Sacroiliac joint (SIJ) biomechanics have been described in both in vitro as in vivo studies [2]. However, a standardized joint coordinate system for sacroiliac joint motion analysis is lacking, impeding interpretation of research results and communication between research groups. Moreover, the joints' complex anatomy, its extensive morphological variability and its small range of motion further limit comprehension of research results. Up to now, to the authors' knowledge, SIJ biomechanics have never been visualized in 3D. The authors of this paper proposed a joint coordinate system for the investigation of SIJ biomechanics [3], based on the procedure applied by Grood et al [1] on the knee. This study combines quantitative biomechanical data, acquired using this standardized procedure, with 3D visualization of SIJ biomechanics.

METHODS

Six cadaveric pelvises were stripped of their soft tissues, aside from the sacroiliac ligaments and the sacrotuberal and sacrospinal ligaments between the sacrum and coxal bones. The pelvises were mounted into a frame, and at least four visual markers were fixated into the sacrum and both coxal bones. Force was applied to the sacrum through a bar fixated in the sacral canal. Movement of the sacrum was induced in 3 directions: nutation – counternutation, lateral flexion and transverse plane rotation. During motion, marker coordinates were captured by the optitrack optical tracking system. A CT scan was taken in order to visualize the markers and bony morphology of the pelvis. Sacrum, both iliac bones and optical markers were 3D reconstructed using Mimics image processing software. Finally, the 3D reconstructed bones and their corresponding markers were linked to the marker coordinates using Matlab software, allowing to visualize 3D motion in the sacroiliac joint.

Motion in both sacroiliac joints was described using the method proposed by Grood et al [1]. Firstly, a Cartesian coordinate system (CCS) for both sacrum and coxal bones was established, based on bony landmarks on these two bony segments. Secondly, a Joint Coordinate System (JCS) was developed based on the body fixed axis of each of the CCSs. Finally, movement around the three axes of rotation of the JCS, nutation – counternutation (e_1 axis), lateral flexion (e_2 axis) and transverse plane rotation (e_3 axis), was described by angles α, β and γ. Translations q_1, q_2 and q_3 were described by vector H, directed from the origin of sacral CCS to the origin of the coxal CCS.

RESULTS AND DISCUSSION

Most motion occurred around the e_1 axis, with an average of little over 4°. Motions around the e_2 and e_3 axes were smaller, both with averages between 2 and 3°. Translations q_1, q_2 and q_3 did not exceed 2mm, with all averages around 1mm.

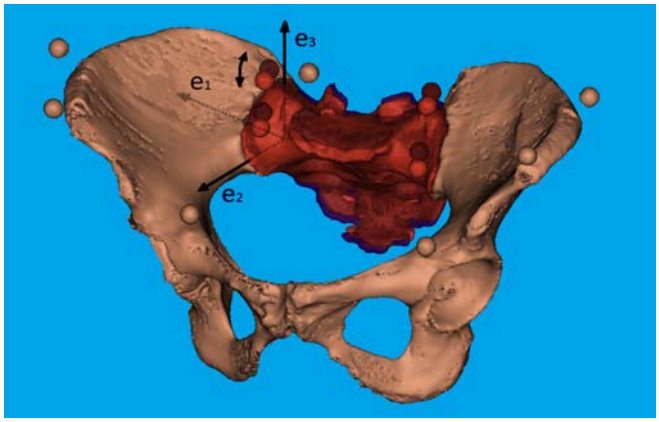

Figure 1: 3D visualization of the sacrum and its accompanying markers at the end range of motion in counternutation (dark red) and nutation (bright red) between the iliac bones (brown, shown with accompanying markers). The JCS of the right SI joint is shown, with axes of rotation e_1, e_2 and e_3.

This study is the first to combine quantitative biomechanical research, using a standardized coordinate system, with 3D joint motion visualization. As joint morphology varies greatly and movement in the SIJ is very small, research results are often difficult to comprehend. Therefore, 3D visualization adds a deeper insight into sacroiliac motion. However, further investigation of SIJ biomechanics and its relation to joint morphology is necessary.

CONCLUSIONS

This article proposes quantitative biomechanical data using a standardized joint coordinate system, combined with 3D visualization of SIJ biomechanics, allowing better interpretation of SIJ biomechanical research.

