized with 0.2% Triton-X, and blocked with 0.2 % gelatin in PBS. After several washes, the cells were incubated with Alexa Fluor488 phalloidin (diluted 1:40, Invitrogen) for 1 hour, and then incubated with 1μg/ml DAPI. The fluorescent images were acquired using a confocal laser scanning microscope (FV3000, Olympus) with a 60× 1.42 NA oil immersion objective lens.

RESULTS AND DISCUSSION

The organization of the actin cytoskeleton and the distribution pattern of the DNA changed during the osteogenic differentiation.

Thick actin stress fibers traversing along the cell were observed in the MSCs before the induction of the osteogenic differentiation. The stress fibers were formed in the lateral sides of the nucleus, and were less on the top of the nucleus. The shape of the nucleus projected from top of the cell was ellipse (Fig. 1a). The orientation direction of the actin stress fibers and the major axis direction of the nucleus were almost the same. DNA density was high at the periphery of the nucleus, compared with the inner nuclear (Fig. 1a).

Seven days after the osteogenic differentiation induction, the thick stress fibers traversing along the cell were observed. Different from MSCs before differentiation, the stress fibers running across the top of the nucleus were formed in the cells after the differentiation induction. The surface of the nucleus under the traversing actin stress fibers were depressed. The shape of the nucleus projected from the top of the cell was ellipse (Fig. 1b), but the peripheral shape was more irregular compared with the MSCs. The orientation direction of the actin stress fibers and the major axis direction of the nucleus were almost the same. The DNA accumulation at the nuclear periphery was not observed in the cells seven days after the differentiation induction (Fig. 1b).

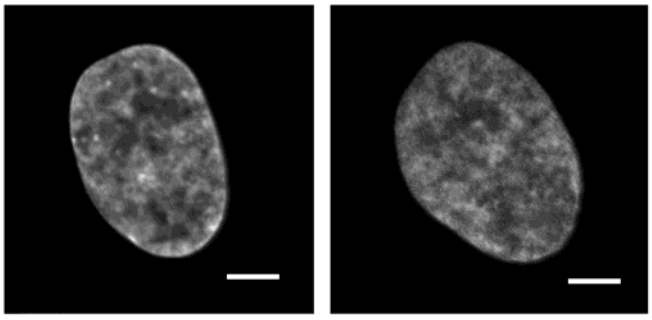

Figure 1: DNA distribution of the cell nucleus in (a) a MSC, and (b) a MSC after seven days of osteogenic differentiation. Scale bars, 5 μm.

CONCLUSIONS

The observation of the actin cytoskeleton and the cell nucleus demonstrated the formation of the stress fibers traversing on the top of the nucleus during the osteogenic differentiation. The dorsal stress fibers could lead to change in the DNA distribution in the nucleus during the osteogenic differentiation. The results will be a basis to understand how intranuclear DNA architecture is affected by the mechanical force in the actin cytoskeleton during the osteogenic differentiation.

P456 - COMPARE LOWER EXTREMITY ELECTROMYOGRAPHY DURING LANDING AFTER VOLLEYBALL BLOCKING

[1,2]**Liu Tsun-Te**, [1]Tang Wen-Tzu,* and [1]Lin Yi-Chun
[1]National Taiwan Sport University
[2]Tamkang University
Corresponding author email: wentzutang@gmail.com

INTRODUCTION

A non-contact anterior cruciate ligament (ACL) injury is both a serious and common problem in volleyball. The combination of high ground reaction forces and the high frequency of jumping and landing during practice sessions and games are thought to be significant determinants of injury[1].

There are several landing techniques used by volleyball players during successful or unsuccessful blocks. Two of these are the 'stick' and the 'step-back' techniques. Players usually use a 'stick' landing after a successful block and a 'step-back' landing after an unsuccessful block [2]. Both the stick landing and the step-back landing can have an impact on biomechanical factors that present a risk for the occurrence of ACL injuries.

The aim of the study is to compare two landing movements (stick VS step-back) on muscle activation level of lower limbs and the difference of the ground reaction force .

METHODS

A single elite male volleyball players participated in the study. None of the subject had a history of hip, knee or ankle surgery within the previous 6 months.
Two force plates (AMTI, Massachusetts, USA). embedded in the floor were used to determine the ground reaction force, with a sampling rate of 1000 Hz. The gluteus maximus, iliopsoas, rectus femoris, biceps femoris, vastus medialis, vastus lateralis, tibialis anterior and gastrocnemius muscles
Were assessed by means of surface electromyography.The experimental setting was based on a real game situation. There was a male volleyball net installed in the laboratory. The upper edge of the net was set 2.43m above the floor. To normalise the height of the jump, a static volleyball was suspended in the space above the net.

The subject performed a jump and block of the static ball above the net. A standing calibration trial was carried out, after which the subject had to perform three successful attempts at a stick landing and three successful attempts at step-back landing(with the right lower extremity stepping back away from the net).

The SEMG signal was analyzed in a period corresponding to a movement cycle: an interval of 200 ms before the time of impact and 200 ms after the time of impact .

The raw electromyography signal was rectified and the root mean square (RMS) values were calculated in the pre-landing phase and in the post-landing phase. Those values were normalized by the MIVC of the full-wave rectified signal.

RESULTS AND DISCUSSION

The aim of the study is to compare two landing movements (stick VS step-back) on muscle activation level of lower limbs and the difference of the ground reaction force .
The main finding of the study is maximum force showed at the First Peak ground reaction force, and it was greater during step-back landing on the right lower limb than stick landing.

ACL injury appears to occur most often just after the initial contact with the ground or during passive loading when F1 occurs [3].

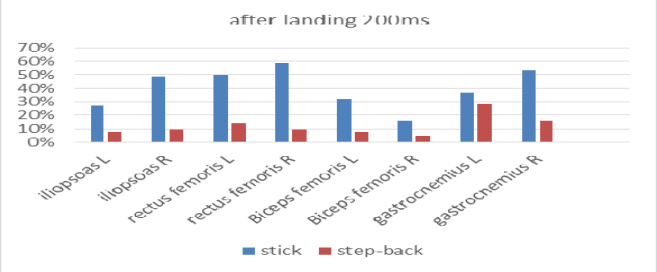

Figure 1: The muscle activation level of lower limbs after landing.

F1 was the time period 200 ms after the time of impact on muscle activation. The RMS values and the timing of onset activity were calculated for the eight studied muscles. the step-back landing presented a lower RMS value post-landing for iliopsoas, rectus femoris, biceps femoris, and gastrocnemius muscles.
The quadriceps and gastrocnemius act as ACL antagonists and may increase PATSF along with resultant ACL loading when the muscles contract, and the hamstrings are an ACL agonist and reduce ACL loading by directly offsetting PATSF[4].

CONCLUSIONS

This study measured the EMG activity and ground reaction force to compare the difference in stick landing and step-back landing, and concluded the lower extremity may be exposed to a risk of ACL injury when stepping back from the net during the initial impact phase after a step-back landing.

P457 - DEVELOPMENT OF AN INFLATABLE SHOULDER REHABILITATION DEVICE FOR HOME CARE USE

Tainsong Chen, Mei Yu Liu and Lan Chin Shiech
National Cheng Kung University
Tainan, Taiwan
Corresponding author email: chents@mail.ncku.edu.tw

INTRODUCTION

Cerebrovascular disease is commonly known as stroke and is ranked as third in the top 10 leading causes of death in Taiwan. According to the Ministry of Health and Welfare in 2007, the prevalence rates of hypertension and hyperglycemia increase with age. Changes in the age composition of the Taiwanese population will lead to it becoming an aged society by 2018 and a "hyper-aged" society by 2025. Therefore, it can be inferred that the Taiwanese society will encounter severe public health problems regarding stroke and post-stroke rehabilitation needs. To counter this, many studies have proposed early passive movement and shown that providing support and protection in the flaccid stage can prevent immobility and soft tissue contracture, and minimize the risk of hemiplegic shoulder pain. Rehabilitation places a heavy burden on physical therapists because a one-on-one interaction with the patient is required (1, 2). The purpose of our study is thus to develop a low-cost and portable rehabilitation device for the rehabilitation of patients at home. Home-based rehabilitation is not only more convenient but also reduces the cost of rehabilitation and burden on physical therapists.

METHODS

The rehabilitation device we developed produces shoulder abduction and adduction by inflating and deflating airbags in the device. The device includes one inflatable vest (using Velcro to fix the vest on the body, being suitable for either arm) and one control box. The control box has three mode buttons: modes I/II/III. Patients simply need to wear the inflatable vest and press the particular mode button as advised by a physical therapist. Then, the rehabilitation device helps patients to complete passive movement. The results of a system stability test showed that the lifting angle variation of our device under different external forces (0–3 kg) was below 3°. It appears that our device has good suitability for users with a wide range of body weights. A positive correlation between external force (0–2 kg) and the pressure in the airbag was identified in a loading vs. airbag pressure experiment. If the same patient's pressure in the airbag steadily rises during the course of rehabilitation, close attention should be paid to the increase in muscle tension. Our shoulder rehabilitation device is one of the most cost-effective and user-friendly devices for stroke patients to perform the passive movement rehabilitation at home.

RESULTS AND DISCUSSION

The system has been implemented and the system configuration shown in Figure 1. This rehabilitation device can provide a simple way for passive shoulder movement training for the stroke patients. The information of the rehabilitation process can be sent to clinics or hospital through WIFI transmission.

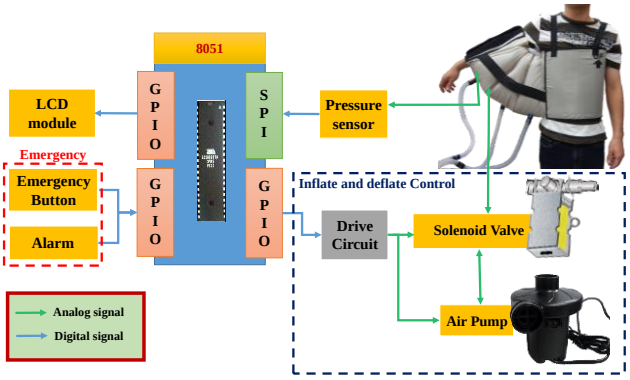

Figure 1: The system configuration

CONCLUSIONS

The developed inflatable shoulder rehabilitation device has good suitability for users with a wide range of body weights. The experiment shows that the lifting angle variation of our device under different external forces is below 3°. In other words, our device can lift most users' arm to almost 90°, which is the maximum setting angle of this proposed device. Finally, it is more safe and smooth than the robot-aided shoulder movement therapy.

P458 - PELVIC FLOOR MUSCLE KINEMATIC PROFILES DIFFER BETWEEN WOMEN WITH AND WITHOUT STRESS URINARY INCONTINENCE

[1] **Catriona S. Czyrnyj**, [1]Michel R Labrosse and [2]Linda McLean
University of Ottawa, Departments of Mechanical Engineering[1] and Rehabilitation Sciences[2]
Corresponding author email: lmclea2@uottawa.ca

INTRODUCTION

Stress urinary incontinence (SUI), the leakage of urine during tasks that increase intra-abdominal pressure (IAP), affects up to 25% of women. This multifactorial disorder is thought to arise from some combination of defects in urethral sphincter function, urethral support, and pelvic floor muscle (PFM) mechanics. The contributions of the PFMs to continence control are currently not well understood.

Transperineal ultrasound (TPUS) imaging has been used to evaluate connective tissue defects, but only one other research group has reported on urogenital kinematic profiles for the purposes of evaluating PFM function. Jones et al. showed differences in the displacement of the anorectal angle (ARA) in women with and without SUI, during coughing [1]. Using our UROKIN software [2], we have the capacity to investigate the biomechanics of the urogenital system to gain a better understanding of pelvic floor mechanics during functional tasks. The purpose of this work was to assess the feasibility of using kinematic profiles generated by the UROKIN software to study differences in PFM function between women with and without SUI.

METHODS

Our local institutional research ethics board approved this study and all women provided written informed consent prior to participating. As part of a larger protocol, women underwent a clinical assessment of PFM strength (Modified Oxford Scale; MOS) and TPUS images were acquired using a GE Voluson-i (GE Healthcare, Canada) system in B-mode. A 3D curvilinear probe (8-4MHz) was used for all imaging, with acquisition angle set to 85°. Participants were imaged in supine while they performed three repetitions of a maximum voluntary contraction (MVC) of their PFMs.

TPUS data were processed using the UROKIN software [2] to yield kinematic curves for several urogenital landmarks. ARA displacements are presented for the purposes of this study. Curves were normalized from rest to 90% of the peak shortening of the levator plate, and were averaged across each group. The magnitude and timing of peak ARA displacements were compared between groups using Student's t-test or Wilcoxon rank sum, as appropriate, and correlations were tested using Spearman's Rho (α=0.05).

RESULTS AND DISCUSSION

Women with SUI were similar to those with no history of SUI in terms of age (47±2 vs 38±3 years) and body mass index (23±1 kg/m^2 vs 26±1kg/m^2), but had lower PFM strength (MOS 3±0.1 vs 4±0.1, $p<0.001$). Compared to the control group, the women with SUI exhibited less anterior displacement (control 12±1mm, SUI 8±1mm, $p<0.01$) and earlier peaks in cranial motion (control 77±9%; SUI 56±7%, $p<0.05$) of their ARAs (Figure 1). The magnitude of the peak anterior displacement (Rho=0.65, $p<0.001$) and the timing of the peak cranial lift (Rho=0.48, $p<0.01$) of the ARA were moderately correlated with PFM strength.