DEVELOPMENT OF A NOVEL WEARABLE SYSTEM FOR THE CLINICAL ASSESSMENT OF MOVEMENT QUALITY AND CONTROL IN LOW BACK PAIN

[1] **Ryan B Graham**, [1] Gulshan Preet Kaur Josan
[1]School of Human Kinetics, Faculty of Health Sciences, University of Ottawa
Corresponding author email: rgraham@uottawa.ca

INTRODUCTION

The use of wearable systems is becoming more common in health care and rehabilitation settings [1-2]. In general, a wearable system for patient monitoring consists of three main components: 1) the sensing and data collection hardware, 2) the communication hardware and software, and 3) the data analysis and display [1]. While there has been great interest in wearable sensors for in-home monitoring to mitigate falls, few researchers have applied such technology to low back pain (LBP) prevention/rehabilitation [3-5].

The goal of the present work was to develop a novel wearable system for the assessment of movement quality and control in LBP patients that is: 1) flexible (i.e. can be easily adapted), 2) powerful (i.e. can carry out simple as well as complex calculations and analyses), 3) efficient (i.e. completely portable and requires minimal user interaction), and 4) inexpensive (i.e. <$500). Presented below is an overview of the current state of the system, which is currently being optimized and tested.

METHODS

The system we developed involves 6 main parts, which are shown in Figure 1. The entire system is run through a custom iPad/iPhone application that we developed using Swift 2.2 and Xcode 7 (Apple Inc., CA, USA). Briefly, the system and custom software functions as follows:

1. Upon opening the application, the user logs in and is then asked to assess a new participant or to reassess an existing participant. The next step involves entering participant demographics as well as having the participant fill out various questionnaires that the user selects. These data are stored to the database as below.
2. The user selects which assessment task(s) they would like the participant to complete, and the app automatically moves through data collection procedures (e.g. sensor placement details and videos of what the participant will need to complete).
3. The system connects to wireless inertial measurement units (IMU) via Bluetooth and collects data for the length of time based on procedures in 2. The collection device provides required feedback such as metronome tones and can also take synchronized videos.
4. On-board calculations can first assess data quality then movement control and quality variables of interest.
5. Raw and processed data are sent to, stored, and organized in an encrypted cloud database. Data can continuously grow and are tagged to be accessed in a certain fashion (i.e. clinic where they were collected, user, participant, date, injury, age, etc.). We also use cloud computing and machine learning to continuously train our algorithms to differentiate groups.
6. Feedback is provided to the user regarding how the participant compares to others. The software can also filter for comparisons (e.g. only compare female LBP patients of between 20 and 30 years of age). Specific feedback is currently being refined, but we will provide z-scores for certain variables, as well as differentiate healthy vs. pathological groups using machine learning.

RESULTS AND DISCUSSION

We have developed a novel wearable system for the assessment of movement quality and control in LBP that meets each of our original criteria. The system is flexible, because the number of sensors and sample rate can be adjusted, and additional movement tasks and analyses can be added at any time. Currently, we are using repetitive trunk flexion tasks and assessing local dynamic stability and quality of trunk movement [6], but are adding to both. The system is powerful, because we can program any type of analysis directly into the application and can also harness cloud-computing and machine learning algorithms to differentiate groups (e.g. healthy vs. LBP). The system is efficient because it walks the user through the required steps and automatically stores tagged data to the database (i.e. Google Cloud) without any user interaction. Finally, the system is inexpensive as we have used (and concurrently validated) off-the-shelf IMU sensors (Meta Motion R, MbientLab Inc., CA, USA), which retail for $78 USD each and can be purchased in bulk. These characteristics make this wearable system ideal for our data collection needs.

CONCLUSIONS

We have developed a wearable system for LBP monitoring that is flexible, powerful, efficient, and inexpensive. We are beginning to test the system on patients, and are concurrently validating all aspects of the system and working extensively on adding additional static and dynamic movement tasks and analysis techniques. Our plan is to create an open source system for the greater biomechanics community to use for collaborative research.

INTRODUCTION

It is not clear if low back pain (LBP) is related with obesity [1-3] but both, LBP and obesity, appear to affect walking [1,4-5]. A better understanding of the specific gait abnormalities may help improve rehabilitation programs and treatments.

The aim of this study was to compute and analyse the impact of obesity on spatio-temporal parameters and center of pressure (COP) displacements during gait in patients with aspecific LBP and to compare those with healthy persons.