Between-group differences in anterior motion of the ARA during PFM MVC suggest that women with SUI have less capacity to shorten their PFMs, likely reflecting weakness of the pubovisceral component of the levator ani group. Despite evidence that the PFMs are still actively contracting (i.e. continued shortening of the levator plate), in the women with SUI, the cranial motion of the ARA plateaus roughly halfway through the task. This finding may point to weakness or connective tissue restrictions within the iliococcygeus component of the levator ani group, as its attachments and orientation suggest that it is primarily responsible for lifting and/or supporting the pelvic organs.

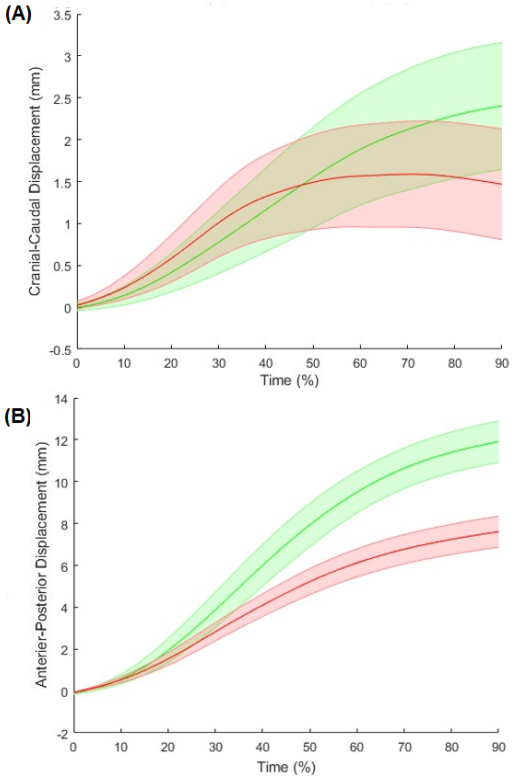

Figure 1: The (A) cranial-caudal and (B) antero-posterior displacement of the anorectal angle during maximum pelvic floor muscle contraction in women with (red) and without (green) stress urinary incontinence (red).

CONCLUSIONS

Using UROKIN, differences between women with and without SUI were detected in the magnitude and timing of anterior and cranial ARA motion during PFM MVCs. These results support the feasibility of UROKIN as a robust approach to the biomechanical assessment of PFM function.

P459 - SIMULATION OF PLATELET AGGREGATION ON ORIFICE FLOW BY DISSIPATIVE PARTICLE DYNAMICS

[1] **Yingming Yi**, and [1]Masaaki Tamagawa
[1]Kyushu Institute of Technology
Corresponding author email: yi-yingming@edu.life.kyutech.ac.jp

INTRODUCTION

White thrombus is one of the serious problems in the development of artificial organs. White thrombus is mainly composed of platelets. Platelet activation, deposition and aggregation are the three important steps in the formation of thrombus. Platelet activation and deposition have been simulated using concentration transport model by our previous work[1]. It was solved by finite difference method(FDM). However, FDM cannot be used to simulate particle dynamics because FDM is an Eulerian method. And platelet aggregation can be expressed by a kind of particle dynamics. On the other hand, other researchers successfully simulated platelet aggregation by dissipative particle dynamics[2]. But they cannot simulate other steps, such as platelet activation and deposition.

Thus in this paper, (i) assuming that platelets are particles, dissipative particle dynamics (DPD) is used to simulate platelet aggregation on orifice flow, (ii) the combination of DPD and FDM will also be proposed to simulate the whole steps in thrombosis.

METHODS

Orifice pipe is the computational target in this research. The diameter of the pipe is 2.2cm, and the length of the fluid domain is 20.7cm. Inlet flow rate is 5 L/min, which corresponds to 5300 for Reynolds number. Launder-Kato k-epsilon turbulent model is used for the computation of flow field. And dissipative particle dynamics (DPD) is used for the simulation of the movement of platelets on the flow.

In this DPD, the motion of each platelet is described by the Newton's law equation[2]. The force on i^{th} platelet includes two terms, they are (i) the force exerted by the fluid and (ii) interaction force with other platelets as in equation(1):

$$\mathbf{F}_i = -\frac{4}{3}\pi a^3(\rho_p - \rho)\frac{d\mathbf{V}_i}{dt} + \mathbf{F}_{interaction} \quad (1)$$

In equation (1), a is platelet radius. ρ_p and ρ are density of platelet and the suspending fluid. $\mathbf{V}_i$ is the velocity of i^{th} platelet, obtained from a local, volume-averaged fluid velocity. $\mathbf{F}_{interaction}$ is the force exerted between the i^{th} platelet and other platelets or the vessel wall surface. In this simulation, 1514 platelets are set uniformly in the fluid region. In addition to that, 168 platelets are set on the wall to simulate platelet aggregation on the wall. And cyclic boundary condition for inlet and outlet is used, which means that platelets which go out the outlet are set at the corresponding position of inlet to keep the constant number of platelets in the fluid domain.

For the next step, this DPD will be combined with FDM. By DPD, the aggregation of platelet on the wall can be simulated, and the aggregation on the wall can be described as the probability to fix platelets on the wall. By FDM, the deposition of activated platelet(AP) can be simulated, and the deposition can be described as the probability to obtain activated platelets from the fluid. And the product of probability(from DPD results) and deposition number of AP (from FDM results) can be thought to be the aggregation of AP on the wall.

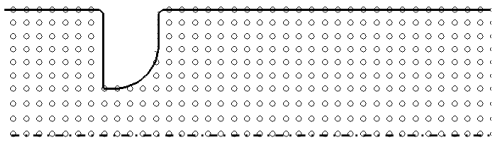
The aggregated number of activated platelets($M_{agg}(x,t)$) is the product of the probability of aggregation($P(x)$) and the deposition number of activated platelets($M_{dep}(x,t)$) as follows:

$$M_{agg}(x,t) = P(x) \times M_{dep}(x,t) \quad (2)$$

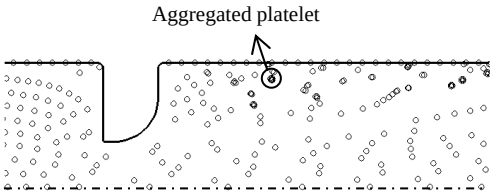
After getting $M_{agg}(x,t)$, total aggregated number of activated platelet will be computed, and its initial gradient will also be computed.

RESULTS AND DISCUSSION

Figure 1 shows the position of platelets at 0s and 0.2s on orifice flow. As is shown in figure 1(a), platelets are uniformly distributed in the flow at first. Figure 1(b) shows the position at 0.2s. It is found that some of them keep separated in the flow, others get aggregated and become clusters. It is also found that more platelets aggregate in the low velocity area. It is thought that the aggregated platelets near the wall have the high probability to adhere on the wall. The adherence will cause thrombosis.



(a) 0.0s



(b) 0.2s

Figure 1: Position of platelets on orifice flow at different time (radius of platelets has been enlarged)

CONCLUSIONS

It is concluded that (i) DPD model is an effective method to simulate the motion of platelets on orifice flow, (ii) the aggregation of platelets occurs during their motion.

P460 - HAND-BIKE: EXPERIMENTAL ESTIMATION OF THE DYNAMIC PARAMETERS OF THE UPPER LIMB

[1]Ghazaleh Azizpour, [1]Abdelmajid Ousdad, [1]**Giovanni Legnani**, [1]Matteo Lancini, [1]Giovanni Incerti and [2]Paolo Gaffurini
[1]University of Brescia
[2]Rehabilitation service, Casa di cura Domus Salutis, Brescia
Corresponding author email: giovanni.legnani@unibs.it

INTRODUCTION

Hand-bikes are three-wheel, hand-propelled vehicles used by people injured in the lower limbs. They are used as a locomotion aid, or as sport equipment even at Paralympic level [1]. Optimization of the vehicle and of its users performance may be supported by dynamic analysis [2]. This kind of study of hand biking requires a good dynamic model of the upper limb. By measuring the forces generated by the hands on the handles and by measuring the arm movements, it is possible to estimate the joint torques generated by the muscles. As a consequence, the total handle forces can be split in different contributions: muscle action, gravity (weight) and dynamic actions. Further developments permit the estimation of the forces exchanged in the human joints. This may contribute to a better understanding of the human motion, in obtaining information for the vehicle optimization, to improve performances or to reduce the risk of injuries for unsuitable cycling style [3]. However, the parameters of the model are generally difficult to be assessed and the use of anthropometric data from literature may result in inaccurate results [4]. This study presents a methodology called "passive test" to perform personalized experimental estimation of the dynamic parameters.

METHODS

The execution of the "passive test" is simple and requires only instrumentation already available in a lab equipped for standard dynamic analysis of handcycling: force sensors in the handle and a camera based motion capture. An optional EMG recording system may support additional verifications. The subject sits in the handbike with one of his/her hand on the handle and relaxed muscles. Straps can be employed to assure the contact even with relaxed muscle. The crank is rotated by an external operator using the other handle. The camera system measures the motion of the arm and the force sensor measures the actions of the handle of the subject under test. Finally, the dynamic parameters of the arm (masses, center of mass, moment of inertia) are evaluated by applying a suitable model to the collected data. In fact, there is a unique combination of the dynamic parameter values that may explain the measured force given the measured movement. By adapting dynamic models used in robotics, the joint torques generated by muscles ($C_q = [c_{shoulder} \quad c_{elbow}]^t$) can be written as[2,5]:

$$C_q = BP - J^t F_{ext} \qquad (1)$$

where B is a suitable matrix depending on the dynamic model and including also the effect of weight, P the vector of the dynamic parameters, J^t is the transpose of a suitable jacobian matrix and F_{ext} is the force at the handle $F_{ext} = [fx \; fy]^t$. Since during the test the muscles are relaxed $C_q = 0$, and so the dynamic parameters are estimated as:

$$P = B_e^+ J^t F_{ext} \qquad (2)$$

where B_e^+ is the pseudo inverse of an extended B matrix containing data from several acquisition instants.

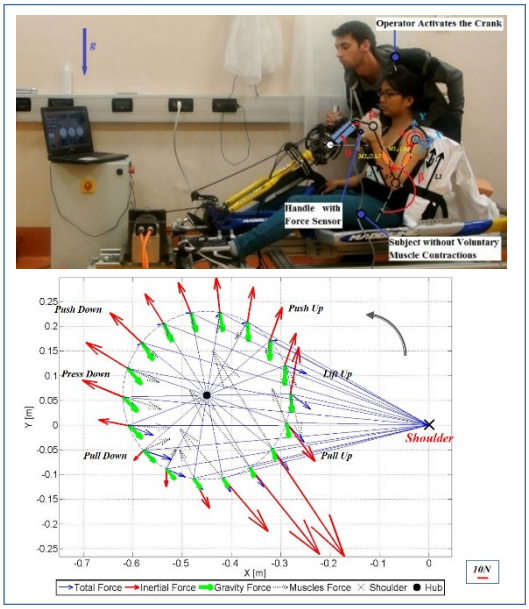

Figure 1: *Top: passive test and details of the model. bottom: the different forces contributions on the handle during an active test.*

RESULTS AND DISCUSSION

Figure 1 top shows the proposed model containing two rigid links articulated by two planar revolute joints (elbow and shoulder). This model considers the motion in the sagittal plane and forms a closed kinematic chain with the HB. Once P is known, by using equation (1) it is possible to evaluate all the contribution (dynamic, weight and muscle) of the forces during normal use of the hand-bike (figure 1 bottom).

CONCLUSIONS

The proposed methodology is a useful tool to estimate personalized sets of dynamic parameters of the upper limb. The test is quite simple and requires just instrumentation which is available in biomechanics lab equipped for experimental analysis of sport biomechanics. It has been successfully applied to several subjects using hand-bikes.

CLINICAL TRIAL OF MICROPROCESSOR-CONTROLLED KNEES IN TRANSFEMORAL AMPUTEES

[1]**Kenton R. Kaufman**, [1]Kathie Bernhardt, and [2]Kevin Symms
[1]Mayo Clinic
[2]Hanger Clinic
Corresponding author email: kaufman.kenton@mayo.edu

INTRODUCTION

The benefits of a microprocessor-controlled knee (MPK) have been well documented in Medicare Functional Classification Level (MFCL) K3 transfemoral amputees (TFA). There have been suggestions that a K2 level TFA will also benefit from this advanced technology by increasing their ambulatory functional level to an unlimited community ambulator (K3) when receiving a MPK [1-5]. Current medical policy restricts MPKs to K3 or K4 amputees and, thereby, potentially limits functional capabilities. Therefore, the purpose of this study was to determine if K2 amputees would benefit from a MPK.

METHODS

Study Design: A prospective clinical trial (A-B-A design) was conducted where only the prosthetic knee was changed. Each subject was tested at baseline using their current NMPK, fit with a MPK and allowed 10 week of acclimation before being tested, and then retested with their NMPK after 4 weeks of re-acclimation. The subjects were randomly assigned a MPK prosthesis from one of four manufacturers (Otto Bock Compact, Ossur Rheo, Endolite Orion, Freedom Innovations Plie). All prosthesis fittings were performed by the subject's own certified prosthetist according to the manufacturer's fitting guidelines with oversight provided by the manufacturer's representative.