METHODS

48 patients with aspecific low back pain (aLBP, 24 females: 41±17 years; 24 males: 39±14 years) and 34 healthy subjects (CG, 16 females: 45±18 years; 18 males: 45±17 years) walked 3 times at 3 different self-selected speeds (slow, preferred, fast) over an electronic walkway (GAITRite Walkway system). The order of gait speeds was randomized and both groups were divided in subclasses according to their body mass index values (BMI) (non-obese: BMI ≤ 25 kg/m^2 – obese: BMI > 25 kg/m^2).

Spatio-temporal and COP parameters were computed from contact data (i.e. velocity, cadence, step length, step time, swing time, posterior-anterior, medial-lateral and resultant COP excursions and velocities). Mixed-model ANOVA was used to investigate the influence of BMI, pathology and velocity on parameters.

RESULTS AND DISCUSSION

Obese subjects presented a decrease of gait velocity, step and stride length, swing and single support phase (Figure 1a), posterior-anterior and medial-lateral COP velocities (Figure 1b). Conversely, base of support and double support phase increased (Figure 1a). No significant differences were observed between patients with aLBP and CG for both spatio-temporal and COP parameters.

CONCLUSIONS

Obesity influenced spatio-temporal and COP parameters but our results did not show any difference between patients with aLBP and CG, nor between obese subjects with aLBP and non-obese subjects with aLBP. These findings are not consistent with the literature where patients with LBP are describe as walking slower with smaller steps and longer stance phases than healthy subjects [6-9]. Furthermore, it was demonstrated that these outcomes were more altered when LBP was associated with obesity [9]. In further studies, due to the heterogeneity of LBP definition, we should extend our LBP sample considering various larger subgroups selected from clinical features such as symptoms, clinical examinations or specific spine damages.

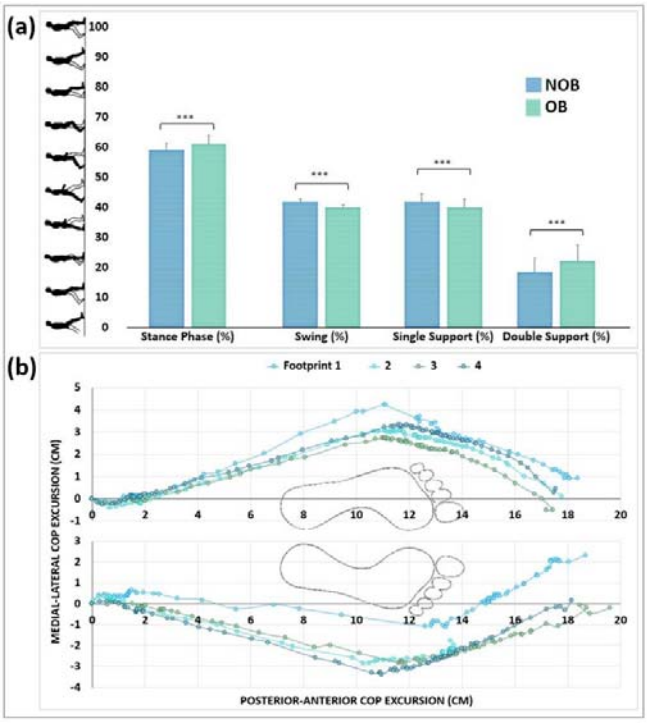

Figure 1: (a) Obese and non-obese gait phases, expressed in percentage of a gait cycle; (b) representation of the resultant COP excursion of a patient with aLBP at slow walking speed (COP_{xy}).

RELIABILITY AND REPEATABLITY OF LASER DISPLACEMENT MECHANOMYOGRAPHY ON LUMBAR SPINE MUSCLES DURING SPINAL EXTENSION AND FLEXION

[1]**Christian Than**, [1]Laura Seidl, [1]Danijel Tosovic and [1]J. Mark Brown
[1]University of Queensland
Corresponding author email: christian.than@uqconnect.edu.au

INTRODUCTION

Mechanomyography (MMG) is a non-invasive technique that determines muscle contractile properties by recording low-frequency lateral oscillations of a muscle belly, following maximal percutaneous neuromuscular stimulation (PNS) [7]. These measurements correlate to the mechanical swelling of a muscle's belly as observed by the displacement of the skin's surface following stimulation [1,5]. Recent literature supports the potential use of MMG as a diagnostic tool for identifying muscle injury [5,8]. Particularly, the technique may be utilized for the diagnosis of injury sites in low back pain (LBP) patients [3]. However, the use of the MMG technique for diagnostic purposes requires further validation. The current study investigates the reliability and repeatability of laser displacement sensor (LDS)-MMG within a healthy cohort not suffering LBP during extension (lying) and flexion (seated) of the spine. The clinical relevance is the elucidation of whether injured LBP patients, with limited mobility, may either lie or sit when diagnosed with MMG in the clinic.