Subjects: 50 unilateral transfemoral amputees over age 55 (mean age 69$\pm$9 years with 4 years' experience using a prosthesis) who were MFCL K2 (with 13 K3 exceptions) were studied. Subjects were excluded if they had neuromuscular problems, a partial amputation of the contralateral limb, were on dialysis, had poor prosthetic socket fit, or had residual limb breakdown. The majority of the subjects were using a Medi knee (53%) or an Otto Bock (3R60, 3R80, 3R90, 3R92, 3R93) knee (27%).

Outcome measures: Patient function was assessed in the free-living environment using tri-axial accelerometers (Actigraph GT3X, Pensacola, FL, USA) worn on the waist, thigh, and bilateral ankles for a period of four consecutive days. Patient satisfaction and safety was measured using the Prosthesis Evaluation Questionnaire (PEQ) and PEQ addendum (PEQ-A).

Data Analysis: A one-factor repeated measures ANOVA was used to determine if there was a difference in outcomes between the MPK and NPMK. Statistical significance was attained when the p-value was <0.05.

RESULTS AND DISCUSSION

The subjects demonstrated improved outcomes when using a MPK. Patients reported a significant reduction in stumbles and falls when receiving a MPK (Figure 1). The subjects spent significantly less time sitting when using a MPK. The mean time/day sitting was 60% at baseline, 50% on the MPK, and 63% when returning to the NPMK. Subjects exhibited improved gait entropy (i.e. more complex movements) when using the MPK (baseline=0.17, MPK=0.29, NMPK=0.25). Subjects reported significantly improved appearance, less frustration and greater utility when using a MPK, as measured by the PEQ.

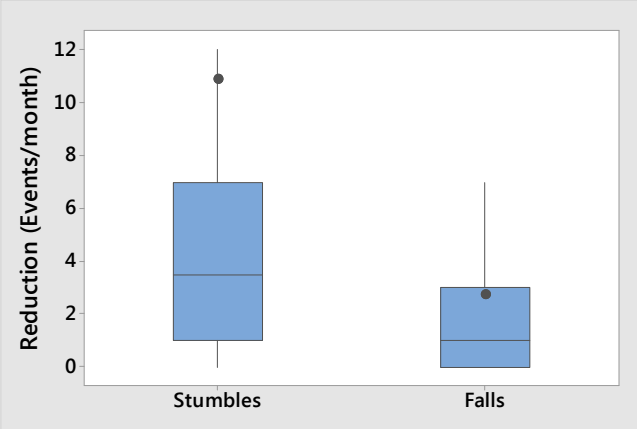

Figure 1: Box plot illustrating a reduction in stumbles and falls when using a MPK. The central line represents the median, the dot represents the mean, and the edges of the box are the 25th and 75th percentiles. The whiskers extend to $\pm$ 1.5 of the interquartile range.

This clinical trial demonstrated that K2 TFAs using a MPK improved their safety and activity, which resulted in increased subject satisfaction. Notably, a reduction in stumbles and falls occurred while the subjects engaged in more physical activity. The increase in activity resulted in a greater exposure to fall risk, but that risk was moderated by the advanced technology.

CONCLUSIONS

The study provides evidence that individuals with TFA and K2 mobility clearly benefit from a MPK.

REGIONAL MODULATION OF VASTI MUSCLE ACTIVITY IN RESPONSE TO ACUTE PAIN PERSISTS AFTER PAIN RESOLUTION

[1]**Alessio Gallina**, [2]Sauro Salomoni, [2]Leanne Hall, [2]Kylie Tucker, [3]S Jayne Garland, [2]Paul W Hodges

INTRODUCTION

Current pain-adaptation theories propose changes in motor strategies as a purposeful adaptation to reduce the stress on painful tissues [1]. As regions within the quadriceps muscle have potential to produce forces in different directions [2], changes in muscle activation may occur non-uniformly and depend on the location of the noxious stimulation.

The objective of this study was to investigate regional redistribution of EMG activation within the vasti muscles in response to noxious stimulation applied to different locations in muscular and non-muscular tissues around the knee. The persistence of altered motor strategies after pain resolution was also investigated.

METHODS

Fourteen participants performed an isometric knee extension task consisting of 5 contraction at 10% of the maximal voluntary contraction performed at baseline, during pain induced by a single bolus injection of hypertonic saline solution in four locations (FP: medial infrapatellar pad; VMD: distal vastus medialis [VM]; VMP: proximal VM; VL: vastus lateralis) and after pain recovery. Contractions were performed when the participants reported a pain level of at least 3/10 and again when pain recovered to 0/10. Surface EMG signals from VM and VL were collected using high-density surface EMG (electrode grids of 13x5 electrodes spaced 8mm), placed across each muscle [3]. The distribution of muscle activation was calculated as the average rectified value (ARV; 13x5 values for each muscle) of each channel of the grid during the hold phase of the ramp. For each condition, muscle activation was calculated as the average of the 5 highest channels of each grid. To characterize spatial variations of the EMG distribution in the pain and after-pain conditions, normalized change scores (NCS) relative to baseline were calculated as 100*(TRIAL-BAS)/BAS, where TRIAL is the ARV distribution during the pain or after-pain condition and BAS is the ARV distribution at baseline (Fig.1). The barycenter of the 5 channels with the lowest NCS was calculated and considered representative of localized inhibition. Friedman and paired Wilcoxon tests were run to test the effect of injection site on muscle activation, separately for VM/VL, during/after pain. Two-way ANOVAs were run to test the effect of location and pain condition on the position of the channels with lowest NCS for VM and VL separately; post-hoc testing was run by testing which conditions were significantly different from 7 (i.e.: the midpoint of the grid).

RESULTS AND DISCUSSION

VM muscle activation decreased by ~10% when VMD was injected (Friedman: P<0.05; Wilcoxon: P<0.01). No significant changes were observed when the other sites were injected or after pain. ANOVA identified a main effect of injection site on the location of the channels that showed large decrease of EMG activity in VM (P<0.05, Fig.1). Preferential inhibition of the distal region of VM was observed when VMD or VL were injected (both P<0.001), and after pain resolution (VMD: P<0.001, VLD and VMP: P<0.05). A main effect of pain/after-pain existed for VL (P<0.05). Preferential inhibition of distal VL was observed after resolution of pain when VL (P<0.001), VMP (P<0.01) and VMD (P<0.01) were injected. Spatial changes in the location of the activation within the vasti appear to persist after pain resolution.

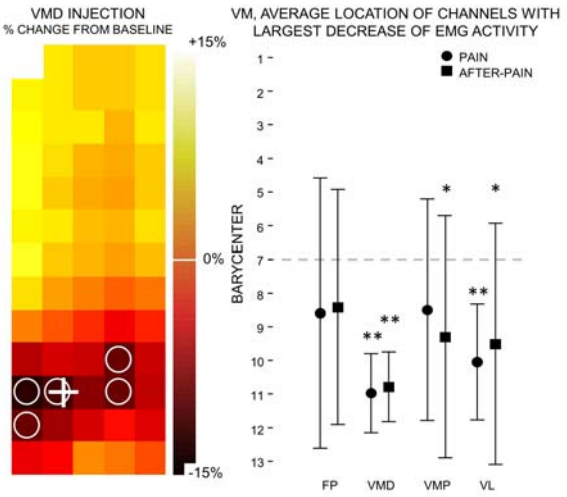

Figure 1: Left: normalized change scores map during VMD pain, channels with largest decrease in EMG activity (circles) and barycenter (cross). Right: Average location of the channels with largest EMG decrease in VM.

CONCLUSIONS

Modulation of vasti activation in response to acute muscle pain is non-uniform. Preferential inhibition of the distal VM can be observed during pain and after pain resolution. Preferential inhibition of the distal VL was observed after pain resolution only. This concurs with the hypothesis of specific reduction of tissue loading in the presence of a noxious stimulus, and implies that recovery of pain does not motivate recovery of motor strategy.

TOWARDS A COHESIVE, MULTI-SCALE UNDERSTANDING OF MOVEMENT BIOMECHANICS

Karl E Zelik
Vanderbilt University
email: karl.zelik@vanderbilt.edu

INTRODUCTION

A grand challenge in the field is to develop a cohesive, mul-ti-scale understanding of movement biomechanics. *Multi-scale* refers to our ability to examine, quantify and think about movement at various physiological measurement scales (e.g., molecular, cellular, muscle-tendon, joint or whole-body). Each scale offers a complementary perspec-tive. *Cohesive* signifies that our qualitative understanding at one scale should be consistent with our understanding at other scales. Likewise, our empirical estimates at one scale should be quantitatively consistent with estimates at other scales. Discrepancies between scales suggest inaccurate estimates or incomplete understanding.

Stated simply, biomechanical estimates should add up properly. If our empirical estimates at one scale are sufficiently accurate and comprehensive, then they should add up to reflect estimates at a larger scale. Similarly, biomechani-cal estimates at a larger scale should be decomposable into constituents at a smaller scale. For instance, I would like to be able to (i) quantify whole-body energy change during movement, then (ii) decompose this whole-body energy change into contributions from each individual joint- or segment-level work source, then (iii) further decompose work done about each joint into contributions from individual muscles, tendons and/or ligaments. Experimentally there are many sources of error in estimating biomechanical work and energy, so perfect quantitative agreement seems unreachable, but compatibility across scales seems like an admirable and attainable goal. Traditionally, whole-body biomechanics (i.e., composite dynamics of the entire biological system) represented the largest scale at which to examine human (or other organism) movement. However, wearable technologies such as prostheses and exoskeletons effectively introduce a larger scale, referred to here as the *augmented-body* scale (i.e., the entire human-device system). Augmented-body dynamics should also be decomposable into biological contributions from the person vs. synthetic contributions from the device; though to experimentally partition human vs. device contributions, care must be taken to account for human-device interface dynamics, as discussed more below.

METHODS

This abstract summarizes efforts to bridge between various scales of biomechanical understanding. My objective is to discuss progress, limitations and challenges related to coalescing: (i) joint and whole-body perspectives, (ii) whole-body and augmented-body perspectives, and (iii) joint and muscle-tendon perspectives. Several experiments on human locomotion will be discussed; though challenges and results presented are also believed to be relevant to non-human animals, to additional movement tasks, and to simulation-based efforts to advance multi-scale biomechanical understanding. One series of gait analysis studies sought to synthesize whole-body dynamics with joint-level dynamics by integrating various empirical estimates of work and energy. Another study explored human-exoskeleton interface dynamics to bridge between (biological) whole-body dynamics and augmented-body dynamics. Most recently, we have integrated ultrasound imaging with motion capture and force measurements in efforts to decompose joint dynamics into contributions from individual muscle-tendon units, and then to further partition muscle vs. tendon work.

RESULTS AND DISCUSSION

Discrepancies between whole-body energy change and summed joint work estimates indicated that energy absorption during the collision phase of walking (just after foot contact) may be dominated by soft tissues in the body [1], as opposed to by muscle or joint work. Corroborating evidence of soft tissue energy absorption has since been observed in experiments on jump landing, running, and obese vs. non-obese gait. Discrepancies between whole-body and joint work also suggested that conventional 3 degree-of-freedom (3DOF) inverse dynamics failed to capture a surprisingly large amount of positive work (e.g., >30% of the net posi-tive work done on/about the body's center-of-mass during the push-off phase of gait, [2]). We found that by extending commonly-used 3DOF inverse dynamics estimates to full 6DOF (rotational and translational power) analysis of the hip, knee, ankle and foot that we were able to resolve the work discrepancy [2]. The 6DOF analysis provided a more complete estimate of work production during walking, revealing that the hip and foot both contribute more to gait kinetics than conventionally estimated. These findings have important implications for assistive technology development and biomechanical simulations. In a separate study on robotic exosuits (soft exoskeletons), we found that in order to decompose augmented-body dynamics into biological vs. device contributions it was critically important to quantify and understand the human-device interface dynamics. The human-device interface absorbed and returned substantial amounts of energy (due to biological soft tissue deformation and synthetic material stretching), which affected estimation and interpretation of the biological work performed by the user [3]. Finally, our recent ultrasound imaging studies have reemphasized the complexity and difficulty of noninvasively partitioning joint kinetics into contributions from individual muscles and tendons [4]. Efforts are ongoing to resolve surprising discrepancies and to unravel non-intuitive findings.

CONCLUSIONS

A central theme of this work is that discrepancies between physiological measurement scales represent opportunities for new insights and learning. In my opinion we should acknowledge and embrace discrepancies, then collaborate to resolve them, in order to move the field closer to a cohesive, multi-scale understanding of movement biomechanics.

MECHANICAL AND BIOCHEMICAL ADAPTATIONS OF CARDIAC MUSCLE TO AEROBIC EXERISE TRAINING

[1] **Kevin R Boldt**, [1]Jaqueline L Rios, [1]Venus Joumaa and [1]Walter Herzog
[1]University of Calgary
Corresponding author email: krboldt@ucalgary.ca

INTRODUCTION

Adaptation of the heart in response to aerobic exercise training has important implications for sport performance, fitness, and health [1]. These adaptations manifest predominantly as structural changes to the heart: proportional increases in heart volume and ventricular wall thickness [2]. However, less is understood about how the heart muscle adapts mechanically and biochemically.

Shortening velocity and power output are dictated by the biochemical makeup (proportions of myosin heavy chain (MHC) isoforms α–MHC and β-MHC) of the actin-myosin crossbridges [3], with larger proportions of α–MHC leading to faster contraction rates and higher power outputs for a given resistance.

The purpose of this study was to evaluate the differences in power output of isolated cardiac muscle cells and MHC composition between hearts from sedentary and exercised rats.

METHODS

Twenty-four 3-month-old Sprague-Dawley rats were randomized into four groups: moderate duration exercise (MD) (n=6), high duration exercise (HD) (n=6), extra high duration exercise (EHD) (n=6), or no exercise (CON) (n=5). Animals were trained on a treadmill for 11 weeks at 25m/min. MD animals completed 30 minutes of exercise 5 days/week, HD animals completed 60 minutes 5 days/week, and EHD animals completed 60 minutes 7 days/week. In weeks 9, 10, and 11, EHD animals also completed 2, 3, and 4 sessions/day (up to 4 hours/day, 7 days/week). One week following the end of the exercise training, hearts were excised and strips of trabecular muscle were skinned in a 1% Triton solution. Half of each sample was frozen in liquid nitrogen for biochemical testing and the other half was dissected further for mechanical testing.

Mechanical testing consisted of isolating and attaching myocyte bundles on one end to a force transducer and at the other end to a length controller. Average sarcomere length was set to 2.4 µm using laser diffraction. Myocytes were maximally activated before the force was dropped to 90% of the maximum force, allowing the sample to shorten. The corresponding shortening velocity was measured. This protocol was repeated for 10% force decrements ranging from 10-100% of isometric force. Force-velocity data were fit to Hill's equation and peak power was calculated.

For biochemical testing, muscles were ground into a powder, dissolved in a sodium dodecyl sulphate buffer, and loaded into 0.75mm thick 7.5% acrylamide separating gels. Electrophoresis was run at 72V for 44 hours at 4°C. Gels were then stained with Coomassie Blue and scanned with a Biorad Calibrated Densitometer to determine relative concentrations of α–MHC and β-MHC isoforms.

Data were analyzed using one-way ANOVAs and Tukey's post hoc testing when indicated. Pearson correlations were conducted between peak power and %α–MHC. The level of significance was set a priori to α=0.05.

RESULTS AND DISCUSSION

There was a dose-dependent decrease in peak power output from the CON to MD and HD animals (p=0.038). However, this trend was reversed for the EHD animals (Figure 1; solid bars). Similarly, the same trend was present for the relative proportion of α–MHC to β-MHC, with a decreasing proportion of α–MHC from CON to HD, with a reversal for EHD (p=0.024) (Figure 1; lined bars).

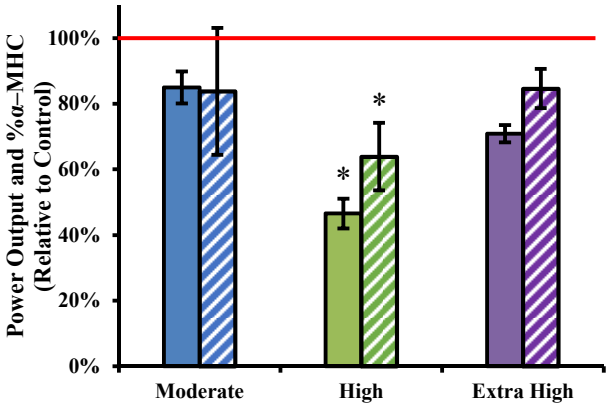

Figure 1: Peak power output (solid bars) and %α–MHC (lined bars) for animals following exercise training. Bars represent mean±SEM. Red line indicates mean control value. *indicates significantly different from controls.

A significant correlation between power output and MHC composition was observed (r=0.668, p=0.003). Therefore, adaptations to the MHC isoform expression are likely a significant mechanism for alterations observed in power output.

CONCLUSIONS

Our data suggest that adaptations of the heart to endurance exercise occur not only at the structural level [2], but also mechanically and biochemically within the muscle cell. Further, this adaptation appears to be dose-dependent, until exercise becomes excessive and adaptation is inhibited.

CHANGES IN PATELLOFEMORAL JOINT MECHANICS IN THE PRESENCE OF QUADRIPCEPS MUSCLE IMBALANCE

[1]**Seong-won Han**, [1]Andrew Sawatsky, [1]Azim Jinha, and [1]Walter Herzog
[1]University of Calgary, Canada
Corresponding author email: wherzog@ucalgary.ca

INTRODUCTION

Patellofemoral pain (PFP), defined as anterior knee pain, is one of the most common chronic diseases of the knee joint [1, 2]. Despite its prevalence, debate as to the etiology of PFP continues [1]. One generally accepted hypothesis is that the imbalance of muscle strength within the quadriceps group may result in mechanical changes in the knee joint that cause PFP. However, there is no direct scientific evidence linking the imbalance of muscle strength to PFP. In addition, a recent study in a rabbit model showed that a partial imbalance caused by weakness of the vastus medialis (VM) did not affect patellofemoral joint pressure [3].

However, in order to study the relationship between quadriceps muscle imbalance and patellofemoral joint pressures systematically, the forces of the individual quadriceps muscles must be controlled independently. Therefore, the purpose of this study was to investigate changes in patellofemoral joint (PFJ) contact distribution when stimulating the different muscles of the quadriceps group to various degrees to simulate systematic muscle weakness experimentally. Based on previous research [3], we hypothesized that patellofemoral joint pressures will not be affected by strength imbalances of the quadriceps muscle group.

METHODS

All experiments were performed on skeletally mature New Zealand white rabbits (n=5). The force in each muscle could be controlled individually by electrical stimulation of the individual nerves of the quadriceps muscles using home-built cuff-type electrodes that were implanted surgically [4]: vastus lateralis (VL), VM, and rectus femoris (RF, vastus intermedius stimulation was combined with RF). Patellofemoral pressure distributions and muscle forces were measured while stimulating the entire quadriceps muscle group simultaneously, stimulating each muscle individually, or stimulating two or three muscles using all possible combinations, producing the same quadriceps forces with different contributions of the individual muscles. All experimental procedures were approved by the Animal Ethics Review Committee of the University of Calgary.

Rabbit knees were held in place by bone pins inserted into the pelvis and femur. A tibial restraining bar was used to hold the knee joint at the target angle and measure the resultant knee extensor force. PFJ pressure distribution was measured by inserting Fuji pressure sensitive films into the patellofemoral joint [3]. Using films of different sensitivity, the joint contact areas, peak pressures, contact area shapes, and average pressures could be calculated using a custom-written analysis program (Matlab).

Patellofemoral joint contact distributions were then compared for corresponding knee angles and knee extensor forces (±5%), but different combinations of individual muscle forces.

RESULTS AND DISCUSSION

Joint contact areas, peak pressures, and average pressures increased with increasing knee extensor muscle forces.

Pressure distributions in force-matched trials varied considerably (Table 1). Typically, average pressures were smaller when all muscles were stimulated simultaneously compared to when only selected muscles were used to produce knee extension.

	ALL	VL+VM	VL+RF	VM+RF
AP[MPa]	7.3	10.6	11.5	9.3
CA[mm^2]	5.0	6.6	7.1	6.6
Contact shape				

Table 1. Representative results from one animal. For the contact pressure distributions, left and right side of the images correspond to the lateral and medial side of the knee, while up and down in the images correspond to proximal and distal, respectively. (AP: average pressure, CA: contact area)

Contact areas and pressure distributions seemed most affected by the loss of VM (VL+RF condition) when compared to stimulating all muscles of the quadriceps group simultaneously, showing the opposite to the results found previously that VM weakness does not affect patellofemoral joint contact distribution to a significant degree [3].

CONCLUSIONS

Patellofemoral joint contact distribution depends greatly on the combination of muscle forces contributing to the resultant knee extensor force. VM weakness appears to affect PFJ contact pressure distribution the most.

ACHILLES TENDON WAVE SPEED TRACKS JOINT TORQUE AND MUSCLE ACTIVITY IN GAIT

Jack A Martin, Emily M Keuler, James R Hermus, Scott CE Brandon, Matthew S Allen and Darryl G Thelen
University of Wisconsin-Madison
Corresponding author email: jamartin8@wisc.edu

INTRODUCTION

Understanding tendon tissue loading is crucial to the investigation of musculoskeletal disorders. Unfortunately, assessing *in vivo* loading remains challenging. Direct approaches are highly invasive[1], and modeling approaches rely on assumptions regarding muscle coordination and tissue geometry [2]. We are exploring the potential for using non-invasive wave propagation measurements to estimate tendon loads during dynamic movement. We recently found that a theoretical model for wave propagation in a tensioned beam predicts that shear wave speed in tendon is directly dependent on axial stress. A subsequent *ex vivo* study [3] confirmed this relationship, yielding a strong correlation between tendon stress and squared wave speed (mean $r^2 = 0.98$). The purpose of the current study was to investigate the potential for measuring *in vivo* Achilles tendon wave speed during gait, and to begin to examine the viability of using wave speed measures to assess tendon loading.

METHODS

Wave tracking. We constructed a custom device to generate and track transient shear waves in the Achilles tendon (Fig 1A). Waves were generated using a piezoelectric actuator (Thorlabs PK4JQP1, Newton, NJ, USA) housed in a 3D-printed enclosure strapped ~7cm superior to the calcaneus. The Achilles tendon was tapped in the transverse direction (20µm displacement) at 50Hz, with each tap sending a transverse (shear) wave along the tendon. Two single-axis accelerometers (PCB Piezotronics 352C23/NC, Depew, NY, USA) were positioned over the Achilles tendon 1cm and 2cm inferior to the tapping device. Transverse acceleration of the tendon was sampled from each accelerometer at 50kHz. Wave speed was calculated based on lag in wave arrival time between the two accelerometers (Fig 1B) after each tap, such that wave speed data were collected at 50Hz.

Gait analysis. Five subjects (3M, 2F) completed walking trials at a range of 5 speeds (0.75-1.75m/s) on a dual-belt, instrumented treadmill (Bertec, Columbus, OH). Ground reactions, lower body kinematics, medial gastrocnemius and tibialis anterior EMG, and tendon accelerations were collected synchronously for 8 seconds at each speed. Inverse kinematics and kinetic analyses were performed to determine ankle joint torque over the gait cycles. EMG data were rectified and low-pass filtered at 300Hz.

Wave speed analysis. Wave speed data were low-pass filtered at 12Hz. Agreement between squared wave speed and muscle activity was assessed visually. Correlation between squared wave speed and ankle torque was assessed using the coefficient of determination.

RESULTS AND DISCUSSION

Achilles tendon wave speeds varied from ~10-60m/s over the gait cycle, with peak speeds corresponding with push-off. There was excellent temporal agreement between wave speed, net ankle torque, and gastrocnemius muscle activity throughout stance (Fig 1C), with squared wave speed being highly correlated with ankle torque across the 5 subjects (mean $r^2 = 0.77$). There was a second distinct increase in wave speed during late swing, corresponding with passive tensioning of the Achilles as the tibialis anterior acted to dorsiflex the ankle in preparation for heel strike.

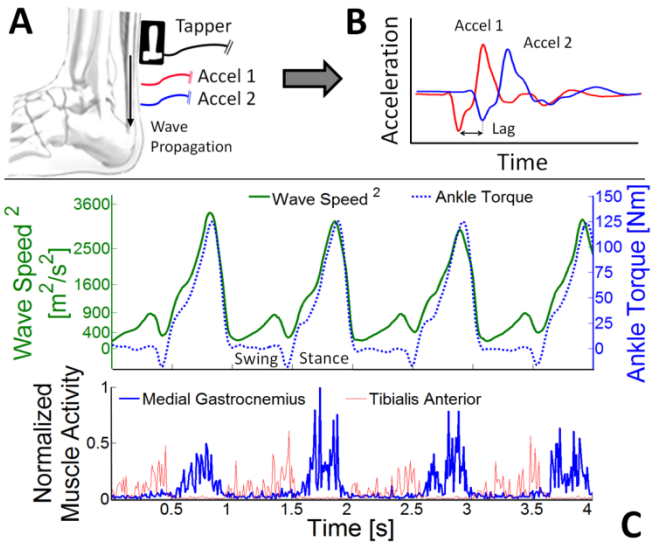

Figure 1: **A)** Schematic of wave speed measurement method. **B)** Example shear waves recorded via skin-mounted accelerometers. **C)** Squared Achilles tendon wave speed, ankle torque, and muscle activity during walking at 1.50m/s for one subject (M, 75kg).

These data establish the viability of using tendon wave speed measures as a proxy for *in vivo* loading. The observed relationships between wave speed, ankle torque, and muscle activity are in agreement with the expectation that squared wave speed will scale with tensile stress [3]. Crucially, we have shown that wave speed can be measured at a high rate using skin-mounted accelerometers, making the system usable for highly dynamic movements. Additionally, the unexpected finding of wave speed increases during swing highlights the potential for this method to reveal changes in tendon loading that can be omitted by traditional modeling approaches and EMG analysis.

CONCLUSIONS

We've shown that shear wave speeds can be measured and used to gauge *in vivo* tendon loading. Future work will focus on adapting the technology for use on other tendons, which could facilitate an array of clinical and research applications.

MUSCLE-TENDON CONTRIBUTION TO AN INCREASED RANGE OF MOTION FOLLOWING PASSIVE STRETCHING IN CHILDREN WITH CEREBRAL PALSY

[1]**Barbara Kalkman,** [2]Lynn Bar-On, [2]Francesco Cenni, [2]Gill Holmes, [2]Alfie Bass, [1]Constantinos Maganaris, [1]Gabor Barton, [2]Kaat Desloovere, [1]Bill Baltzopoulos, [1]Thomas O'Brien

INTRODUCTION

Stretching is often used to increase/maintain joint range of motion (ROM) in children with cerebral palsy (CP). An acute bout of stretching can increase ROM in children with CP[1], but during passive joint rotation of the ankle the tendon lengthens more and muscle less in children with CP compared to typical developing children[2]. This reduced stretching stimulus to the muscle might explain the negative and highly variable outcomes of long-term stretching interventions[3]. Therefore, this study aimed to determine the acute changes in muscle-tendon properties that contribute to increased ROM after a bout of stretching in children with CP.