METHODS

Healthy male and female subjects (mean ± standard deviation, 25±9.42 years, BMI 21.79 ±2.99, n=34) were recruited for two separate testing sessions. Ten lumbar zygapophyseal joints, as well as two bilateral sites over the sacrum, were located via palpation and ultrasound. Participants were then placed prone on a padded plinth with a pillow underneath the anterior superior iliac spine to prevent excessive spinal lordosis during testing.

MMG was recorded from erector spinae and multifidus muscles overlying the 12 low back sites. Two stimulatory electrodes (50mm inter-electrode distance) were placed on the skin to activate muscles at each site. To measure radial muscle belly displacement following PNS, a LDS was positioned perpendicularly overlaying the muscle belly and midway between the two stimulatory electrodes. Muscles were then maximally stimulated following a twitch stimulus [9]. Stimuli of increasing current (mA) were delivered whilst maintaining a constant voltage (400V) and duration (200us) (Digitimer DS7AH) until a maximum muscle contraction was observed without distortion of the sinusoidal MMG waveform [9]. Thirty second intervals were provided between stimuli to minimize fatigue from overstimulation.

The MMG protocol was then repeated for all 12 sites with subjects in a flexed spine position. This consisted of subjects seated in a modified testing chair with their chest against the backrest, whilst straps were secured around the upper thorax. A second testing session was repeated a week later. A two-way ANOVA with Tukey's post-hoc was used to locate significance between sessions, and positions, with respect to site.

RESULTS AND DISCUSSION

There were no significant differences between separate testing sessions for the same position ($P>0.05$). The intra-class correlation coefficients (ICCs) in extension for maximal muscle displacement (Dmax), contraction time (Tc) and velocity of contraction (Vc) were classified as 'very good' (0.8-0.9) whilst half-relaxation time (½Tr) and half-relaxation velocity (½Vr) were 'poor' (0.4-0.5) and 'good' (0.7-0.8), respectively. In flexion, Dmax, Tc and Vr were 'excellent' (>0.9), whilst ½Tr and ½Vr were 'fair' (0.6-0.7) and 'very good', respectively [2]. On both sides of the spine, Dmax and ½Vr for L1/L2, L2/L3, L3/L4, L4/L5 and L5/S1 were significant ($P<0.05$) between extension and flexion. Tc was significant ($P<0.05$) for all sites, Vc was significant ($P<0.05$) for only L1/L2 on both sides. ½Tr was not significant ($P>0.05$) for any site between positions.

CONCLUSIONS

The majority of MMG-derived muscle contractile properties were determined to be reliable measures in both extension and flexion of the lumbar spine. However, flexion of the lumbar spine does appear to provide more reliable results as suggested by higher ICCs. Significant differences between extension and flexion of the spine indicate that joint position has an effect on lumbar paraspinal muscle contractile properties [6,4].

A 4D CT STUDY OF ULNAR VARIANCE DURING DYNAMIC, *IN VIVO* FOREARM ROTATION

[1] **Desney Greybe**, [2] John Troupis, [3] Jacqui Hislop-Jambrich and [1] Thor Besier

[1] Auckland Bioengineering Institute, University of Auckland, Auckland, New Zealand
[2] Department of Medicine, Monash University, Melbourne, Australia

INTRODUCTION

For many years, the relative length of the ulna with respect to the radius has been considered an important factor in wrist joint mechanics [1]. This relative length has been termed ulnar variance and is the distance between the distal edge of the radial sigmoid notch and the distal apex of the ulnar head's articular dome [2]. A negative value corresponds to an ulna that is shorter than the radius. Similarly, a positive value represents an ulna that is longer than the radius.

Ulnar variance is known to influence loading across the ulnocarpal joint and its associated structures [3]. As such, it has direct implications in clinical disorders such as Ulnocarpal Impaction Syndrome [4]. Ulnar variance is also known to change with forearm posture, making the relationship more complicated. The ulna shifts distally, relative to the radius, as the arm moves from a supinated to pronated position [5]. However, to date this has only been demonstrated using cadaveric models or based on static, *in vivo* positions.

The goal of this study was to evaluate how forearm pronation and supination affects ulnar variance during active, *in vivo* forearm rotation, using dynamic (4D) CT data.

METHODS

The right wrists of five volunteers (26 ± 2 years) were 4D CT scanned (TOSHIBA Aquilion ONE) while they performed active forearm pronation and supination. The forearm movements were timed to take one second for each movement direction and were performed to the end ranges of motion. Full 3D CT volumes were captured at approximately 6 Hz, with an in-plane resolution of 0.65 mm and a slice thickness of 0.5 mm. A custom, python-based pipeline was used to automatically segment the radius and ulna bones in each image stack. An Iterative Closest Point algorithm was used to register the respective data clouds and calculate radius and ulna bone transformations. The segmented data were also fit to parameterised bone models. These were used to define the anatomical coordinate system and the anatomical landmarks that were used to calculate ulnar variance at each time step.

RESULTS AND DISCUSSION

Regardless of movement direction, the ulnar head was located more distally with the forearm in a pronated position than in a supinated position. This is consistent with previously reported data, based on static forearm positions and cadaveric models. Average ulnar variance was - 2.6 ± 1.0 mm when maximally supinated and 2.2 ± 0.7 mm when maximally pronated. This represents, on average, ~ 5 mm change in ulnar variance through the forearm's range of motion. Ulnar variance also tended to be more positive when actively supinating than when pronating the forearm. The difference was significant when the forearm was in a neutral position ($p < 0.05$). Ulnar variance was 0.4 ± 0.4 mm while supinating and - 0.4 ± 0.4 mm while pronating. This is an important result as ulnar variance directly affects the load transmitted from the carpus of the hand to the head of the ulna. A change from - 1 mm to + 1 mm can almost double the load at the ulnocarpal joint [4]. Therefore, understanding the relative positions of the bones during dynamic movement, ideally under varying muscle loads, is important for accurately studying wrist joint mechanics.

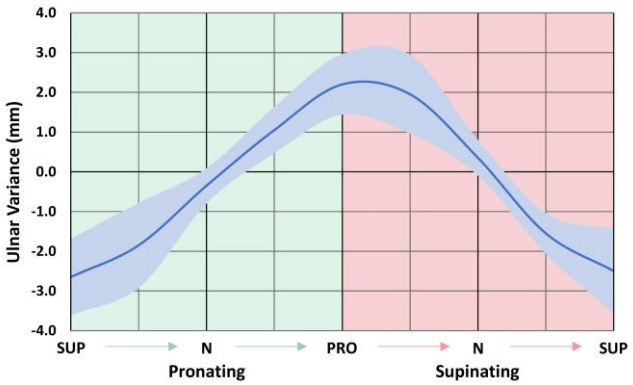

Figure 1: Ulnar variance with active forearm pronation and supination. Blue line gives mean ulnar variance and lighter blue band represents one standard deviation. (SUP = maximally supinated forearm, N = neutral forearm and PRO = maximally pronated forearm).

CONCLUSIONS

This study provides evidence that the relationship between ulnar variance and forearm rotation differs between dynamic and static analyses and depends on movement direction. The analysis will be expanded to include a larger data set to allow more confident conclusions to be drawn.

SCIATIC NERVE STIFFNESS INFLUENCES THE MAXIMAL ANKLE RANGE OF MOTION

[1,2]**Ricardo J. Andrade**, [2,3]Sandro R. Freitas, [1,4]Guillaume Le Sant, [1]Lilian Lacourpaille, [1,5]François Hug, [1,6]Raphäel Gross, [1]Antoine Nordez

INTRODUCTION

The maximal range of motion (ROM) of a joint is an important functional parameter to estimate the maximal muscle length or muscle extensibility [1]. It is a long-held belief that maximal dorsiflexion ROM is restricted by the tension within the calf muscles [2]. However, it is thought that peripheral nerves may also limit the ROM [3], but it has never been demonstrated. This study aimed to determine: 1) whether the sciatic nerve stiffness assessed using ultrasound shear wave elastography is correlated with the maximal dorsiflexion ROM (experiment I); and 2) whether a 6-min static stretch of the sciatic nerve increases the ankle's maximal ROM (experiment II).