METHODS

Eleven children with spastic CP participated (age:12.1±3y, 5/6 hemiplegia/diplegia, GMFCS level:7/4, I/II) in this study. Each child received 3 sets of 5x20 seconds passive, static dorsiflexion stretches separated by 30-sec rest, and 1-minute rest between sets. Stretches were applied by a physiotherapist. Pre- and immediately post-stretching, ultrasound (Telemed, Lithuania) was used to measure medial gastrocnemius fascicle lengthening (Figure 1) continuously over the full ROM and a ROM common to pre- and post-stretching. Simultaneously, 3D motion of 2 marker clusters on the shank and the foot was captured (OptiTrack, US) to calculate ankle angle according to ISB guidelines[4] and ankle joint torque was calculated from manually applied torques and forces on a 6DoF load cell (ATI mini45: Industrial Automation).

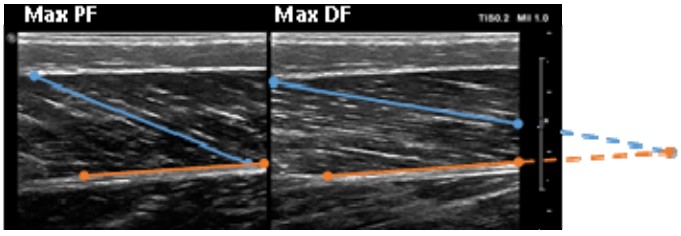

Figure 1: Example of ultrasound images at maximal plantarflexion (PF) and maximal dorsiflexion (DF). Fascicle length was tracked automatically through the full ROM.

RESULTS AND DISCUSSION

Total ROM increased by 9.9±12 degrees after stretching (p=0.016), of which 5.2±4.4 degrees showed in the dorsiflexion direction (p=0.004). At end ROM maximal ankle joint torque increased by 2.9±2.4 Nm (p=0.003) and over the full ROM fascicle lengthening was 2.8±2.4 mm greater (p=0.009). Over a common ROM there were no differences in fascicle lengthening or torque changes pre to post stretching. These results indicate that an acute bout of stretching did not alter the passive mechanical properties of the medial gastrocnemius muscle. This contrasts a similar study in typically developed adults[5] which found that stretching increased fascicle and muscle lengthening over a common ROM. The current lack of changes in muscle properties could possibly be explained by a smaller relative stretching stimulus to the muscles of children with CP, as reported previously[2].

The increased ROM and fascicle length at maximal dorsiflexion are most likely caused by an increase in manual torque applied to dorsiflex the ankle joint post-stretching (Figure 2). This may be due to an increase in the participants' tolerance to stretch, a mechanism that was first identified by Magnusson et al.[6]. Irrespective of the cause, we do see an acute increase in the stretching stimulus of the muscle fascicle after a bout of stretching.

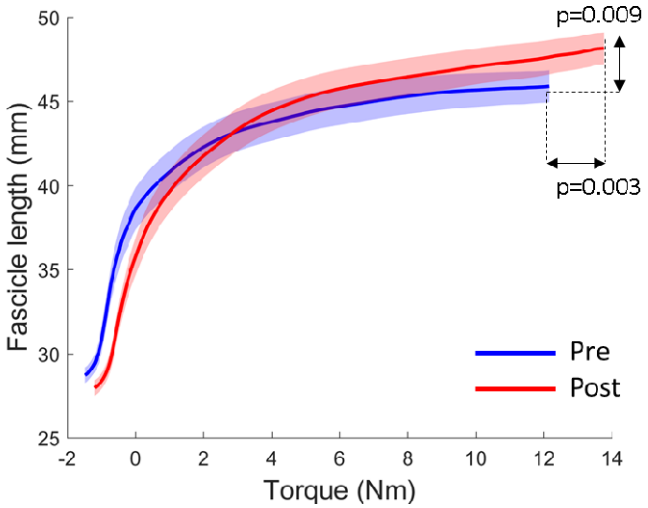

Figure 2: Medial gastrocnemius fascicle length relative to torque applied to dorsiflex the ankle joint before (blue) and after (red) an acute bout of stretching (mean and 95% CI).

CONCLUSIONS

A single bout of repeated stretches increased ankle ROM in children with CP, which was partially achieved by elongation of the muscle fascicles. However, the passive properties of the muscle fascicles remained unaltered by the stretching bout.

ASYMMETRIC TIBIOFEMORAL KINEMATICS ARE ASSOCIATED WITH ACL RECONSTRUCTION GRAFT GEOMETRY

INTRODUCTION

Subtle asymmetries in tibiofemoral (TF) kinematics have been detected in ACL reconstructed (ACLR) knees [1,2]. These altered kinematics shift the cartilage contact regions, which is theorized to initiate progression into osteoarthritis [3]. Thus, restoring normal kinematics with ACLR could prevent early cartilage degradation. Prior *ex vivo* studies have shown that graft tunnel placement impacts the anterior-posterior laxity [4] and internal rotation of the knee [5]. Further, gait analysis has identified potential links between ACL graft orientation and knee rotation [6]. However, conventional motion analysis lacks the precision to capture subtle changes in secondary TF kinematics that may impact cartilage loading. In this study, we used dynamic MRI to investigate links between TF kinematics and ACL geometry during active movement. We hypothesized that non-anatomical graft orientation would be related to asymmetries in anterior tibia translation and internal rotation.

METHODS

The bilateral knees of 18 subjects that underwent a primary unilateral, isolated ACLR were tested (9 M, 24.8±5.7 yrs, 78.9±16.5 kg, 20.2±8.7 months post-op, 9 PT grafts). Bilateral, high resolution MR images were collected and segmented to create bone and ACL geometries for the ACLR and intact knees. The location of the ACL femoral and tibial attachments and the orientation of the ACL relative to the tibia plateau were measured bilaterally (Fig. 1A). Non-anatomical ACL graft geometry was characterized by subtracting the intact from the reconstructed metrics.

During the dynamic MRI protocol, subjects lay supine in the MR scanner with their leg attached to an inertial loading device. Subjects performed cyclic knee flexion-extension at 0.5 Hz for 5 min while dynamic volumetric images were continuously acquired [7]. Images were retrospectively sorted and reconstructed into 60 frames over the motion cycle. Six degree of freedom TF kinematics were measured by optimally registering the bone geometries to the image sets at each frame. We then extracted the TF kinematics at peak knee flexion and extension and the range in TF kinematics through extension. Kinematic asymmetries were determined by subtracting the intact from the reconstructed metrics. We computed Spearman's correlation coefficient (R) between the kinematic and ACL geometry asymmetry metrics with significance set at $p<0.05$.

RESULTS AND DISCUSSION

Sagittal orientation of the ACL graft was correlated with asymmetric anterior translation (R=0.56), internal rotation (R=0.50), and adduction angle (R=0.54) at peak flexion (Fig. 1B). Frontal plane orientation of the ACL graft was correlated with lateral translation at peak flexion (R=0.50), internal rotation at peak extension (R=0.58), and lateral translation range (R=-0.52). Additionally, the superior location of the femoral attachment was correlated with lateral translation at peak flexion (R=0.58) and extension (R=0.56), while the lateral location of the tibial attachment was correlated with internal rotation at extension (R=-0.61).

Our results suggest that non-anatomical ACL graft placement may contribute to asymmetries in *in vivo* knee mechanics. Abnormally high anterior tibia translation was associated with a more vertically oriented ACL graft, which is consistent with a previously observed relationship between the neutral anterior tibia position and ACL orientation [6]. We also found that a more horizontal graft in the sagittal plane was linked with greater external tibia rotation. Given that there is a bias towards external rotation in ACLR knees [1,2], our data suggest that this abnormality may be modifiable via graft placement.

CONCLUSIONS

This study elucidates links between ACL graft geometry and kinematics in reconstructed knees, which may be important to consider when planning ACLR procedures that can best restore normative mechanics.

THE EFFECT OF ANTERIOR CRUCIATE LIGAMENT RECONSTRUCTION IN HIGH-FUNCTIONING PATIENTS DURING DEMANDING DYNAMIC TASKS

INTRODUCTION

Studies examining anterior cruciate ligament (ACL) injured populations have come to varying conclusions in regards to the muscle activation and biomechanical strategies employed through a variety of tasks. This could be attributed to treating the variables as discrete values and/or cross-sectional designs. The purpose of this study was to evaluate neuromuscular and biomechanical movement strategies implementing by high-functioning ACL injured patients. This purpose was achieved by comparing the patient-related outcome measures (PROMs), muscle activation and biomechanical properties of healthy controls (CON), ACL deficient (ACLd) patients and these patients 10 months post-reconstruction (ACLr) by using a time-sensitive statistical method.

METHODS

The 20 patients who were tested in the ACLd and ACLr state were matched to 20 healthy control participants. Upon arrival, all participants completed PROMs (KOOS, KNEES-ACL, IKDC, Tegner, and Lysholm) and then performed 3-5 successful jump lunge and side cut maneuvers. Whole-body kinematics were collected with a 10-camera system (Vicon, UK), ground reaction forces (GRF) with a force plate (AMTI, USA), and electromyography (EMG) with a ten-channel system (MQAir, Denmark).

Linear envelopes and GRFs were quantified through MATLAB (Mathworks, USA) while scaling, inverse kinematics, and inverse dynamics were performed based on the Rajagopal model [1] using a MATLAB-OpenSim (Simtk, USA) interface.

Differences in PROMs were tested for significance using independent (CON vs ACLd, CON vs ACLr) and dependent (ACLd vs ACLr) T-tests using SPSS (IBM, USA). Differences in linear envelopes; GRFs; hip, knee, and ankle sagittal plane angles and moments were tested for significance using independent (CON vs ACLd, CON vs ACLr) and dependent (ACLd vs ACLr) T-tests using statistical parametric mapping through MATLAB. Alpha was corrected for multiple comparisons, which made significance determined by p-values < 0.025.

RESULTS AND DISCUSSION

All PROMs showed significantly greater functionality scores for CON compared to both the ACLd and ACLr. Compared to the ACLd, ACLr reported higher functionality in all PROMs except the KOOS-Symptoms, KOOS-Pain, and KOOS-Activities of Daily Living.

No differences between all three groups in EMG linear envelopes were observed during the side cut while during the jump lunge, ACLd had a greater medial gastrocnemius activation than CON between 91-103ms (p=0.018) post-contact and ACLr had a greater biceps femoris activation than CON 239-300ms post-contact (p<0.001).

The medial GRF during the side cut indicated CON had a greater medial force mid to late stance compared to both ACLd and ACLr, while ACLr had a greater medial GRF in early stance compared to ACLd.

No differences in sagittal hip, knee, and ankle angles were observed during the side cut (Figure 1) while the knee was observed to be significantly less flexed in the ACLr compared to CON from 84-196ms post-contact in the jump lunge (p=0.007).

The knee extensor moment was significantly greater for the CON group compared to both injured groups in the side cut (Figure 1) and jump lunge.

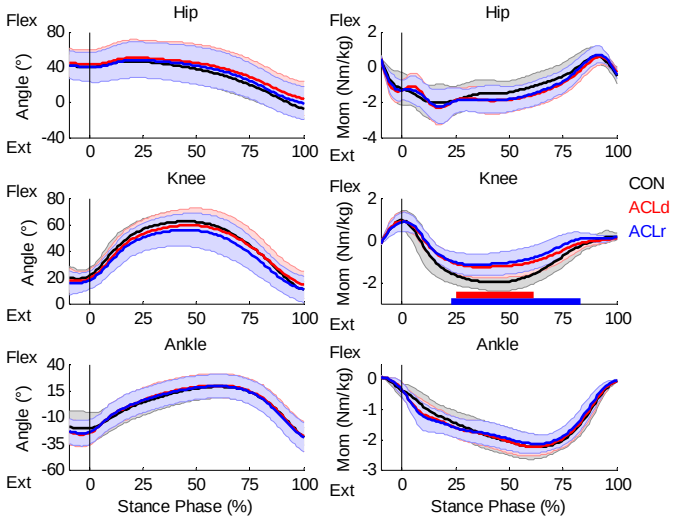

Figure 1: Sagittal plane angles and moments during the side cut movement. Black vertical line represents time at contact; red horizontal bar represents significance between CON and ACLd; and blue horizontal bar represents significance between CON and ACLr.

CONCLUSIONS

With the application of this test-retest design, it was found that ACL injury is associated with lower scores in subjective stability/functionality, changes in muscle activations and movement characteristics. After reconstruction, patients report significantly improved functionality from their ACLd state although these changes were not reflected in their muscle activations and movement profiles. These findings suggest that in high-functioning ACLd patients, ACL reconstruction may improve their self-reported function; however, no changes are observed in their neuromuscular and biomechanical measures. Therefore, rehabilitation programs may be improved by having return to play standards set based on high-functioning patients rather than healthy, uninjured standards that even after reconstruction, high-functioning, self-confident patients fail to achieve.

SIMULATION OF A PASSIVE ASSISTIVE DEVICE TO REDUCE RUNNING EFFORT

[1] **Cara G. Welker**, [1]Cole S. Simpson, and [1-2]Elliot W. Hawkes
[1]Stanford University [2]University of California, Santa Barbara
Corresponding author email: ewhawkes@stanford.edu

INTRODUCTION

Locomotion is a central part of our everyday lives and plays a huge role in physical and mental health. Because humans are very adept at locomotion as a result of evolution and learning, increasing gait efficiency has proven difficult. Although several groups have increased human walking efficiency using powered exoskeletons, only one unpowered device (an ankle exoskeleton) has increased walking efficiency [1]. However, no one has yet determined a way to increase running efficiency with an ungrounded, unpowered device.

Most of the energy required for running is used to support the body against gravity and propel the body forward. However, one study suggests that the cost associated with leg swing is approximately 20% of the total metabolic cost [2]. This finding suggests that a device used to assist leg swing could reduce the energetic cost of running, and we wondered if we could parametrize a passive device to do so.

METHODS

Using OpenSim 3.3 [3], a musculoskeletal model with 23 degrees-of-freedom and 92 musculotendon actuators was scaled to match subject data from Hamner *et al.* (1.83 m tall, 65.9 kg) [4]. A linear spring with a dead-zone (our passive assistance device) was added to the model as an object in the Pathspring class connecting the left and right legs and attached to various locations on the ankles, shanks, and knees. The optimal muscle activations were then computed using the computed muscle control (CMC) tool [5] and experimental running data from Hamner *et al.* (3.96 m/s) [4]. Running effort was computed as the sum of the squared muscle activations over the gait cycle [6].

In order to determine the device parameters, experimental joint torques were divided by the moment arm between each joint and the device's line of action. These normalized torques were plotted against the length of the linear spring to determine an ideal resting length and linear stiffness such that the device provided assistive torques with a magnitude equal to or smaller than experimental joint torques.

RESULTS AND DISCUSSION

Most of the various device attachment points reduced running effort, but because the most significant decreases were seen when the device was attached to the ankles, subsequent calculations were performed with this geometry path. Using the plots of normalized torque versus length of the linear spring, a resting length of 0.5 m was selected because it was the minimum length such that the band never resisted experimental joint torques. Additionally, a linear stiffness of 60 N/m ensured that the torque provided was less than the magnitude necessary for running.

Simulations performed with the chosen inputs for the parametrized spring attached at the ankle showed a total decrease in effort of 7.37%, with a 9.65% decrease for the right leg and a 4.96% decrease for the left leg over one gait cycle (see Figure 1). This difference between the two legs is likely due to asymmetric step lengths, which resulted in more assistive forces applied to the right leg in swing phase.

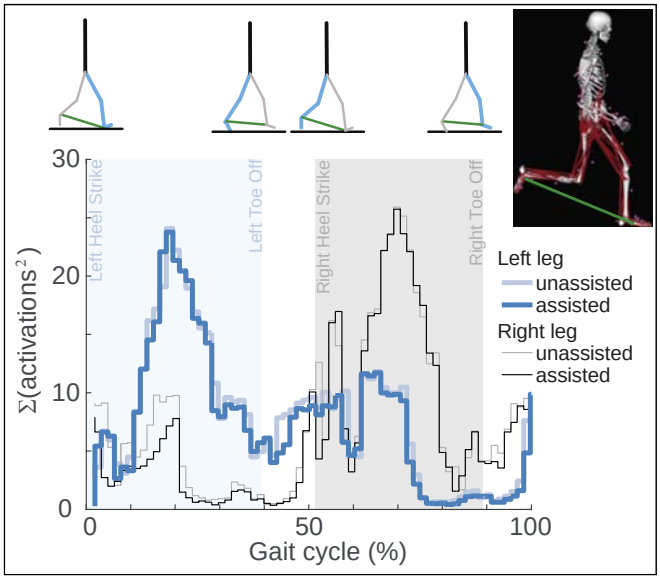

Figure 1: Sum of the muscle activations squared with and without the assistive device over one gait cycle.

This analysis assumes that our device does not change running kinematics and ground reaction forces. Because the selected parameters resulted in applied forces under 30 N, kinematic changes would likely be small and may even improve efficiency as the user learns how to best use the device.

CONCLUSIONS

Our simulations suggest that it is possible to create an assistive device to reduce running effort in the form of an elastic band attached between the two ankles, a simple and lightweight solution compared to other exoskeletons. Assuming a simple model of a linear spring with a dead-zone, an ideal resting length and linear stiffness of 0.5 m and 60 N/m, respectively, were calculated so the device would only assist the experimental knee and hip joint torques. Simulations with this implemented device reduced running effort by more than 7%.

BIOMECHANICALLY-ASSISTIVE GARMENT OFFLOADS LOW BACK DURING LEANING AND LIFTING

Erik P. Lamers, Aaron J. Yang and Karl E. Zelik
Vanderbilt University
Corresponding author email: erik.p.lamers@vanderbilt.edu

INTRODUCTION

Low back pain is the leading cause of limited physical activity, affecting 80-85% of adults in their lifetime [1]. Development of low back pain can result from elevated, prolonged and/or repetitive forces on the spine, which commonly occur during daily activities such as leaning and lifting. Wearable assistive devices (e.g., exoskeletons) are emerging as a potential means of mitigating low back injury risks and associated pain, by offloading the lumbar spine. The majority of these exoskeletal devices have bulky form-factors (designed for use in industrial settings), but are impractical for daily use at home or in other business, social or clinical settings. An appealing, low-profile alternative may be to adapt clothing by embedding structures that assist movement biomechanics. These structures could be entirely passive (springs), quasi-passive (clutchable springs), or active (actuated); where both quasi-passive and active might be controlled via feedback from wearable sensors. The purpose of this initial study was to investigate the degree to which a biomechanically-assistive garment could passively offload lumbar muscles and discs during leaning and lifting.

METHODS

We developed a biomechanically-assistive garment prototype that passively assists lumbar extension during leaning and lifting, and is sufficiently low-profile to be worn as (or under) clothing. We then tested 7 healthy subjects performing leaning and lifting tasks with vs. without the prototype to assess its effect on lumbar muscle activity, which was used as an indicator of biological tissue loading. The prototype consists of an upper-body interface (shirt), a lower-body interface (shorts), and elastic bands which run along the back, connecting the upper and lower interfaces (Fig. 1A). As the user leans forward, the elastic bands stretch, providing a lumbar extension moment, which reduces moments required by the muscles. Because the elastic bands act with larger moment arms about the spine (than muscles), they provide equivalent extensor moments with smaller force magnitudes, resulting in reduced compressive forces on the spine. Subjects performed 10 trials: (3 leaning angles + 2 lifting weights) x (2 conditions, i.e., with and without the prototype), while we recorded kinematics, force and electromyography (EMG) data. Each subject gave informed consent prior to participation. Subjects leaned forward to a pre-determined angle (30°, 60°, 90°) for 30 seconds while holding a 4.5 kg weight to their sternum. Subjects then lifted a weight (12.7 or 24 kg) using a squat posture. Mean and peak EMG were the main outcomes for the leaning and lifting trials, respectively. Intersubject means and standard deviations were computed. T-tests were performed to assess significance (alpha = 0.05).

RESULTS AND DISCUSSION

Wearing the prototype during leaning and lifting tasks reduced erector spinae EMG activity (Fig. 1B). Mean EMG was reduced by 15% ± 19% (p=0.07), 27% ± 10% (p=0.001) and 43% ± 33% (p=0.02) for the 30°, 60° and 90° leaning conditions, respectively (Fig. 1C). Peak EMG was reduced by 10% ± 22% (p=0.12) and 11% ± 22% (p=0.07) for the 12.7 kg and 24 kg lifting trials, respectively.

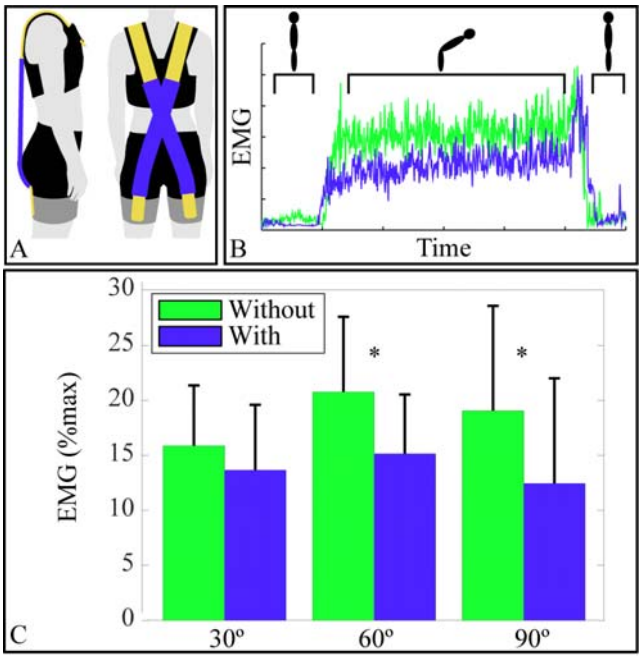

Figure 1: (A) Wearable prototype. (B) Representative EMG vs. time plot for leaning. (C) Mean erector spinae EMG was reduced during leaning With (blue) vs. Without (green) the biomechanically-assistive garment prototype.

These EMG reductions suggest that the prototype reduced lumbar muscle forces. Since these muscle forces constitute the majority of compressive force on the lumbar spine [2], these findings suggest that lumbar disc loading may also be reduced. These results demonstrate the feasibility of biomechanically-assistive garments to reduce lumbar muscle and disc loading, which may help mitigate overuse and/or overloading risks that can lead to low back injury and pain. Future prototypes will integrate quasi-passive structures and wearable sensors in order to control the magnitude and timing of assistance.

CONCLUSIONS

We found that passive, biomechanically-assistive garments are capable of offloading low back muscles, and potentially discs, during leaning and lifting, which may reduce force-induced injury risks.

INTRODUCTION

The measurement of human kinematics is fundamental in rehabilitation, training, and injury prevention. Inertial Measurement Units (IMUs) are a promising and less resource-demanding alternative to stereophotogrammetry motion capture systems. However, their use is still limited because of the inaccuracies in the estimation of joint angles. A possible source of error is the use of simplified anatomical models that do not correctly reflect the real kinematics of human joints. Also, orientations calculated from IMUs are often directly applied to the model segments in a direct kinematics fashion [1], which can be susceptible to noise and errors in IMU placement and registration. Alternatively, inverse kinematics (IK) algorithms use a global optimization to estimate joint angles and overcome the major limitations of direct kinematics [2]. However, IK is commonly used to track the three-dimensional (3D) position of markers [2], and its potential in tracking 3D orientations from IMUs to estimate human kinematics is largely unexplored.

OpenSim [3] is a popular open-source software for biomechanical analysis that permits using realistic representations of joint kinematics and personalized musculoskeletal anatomy [4]. This study is (1) developing an OpenSim plugin to estimate joint angles in the lower limbs by solving IK from 3D orientation provided from IMUs, and (2) evaluating the proposed method by comparing orientation-based and marker-based IK estimates of joint angles during gait in the lower limbs.

METHODS

A single healthy subject was recruited for this study. Eight IMUs (Noraxon, Scottsdale, AZ, US) were placed each on a single body segment (thorax, pelvis, thighs, shanks, and feet). Reflective markers were placed on the subject's bony landmarks and rigid clusters of 3 markers were attached to each IMU. A 12-camera motion capture system (Vicon, Oxford, UK) was used to collect marker trajectories through Vicon Nexus (v. 2.3), while IMU orientations were acquired through Noraxon myoRESEARCH (v. 3.8) software and exported as quaternions. Marker and IMU data were synchronously collected via a common trigger signal, and sampled at 200Hz and 100Hz, respectively.

The standard OpenSim *gait2392* model was scaled to match subject's anthropometry using bony landmark markers from a static pose trial. Position and orientation of IMUs were registered to the model using the data from the marker clusters. IMU orientation-based IK [5] was implemented in an OpenSim plugin in which a global optimization calculates joint angles minimizing errors between experimental IMUs and virtual IMUs placed on OpenSim model.

Hip and knee flexion-extension, and ankle plantar-dorsiflexion angles were estimated for seven gait cycles using both IMU orientation-based and marker-based IK and then time normalized to the gait cycle. Root Mean Squared Error (RMSE) and coefficient of determination (R^2) were used to compare the results. Averages and standard deviation (SD) were reported in a plot as time-series.

RESULTS AND DISCUSSION

Sagittal plane joint angle estimates from IMU orientation-based and marker-based IK showed good agreement (Figure 1), with RMSE±SD of 4.34±0.56 deg for hip, 6.18±1.62 deg for knee, and 4.29±1.11 deg for ankle; and with R^2±SD of 0.93±0.03 for both hip and knee, and 0.75±0.08 for the ankle. Further investigations are required to assess the IMU orientation-based IK in other planes of motion and during different tasks. Also, more care in avoiding magnetic interference during data collection (i.e. force platforms) will potentially improve the quality of the results.

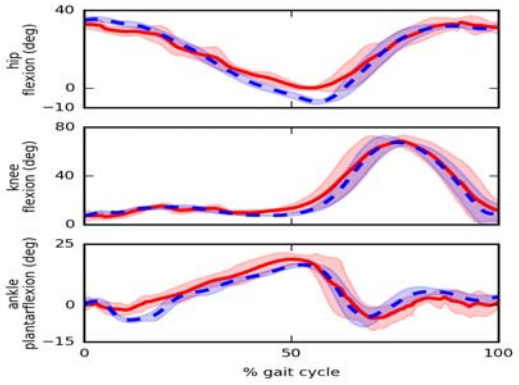

Figure 1: Joint angles: marker-based IK (blue) and IMU orientation-based IK (red) averages. Standard deviations are shown as shaded bands.