METHODS

Sciatic nerve and *gastrocnemius medialis* (GM) shear wave velocity (SWV), an index of stiffness, was assessed using elastography. In both experiments, the knee of the tested lower limb was fully extended, and passive maximal dorsiflexion ROM was assessed with the hip neutral (HIP-neutral, 0°) or flexed at 90° (HIP-flexed), where the maximal dorsiflexion ROM is known to be considerably lower [3]. In the experiment I, the ROM difference between these two hip positions (ΔROM) was calculated for 29 healthy participants. The sciatic SWV was then assessed in HIP-neutral during one ankle rotation (2°/s). Pearson (*r*) correlation coefficients were calculated at different ankle angles to determine whether the ΔROM depends on the sciatic nerve stiffness.

In the experiment II, 15 healthy participants performed Stretch and Control sessions, in a randomized order. In both sessions, the maximal dorsiflexion ROM (HIP-neutral and HIP-flexed), ankle torque, the electromyography (EMG) of calf and *tibialis anterior* muscles, and SWV of the sciatic nerve and GM were assessed before and immediately after the intervention. Participants underwent a total of 6-min rest in HIP-neutral (Control session) or sciatic nerve stretching (Stretch session), where the hip joint was passively flexed, and followed by thoracic and cervical flexion. During both interventions, the knee of the tested lower limb remained in full extension, and the ankle angle was maintained in neutral position (0°) to minimize the stretch of the calf muscles. Repeated measures ANOVAs were performed to analyze the effects of nerve stretch of the aforementioned variables.

RESULTS AND DISCUSSION

In the experiment I, large correlations were observed between the sciatic nerve stiffness and the maximal ROM in dorsiflexion ($0.570 < r < 0.712$, $p < 0.001$, Figure 1A), suggesting that nerve stiffness can play an important role on the maximal dorsiflexion ROM. In the experiment II, the nerve stretching induced a 13.3% (±7.9%) decrease in the sciatic stiffness ($p < 0.0001$) and an increase in the maximal dorsiflexion ROM (+25.1% ± 20.1%; $p < 0.0001$); in the absence of any changes in GM stiffness, ankle torque, and EMG (Figure 1B). No changes were found for all the variables in the Control session. These results showed that it is possible to considerably alter the maximal dorsiflexion ROM without stretching the calf muscles. As the sciatic nerve stiffness decreased, we are confident that the increase in maximal ROM is due to the decrease in sciatic nerve stiffness. A further analysis showed that after the nerve stretch (Stretch session) the increase in maximal dorsiflexion ROM in HIP-flexed, position that strongly stretches the sciatic nerve, was correlated to the decrease in the nerve stiffness ($r = -0.529$, $p = 0.042$; Figure 1C).

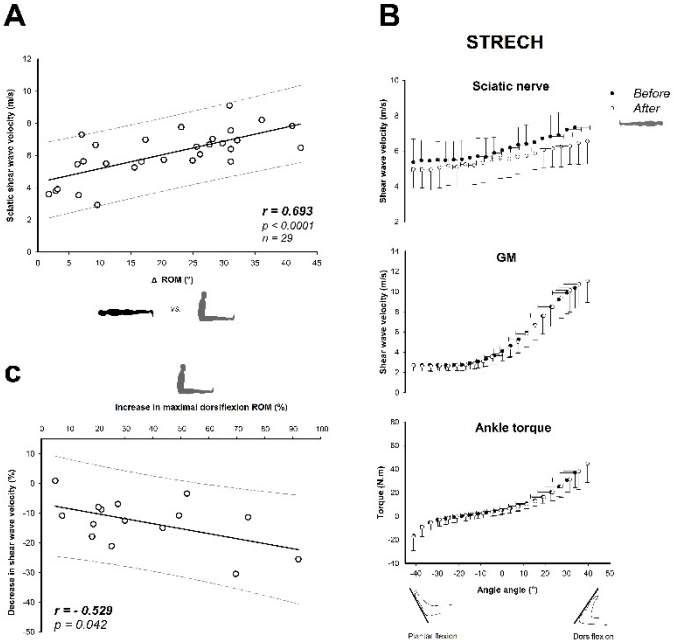

Figure 1: **A**, Correlation between the SWV and the ΔROM; **B**, Effects of nerve stretch (Stretch session) on the sciatic nerve and GM SWV and ankle torque; **C**, Correlation between the changes induced by the nerve stretch in sciatic nerve SWV and maximal dorsiflexion ROM (HIP-flexed).