CONCLUSIONS

During gait, sagittal plane joint angles estimated via the IMU orientation-based IK OpenSim plugin closely matched results from marker-based IK. While further validation is needed, these results could lead to exciting and innovative out-of-the-laboratory applications.

PREPARATORY TRUNK ANGULAR MOMENTUM PREDICTS ACL INJURY RISK DURING SIDESTEPPING

[1]Jonathan M D Staynor, [1]Jacqueline A Alderson, [2]Jeffrey A Reinbolt, [1]Marcel Rossi and [1]Cyril J Donnelly
[1]University of Western Australia
[2]University of Tennessee

INTRODUCTION

Simulation research has shown that lateral positioning of the whole-body center of mass is an important factor influencing peak knee valgus moments (PKVM) and associated anterior cruciate ligament (ACL) injury risk, during unplanned sidestepping [1]. The trunk is the heaviest body segment, with the greatest individual-segment impact on whole-body center of mass. Experimental research has observed associations between weight acceptance (WA) trunk kinematics and ACL injury risk [2], which is important given peak injury risk occurs during WA [1]. However, there is at least a 25ms electromechanical delay in muscle force production [3], limiting the opportunity for the neuromuscular system to modulate trunk position within the WA time frame (20-30ms). It is probable that preparatory trunk segment mechanics during the flight phase prior to WA, influences subsequent WA kinematics and ACL injury risk. The aim of the current study was to investigate the influence of preparatory trunk angular momentum ($\mathbf{H}_T$) on PKVM during the WA phase of unplanned sidestepping. It is hypothesized that multi-planar preparatory $\mathbf{H}_T$ will predict PKVM during WA.

METHODS

Eighteen male participants (22±5yrs, 1.85±0.06m, 80±10.0kg) completed an established unplanned sidestepping protocol [1]. Kinematic and kinetic data were collected as part of another study [1], and low pass filtered at 14Hz. A participant specific skeletal model [1] and anthropometric segment inertial parameters [4] were used to estimate 16 body segments and whole-body center of mass position. PKVM during WA were calculated via inverse dynamic procedures [2] and normalized to participant mass and height (kg.m). Segmental angular momentum ($\boldsymbol{H}_{seg}$) was calculated about the whole-body center of mass for the head, thorax, middle torso and lower torso segments during the flight phase (toe-off to one frame before landing) prior to WA:

$$\boldsymbol{H}_{seg} = (\boldsymbol{CM}_{seg} - \boldsymbol{CM}_{WB}) \times m_{seg} (\boldsymbol{V}_{seg} - \boldsymbol{V}_{WB}) + \mathbf{I}_{seg}\boldsymbol{\omega}_{seg} \quad (1)$$

Where *seg* refers to the segment, *WB* to whole-body, ***CM*** to center of mass, *m* to mass, ***V*** to velocity, **I** to moment of inertia and $\boldsymbol{\omega}$ to angular velocity. $\mathbf{H}_T$ was calculated by summing the angular momentum of the head, thorax, middle torso and lower torso segments and normalized to participant mass, height and approach velocity ($kg.m^2.s$).

Using 80% of the trials (n=49) a linear mixed model was implemented to predict PKVM from three-dimensional preparatory $\mathbf{H}_T$. Participants were modelled as random factors to account for within-subject variability. Independent variables were mean single plane $\mathbf{H}_T$ (frontal, sagittal and transverse), and were removed from the model manually in order of highest *p* value until all remaining independent variables were significant (α=0.05). The regression model was externally validated against the remaining 20% of the trials (n=12) using a paired samples t-test and Cohen's *d* effect size to compare predicted vs measured PKVM.

RESULTS AND DISCUSSION

Sagittal plane $\mathbf{H}_T$ did not significantly correlate with PKVM ($p \geq 0.05$), and was removed from the model. Significant correlations were found between frontal, and transverse plane $\mathbf{H}_T$, and PKVM (Table 1). The regression equation was deemed capable of predicting PKVM as there was no significant difference ($p \geq 0.05$) between predicted (0.63±0.21) and measured (0.65±0.29) moments, with differences shown to be small in effect size (d=0.10). This observation suggests that multi-planar $\mathbf{H}_T$ were capable of predicting PKVM and ACL injury risk during unplanned sidestepping.

Table 1: Parameter coefficients (β) and standard error (SE) for significant H_T predictors of PKVM.

Parameters	β	SE	p
Intercept	0.57	0.07	<.001
Frontal H_T	-177.37	46.38	<.001
Transverse H_T	461.93	137.86	.002

Increases in frontal $\mathbf{H}_T$ (e.g. momentum acting to laterally flex the trunk towards the change of direction) were negatively correlated with PKVM. This is in agreement with experimental research which reported increased PKVM with increased peak lateral trunk flexion away from the change of direction during WA [2]. Increases in transverse $\mathbf{H}_T$ (e.g. momentum acting to rotate the trunk towards the intended change of direction) were positively associated with PKVM. It is possible that preparatory $\mathbf{H}_T$ in the transverse plane requires an athlete to adopt kinematic postures during WA, such as a wide lateral foot placement [2], that are associated with high PKVM. This rationale is currently speculative and is being investigated within a larger sample size (n=40).

CONCLUSIONS

The current study has established a link between preparatory $\mathbf{H}_T$ and PKVM during the WA phase of unplanned sidestepping. These findings provide a rationale to investigate how an athlete's preparatory mechanics influences ACL injury risk during non-contact movement.

INTRODUCTION

Multicellular dynamics have a key role in determining the macroscopic behaviors of living tissues during development, homeostasis, and disease. Especially, based on chemical regulatory pathways, autonomous tissue dynamics emerge from the integration of various cell mechanical behaviors in three-dimensional (3D) space, such as cell deformation, movement, division, and apoptosis. Typical examples of 3D multicellular dynamics are the epithelial deformation in morphogenesis, the collective cell migration in cancer metastasis, and the regeneration of high-order tissue structures. However, while such 3D multicellular dynamics is fundamental to general soft tissue dynamics, little is about how individual cell behaviors are spatiotemporally coordinated across the macroscopic tissue dynamics. To investigate general multicellular dynamics, we developed a versatile mathematical model for simulating 3D multicellular dynamics based on the 3D vertex model framework[1-7].

METHODS

In the 3D vertex model, an individual cell shape is represented by a polyhedron comprising the arbitrary number of polygons. Each polygon expresses the boundary face between neighboring cells, and comprises the arbitrary numbers of vertices and edges. Since all polygons are shared by neighboring polyhedrons, all vertices and edges compose a single network that expresses the entire structure of a 3D cell aggregate (Fig. 1).

In the network, as a topological constraint, each vertex is connected to exactly four edges, by which each vertex coordinate corresponds to a meeting point of exactly six boundary faces. Moreover, the topology of the network and the numbers of vertices and edges are dynamically rearranged to express the changes in the configuration and number of cells.

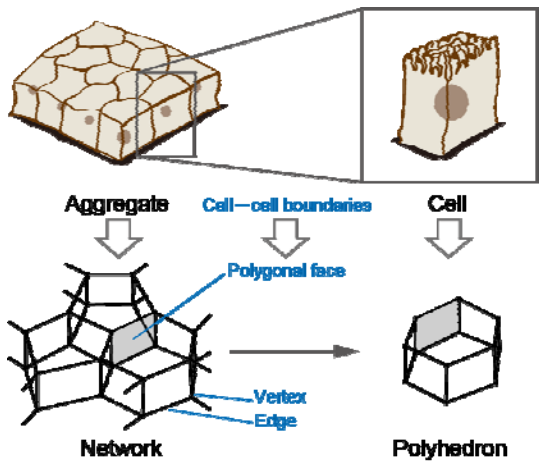

Fig. 1: 3D Vertex Model for Simulating 3D Multicellular Dynamics

RESULTS AND DISCUSSION

The model enables to express the entire degree of freedom of multicellular kinetics at the single cell level, i.e., cell deformation, rearrangement[7], division[6], and death[1] in 3D space. Moreover, the model expresses active and passive mechanical behaviors of individual cells such as cell viscoelasticity and active force generation[4]. Furthermore, by coupling intercellular molecular signaling with cell mechanical behaviors, the model successfully expresses the coupling phenomena of mechanical deformation and chemical patterning[3]. Computational simulations using the model provided quantitative predictions of 3D multicellular dynamics at the single cell level. Several studies have demonstrated the applicability and usefulness of this model for analyzing general multicellular tissue mechanics, such as epithelial deformation and collective cell migration.

CONCLUSIONS

This study focuses on understanding the self-organizing mechanisms of living tissues in the processes of development, homeostasis, and disease. To investigate well-organized dynamics of multicellular tissues in the living body, we developed a powerful mathematical tool to analyze dynamics of general multicellular tissues, and revealed the regulation mechanisms of the autonomous processes of organogenesis. This work will contribute to the multiscale biomechanics of tissue dynamics by bridging the mechanical hierarchy of structures and functions ranging from the microscopic cellular level to the macroscopic organ level.

INTRODUCTION

Cells in the epithelial tissue are physically organized by the formation of cell-matrix and cell-cell adhesions. The later are mediated by the calcium-dependent cell adhesion receptor called E-cadherin (E-cad), and are required for development[1-4], while a loss of these adhesions is associated with cancer development and metastasis.[5] E-cad is a multidomain protein wherein the extracellular domain (ECD) forms the adhesive homotypic interaction while the intracellular domain (ICD) interacts with the cytosolic β- and α-catenin as well as the actin cytoskeleton.[2-4,6-9] A force-dependent conformational change in α-catenin allows sensing of mechanical tension in the tissue.[10-16] Here we study the mechanism of cell-cell adhesion formation and mechanical signaling using hybrid live cell-supported lipid bilayer assays, which has been successfully utilized in dissecting adhesion and signaling by a number of other receptors including the T-cell receptor[17-19], the EphA2 tyrosine kinase[20,21] and integrin receptor[22-24].

METHODS

Adhesion formed by MKN28 epithelial cells on supported lipid bilayers functionalized with fluorescently labeled E-cad-ECD was monitored by epi-fluorescence microscopy while cell-bilayer contact was imaged by Reflection Interference Contrast Microscopy (RICM). Activation of α-catenin was determined by the staining of cells with a conformationally sensitive antibody, α18, which binds specifically to the active conformation.[12] E-cad clusters were physically manipulated by creating nanoscale features on the substrate using nanolithography.[17-21,25]

RESULTS AND DISCUSSION

Interaction of cells with the E-cad-ECD functionalized bilayer resulted in an enrichment of the protein on the bilayer. However, very few cells formed adhesion on fluid supported lipid bilayers while they did so readily on viscous bilayers suggesting a step of kinetic nucleation in the process of E-cad clustering. Cells formed micron-scale clusters of E-cad by extending and retracting filopodia on the bilayer surface.[26] Staining of cells adhering to bilayers with the α18, either in control or in low acto-myosin tension condition, showed the presence of activated α-catenin in both conditions. On the other hand, a restriction of E-cad clustering by creating physical barriers on the substrate revealed that α-catenin is activated during the micron-scale clustering of E-cad. These suggest that micron-scale clustering induced activation of α-catenin is sustained in the absence acto-myosin tension.[27]

CONCLUSIONS

Filopodia retraction-mediated clustering of E-cad involves a step of kinetic nucleation, and is associated with a sustained activation of α-catenin.[1,26,27]

INTRODUCTION

We have been developing a computational biomechanics especially on cellular scale physiological flow problems [1-4]. In cellular scale, fluid motions are typically dominant by the viscous effect, not by the inertia, and the flows can be assumed as the Stokes flow. To solve Stokes flow problems, we used a boundary element method (BEM) because BEM can explicitly treat viscous stress jump across cell membrane and it shows high accuracy with reasonable mesh size and time step. In this paper, we briefly review our recent work of cellular scale physiological flow problems solved by a BEM.

METHODS

Assume that fluid flow is governed by the Stokes flow. Flow field around cells can be expressed by the following boundary integral equation:

$$\boldsymbol{v} = -\frac{1}{8\pi\mu}\int \boldsymbol{J}\cdot\boldsymbol{q}\,dS + \frac{\lambda}{8\pi}\int \boldsymbol{v}\cdot\boldsymbol{T}\cdot\boldsymbol{n}\,dS, \qquad (1)$$

where μ is the viscosity of extracellular fluid, λ is the viscosity ratio of inner cytoplasm and outer fluid, S is the surface of cell membrane, $\boldsymbol{n}$ is the outward unit normal vector on the surface, and $\boldsymbol{J}$ and $\boldsymbol{T}$ are single- and double-layer potentials of the Green's function, respectively. The surface load $\boldsymbol{q}$ is given by the membrane mechanics. The membrane is modeled by a hyper-elastic material and the equilibrium equation is solved by a finite element method. Once the surface load $\boldsymbol{q}$ is given, equation (1) is solved by a BEM.

RESULTS AND DISCUSSION

We first investigated single red blood cell (RBC) motions flowing through a thin micro-pore (Fig.1a). The resulting RBC deformation towards the flow direction is suppressed by increased cytoplasm viscosity, while the gap between the membrane and solid wall becomes smaller with the cytoplasm viscosity. We analyzed transit time and found that the nondimensional transit time increases nonlinearly with respect to the viscosity ratio, whereas it is invariant to the membrane elasticity. These results will be useful for designing a microfluidic device to measure cytoplasmic viscosity.

We next investigated hydrodynamic interactions of RBCs (Fig.1b). The hydrodynamic interaction induces self-diffusion of RBCs even without Brownian motions. We analyzed flow-induced RBC diffusion by calculating the pairwise interactions between RBCs in simple shear flow. The shear-induced RBC diffusion is significantly anisotropic and the diffusivity monotonically decreases with the viscosity ratio of inner and outer liquids. The scaling argument also suggests that the diffusivity is proportional to the shear rate and haematocrit in a semi-dilute environment.

We also investigated sperm cell swimming in a fluid flow (Fig.1c). When a sperm cell swims in a shear flow, it can hydrodynamically change its swimming direction, allowing it to swim upwards against the flow. Which suggests that the upward swimming of sperm cells can be explained using fluid mechanics. Mammalian sperm cells must swim against the flow in the oviduct to find the egg cell. Thus such upward swimming is important for the fertilization process.

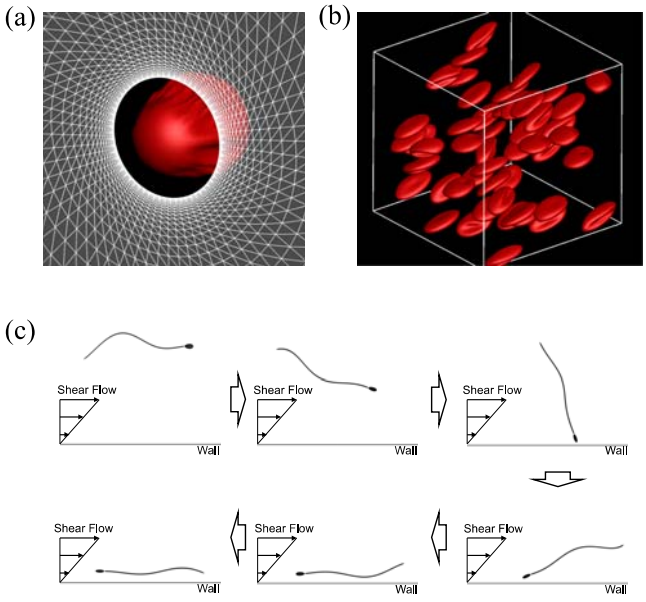

Fig.1 Computational results of cellular flows (a) single RBC flowing through a thin micro-pore (b) hydrodynamic interactions of RBCs in a semi-dilute suspension (c) upstream swimming of a sperm cell in shear flow near a boundary wall.

CONCLUSIONS

In this study, we have developed a computational biomechanics on red cell suspensions and swimming of a sperm cell. Our findings would be helpful for better understanding of cellular mechanics and utilizing micro fluidic devices. We expect to develop a model that can express biological functions based on mechanics by integrating cellular and macroscopic biomechanics in the near future.

ELASTIC MODULUS AND NANOSTRUCTURE OF A SINGLE TRABECULA IN BOVINE CANCELLOUS BONE

[1] **Satoshi Yamada**
[1] Division of Human Mechanical Systems and Design, Faculty of Engineering, Hokkaido University
Corresponding author email: syamada@eng.hokudai.ac.jp

INTRODUCTION

The cancellous bone is organized into a three-dimensional network of single trabeculae, and its strength depends on the network. The elastic modulus, strength, and nanostructure of single trabeculae are important factors in determining the strength of the cancellous bone. Accordingly, a single trabecula must be investigated to further understand the impact of aging, osteoporosis, and medicines on the risk of fracture of the cancellous bone. However, few studies have executed measurements of the elastic modulus on a single trabecula because of the technically challenges such studies present. Furthermore, the nanostructural effects on the mechanical properties of a single trabecula have not been elucidated, although various studies have been conducted on multiscale mechanical characterization in the cortical bone [1]. Thus, this study aimed to elucidate the elastic modulus of a single trabecula and the nanostructural effects on its mechanical properties.

METHODS

First, we investigated the elastic modulus of relatively large trabeculae by tensile tests and assessed the nanostructural effects at the hydroxyapatite (HAp) crystal scale on the elastic modulus by X-ray diffraction (XRD) techniques [2]. In this study, 18 trabeculae (at least 3 mm in length) were dissected from the edges of the cancellous bone in the proximal epiphysis of 3 adult bovine femurs. The specimens were fixed to thin metal jigs using superglue, and the tensile tests were conducted using a small tensile testing device under optical microscopic observation. Second, the specimens were perpendicularly irradiated with collimated characteristic X-rays of Mo-Kα and an XRD pattern was detected using an X-ray imaging plate to investigate the *c*-axis orientation of the crystals within a single trabecula and the degree of crystal orientation, evaluated as $\langle\cos^2\beta\rangle$ [1]. To investigate the deformation behavior of the crystals under the loadings, tensile tests were also conducted during XRD measurements. The HAp crystal strain ε^H in the longitudinal direction was calculated at each loading condition. Furthermore, energy-dispersive X-ray spectroscopy was performed on the cross-section of the specimens to evaluate the mineral content.

Although such tensile tests are suitable for the observation of the crystal deformation behavior, it is rather difficult to completely isolate, fix, and examine small bone specimens. While three-point bending tests do not require fixation of the specimen to a jig with a resin or glue, the tests generally require complete isolation of the specimen, deflection measurements at high resolution, and very precise loading. Therefore demonstrate a novel experimental method to investigate the elastic properties of a single trabecula on the basis of cantilever bending [3]. The micro-cantilever bending (MCB) test does not require a specimen to be isolated completely from the cancellous bone, and the specimen can be fixed easily during the test. A total of 10 rod-like trabeculae (1.12 ± 0.17 mm in length) inside the cancellous bone were dissected from the proximal epiphysis of an adult bovine femur. A specific single trabecula was isolated while keeping one extremity connected to the cancellous bone. The specimen was fixed into a holder almost vertically by embedding the cancellous bone portion in the epoxy resin. The load was perpendicularly applied to the free end. The elastic modulus in the longitudinal direction was calculated from the force–deflection relationships. The specimen was assumed to be a vertical circular cylinder of orthotropic material, and the shear stress was considered to be negligible. Then, we evaluated the degree of *c*-axis orientation of the crystals using XRD.

RESULTS AND DISCUSSION

The elastic modulus of single trabeculae was 11.5 ± 5.0 GPa by tensile tests [2] and 9.1 ± 5.4 GPa by MCB [3]. There was no significant difference between them and the values were observed to be at 42% of the cortical bone specimens taken from a bovine femoral diaphysis [1]. The mineral content was significantly smaller than in the cortical bone [2]. The *c*-axis of the HAp crystals aligned in the longitudinal direction within a single trabecula and were independent of the bone axis [2]; moreover, $\langle\cos^2\beta\rangle$ was smaller than the cortical bone [1]. The crystals were linearly deformed under tensile loading and the ratio of ε^H to tissue strain (strain ratio) had significant correlation with the elastic modulus [2]. However, the mineral content and $\langle\cos^2\beta\rangle$ did not vary broadly and did not correlate with the elastic modulus, although there were statistical correlations in both single trabeculae and cortical bone specimens, suggesting that a single trabecula may have a particular elastic modulus and nanostructure locally, and the difference in the elastic modulus between trabecular and cortical bone tissue may depend on the crystal orientation and mineral contents. Furthermore, the strain ratio may represent the nanostructure of a single trabecula and would determine the elastic modulus as well as mineral content and orientation. This study demonstrated the differences of the elastic modulus and nanostructure between a single trabecula and the cortical bone and the relationship between the elastic modulus and crystal orientation and deformation. The investigation of the effects of the elastic modulus, strength, and structure at the trabeculae scale on the strength of the cancellous bone is an essential topic to consider in future studies.

RESPIRATORY RESPONSES DURING CLINICAL WALKING AND DAILY-LIFE ACTIVITIES ARE DIFFERENT IN PEOPLE WITH CHRONIC OBSTRUCTIVE PULMONARY DISEASE

[1] Sidney Baroi, [2] Renae McNamara, [3] Simon Gandevia, [2] David McKenzie, [1,3] **Matthew Brodie**
[1] University of New South Wales, [2] Prince of Wales Hospital, [3] Neuroscience Research Australia, Australia

INTRODUCTION

Chronic obstructive pulmonary disease (COPD) is a progressive lung disease that is life threatening. Worldwide over 65 million people live with COPD [1] resulting in 3 million instances of early mortality each year. People with COPD have impaired ability to transport oxygen across the air-blood barrier between the alveoli and capillaries. During walking and activities of daily living (ADLs) muscle work is increased. People with COPD may have difficulty meeting the oxygen demand required to produce cellular ATP energy, find walking tiring and are therefore at increased risk of sedentarism, cardiovascular disease and depression.

In the clinic, lung function is often assessed **at rest** using a spirometer to measure forced expiratory volume in the first second (FEV_1). The GOLD threshold for moderate versus severe COPD is 50% of the predicted FEV_1 value based on patient demographics [2]. However, **in daily-life** it is not known how **activity** may influence respiratory responses for people with moderate to severe COPD. In this paper we used a wearable device to measure the effect of walking on respiratory frequency (breaths per minute) both in the clinic and during daily-life. Contrasting responses between people with different severity of COPD are discussed.

METHODS

Ten people with moderate to severe COPD (age 72.3 ± 10.8 years, BMI 28.2 ± 6.9 and FEV_1 41 ± 10 % predicted) gave informed consent before being assessed at Prince of Wales Hospital (ethical approval HREC 15/325). Physical assessments included the six-minute walk test (6MWT), the 30 second sit-to-stand test (STS) and the upper limb endurance exercise test (ULEET), 6 minutes lying and 6 minutes sitting. During the clinical assessments and for the subsequent 35 hours participants wore a Zephyr Bioharness (www.zephyranywhere.com). The wearable device included a flexible strap located at sternum height that measured chest expansions and contractions associated with breathing and a triaxial accelerometer that measured activity levels.

RESULTS AND DISCUSSION

In the clinic, the type of activity performed had a significant effect ($p<0.001$) on respiratory frequency and intensity level. Walking (6MWT) increased the breathing rate most.

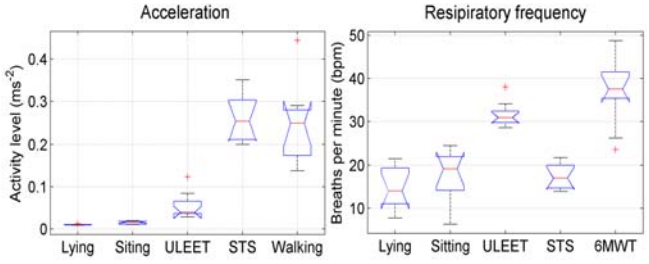

Figure 1: *Clinical assessment of intensity level and respiratory frequency during different activities.*

As 8 of the 10 participants were below the GOLD 50% threshold, a median split (37% FEV_1 predicted) was used to group people as having ***'Severe'*** versus ***'Moderate'*** COPD.

During the 6MWT the *Moderate* group had significantly ($p=0.04$) greater capacity to increase respiratory frequency (↑ 29 ± 10 bpm) than the *Severe* group (↑ 16 ± 7 bpm).

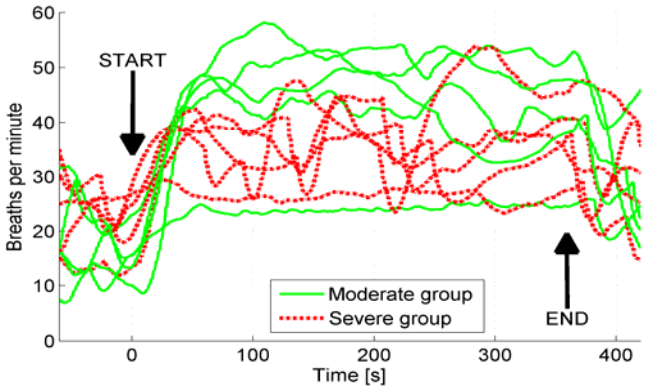

Figure 2: *Increased breathing rate during the 6MWT.*

In daily-life, no difference was observed in the time the device was worn between the *Moderate* (32.3 ± 2.4 hours) and *Severe* (33.1 ± 1.6 hours) groups. The *Moderate* group spent a significantly ($p=0.04$) greater proportion of time being active (23 ± 5 %) than the *Severe* group (17 ± 3 %). This indicates that the *Moderate* group may have been relatively less affected by COPD during ADLs.

Both groups spent a similar proportion of time (3 ± 2 %) engaging in high intensity (HI) ADLs (≥ 0.02 ms^{-2}). However, respiratory frequency in the *Severe* group (26.2 ± 3.9 bpm) was significantly higher ($p=0.008$) than the *Moderate* group (17.4 ± 3.8 bpm). This indicates that for the *Severe* group the respiratory systems may have had to work harder to meet oxygen demand during ADLs.

Clinical vs daily-life respiratory response. A significant interaction between HI ADLs, the 6MWT and COPD severity was observed (2-way ANOVA $p=0.01$). For the *Moderate* group, breathing rate was significantly higher ($p=0.008$) during the 6MWT (42.4 ± 11.0 bpm) compared to HI ADLs (17.4 ± 3.8 bpm). However, for the *Severe* group, the smaller difference in breathing rate between the 6MWT (35.0 ± 4.9 bpm) and HI ADLs (26.2 ± 4.0 bpm) did not reach significance. This indicates that the *Severe* group may have been at greater risk of exceeding respiratory capacity during ADLs than the *Moderate* group.

CONCLUSIONS

The remote assessments revealed differences in respiratory responses during exercise for people with *Moderate* versus *Severe* COPD. The clinical and daily assessments provided complementary information that may be useful to prevent future hospitalizations. Lager studies are now required.