CONCLUSIONS

The present study shows that: 1) the maximal dorsiflexion ROM can be limited sciatic nerve stiffness, a non-muscular tissue; and ii) a sciatic nerve stretching induces a significant decrease in local nerve stiffness that is accompanied by an increase in ankle's flexibility without altering calf muscles stiffness and ankle torque.

COMPARISON OF IN VIVO TIBIOTALAR AND SUBTALAR KINEMATICS IN CHRONIC ANKLE INSTABILITY PATIENTS AND ASYMPTOMATIC CONTROLS: A HIGH-SPEED DUAL FLUOROSCOPY STUDY

[1]**Koren E Roach**, [1]K. Bo Foreman, [1]Alexej Barg and [1]Andrew Anderson
[1]University of Utah
Corresponding author email: Koren.Roach@utah.edu

INTRODUCTION

Chronic ankle instability (CAI) often results from trauma to the ankle and is associated with persistent feelings of instability, pain, and frequent ankle sprains [1]. It is clinically hypothesized that deleterious angular and translational (i.e. kinematic) motion at the tibiotalar and subtalar joints causes ankle osteoarthritis (OA) in CAI patients [2]. However, *in vivo* measurements of tibiotalar and subtalar motion in CAI patients are not currently available, and thus, the pathogenesis of OA in CAI patients is unknown.

Joint kinematics are often derived from motion capture techniques that track the positions of reflective markers adhered to the skin over bony landmarks. However, skin-marker motion capture cannot distinguish between motion of the tibiotalar and subtalar joints as there are no reliably palpable landmarks for placement of a skin marker about the talus. Dual fluoroscopy (DF) is an imaging modality that accurately measures three-dimensional *in vivo* bone movement and can be used to identify the independent roles of the tibiotalar and subtalar joints. The purpose of this study was to use DF to evaluate and compare *in vivo* tibiotalar and subtalar joint kinematics between CAI patients and asymptomatic controls during activities of daily living.

METHODS

After obtaining Institutional Review Board approval (IRB#65620) and informed consent, ten healthy control subjects (5M/5F; 30.9±7.2 yo; BMI: 23.5±3.5) and four CAI patients (1M/3F; 30.8±4.1 yo; BMI: 25.8±3.4) were enrolled in this study. Subjects performed a single-leg balanced heel-rise and treadmill gait at 0.5 and 1.0 m/s while DF images were acquired. Subject-specific CT scans were used in conjunction with the DF data to quantify *in vivo* tibiotalar and subtalar joint kinematics for all subjects. Kinematic results from the CAI patients were compared to the controls.

RESULTS AND DISCUSSION

During balanced heel-rise, 70%, 58% and 65% of the measured CAI tibiotalar internal/external rotation (IR/ER), subtalar inversion/eversion (In/Ev) and subtalar IR/ER, respectively, fell outside the 95% confidence interval (CI) of the control subjects. In addition, CAI patients frequently exhibited greater tibiotalar and subtalar IR/ER and subtalar In/Ev (Figure 1) with an opposing trend when compared to controls. These biomechanical differences may indicate a protective mechanism used by CAI patients to prevent further injury. During 0.5 m/s gait, 50% and 60% of CAI tibiotalar dorsi/plantarflexion (D/P) and subtalar IR/ER, respectively, fell outside the 95% CIs of the control subjects. During 1.0 m/s gait, 62%, 65%, and 73% of CAI subtalar D/P, In/Ev, and IR/ER, respectively fell outside the 95% CIs of the control subjects.

CAI patients often exhibited less rotational and translational range of motion (ROM) in both joints. Most CAI patients demonstrated consistently less In/Ev ROM for both joints, although individual ROM values were not always outside the 95% CIs of the controls. During gait, all CAI patients exhibited less tibiotalar translational ROM than the mean of the controls. The reduced ROM exhibited by the CAI patients may indicate a compensatory mechanism to limit movement in the ankle and reduce the risk of further injury.

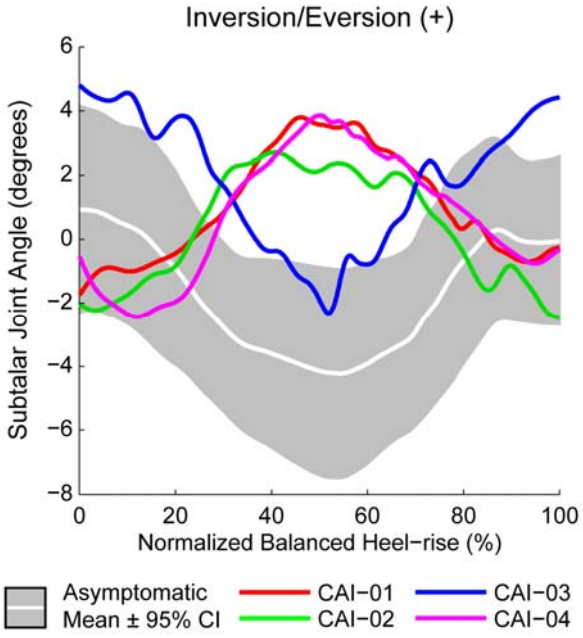

Figure 1: Subtalar inversion/eversion (+) joint angles of patients with chronic ankle instability (CAI) compared to asymptomatic control subjects during a single-leg balanced heel-rise activity.

CONCLUSIONS

Our results suggest that altered tibiotalar IR/ER, subtalar In/Ev and IR/ER, and reduced translational ROM may be biomechanical characteristics of CAI. These data could clarify the pathomechanical characteristics of this condition and illuminate the steps required to refine current diagnosis and treatment strategies.

INTRODUCTION

Juvenile idiopathic arthritis (JIA) is an autoimmune musculoskeletal disorder causing a chronic inflammatory process of the synovial membrane that mainly affects large, load bearing joints such as the knee and ankle [1]. JIA causes swelling and pain, and the inflammation is generally treated with anti-inflammatory drugs. As a consequence of a persistently active disease condition, joint cartilage can result permanently damaged, making JIA the leading cause of childhood disability due to a musculoskeletal disease.

It is still unclear whether an altered gait pattern might have a role in the process of JIA progression that leads to cartilage damage. If on one hand, it might be hypothesized that an inflammation in one of the ankle joints might induce a protective walking strategy aiming at minimizing its loading, on the other hand it is also plausible to hypothesize that an asymmetric gait pattern, causing excessive loading of the joint, might have been the reason for its persistent inflammation. This study aimed at verifying the plausibility of these two hypotheses in a group of children presenting at least one ankle joint affected by JIA, by investigating the values of the ankle joint contact force (JCF) in the two limbs.

METHODS

20 patients affected by JIA (gender: 5 males, age: 11.5±3.1 years old, height: 145±17 cm, mass: 45±18 kg) were recruited over three years in two Italian research hospitals (G. Gaslini, Genova and Bambino Gesù, Rome). The patients' condition was evaluated at three time points: baseline, and after 6 and 12 months. The assessment consisted in rheumatologic visit, clinical gait analysis and magnetic resonance imaging (MRI). The MRI scans included multiple sequences of high resolution ankle and foot scans at baseline and month 12, and a full lower limb scan at month 6. For the purpose of this study, a subset of nine datasets were isolated, corresponding to those recorded from six different children when their pathology was involving only one ankle.

Three-dimensional, patient-specific bone geometries were obtained through segmentation of the MRI images and used to generate musculoskeletal (MSK) models of the lower limbs at the three time points. NMSBuilder was used at this purpose [2]. The hip joint was modelled as a ball and socket joint and the knee and ankle joints as hinges; the joint parameters were identified by fitting appropriate analytical surfaces to the bone geometries. A semi-automatic supervised atlas registration procedure was performed to map muscle attachments onto the personalized bone geometries and adjust the resulting muscle paths using the medical images as reference. Muscle strength was calculated by scaling the maximum isometric forces of an existing reference model [3] using the patient's weight. MSK models and gait analysis data were then used to simulate the patients' walking patterns, estimate the muscle-tendon forces using the static optimization method and finally calculate the JCF acting at the tibiotalar joint. All simulations were performed using OpenSim [3]. Peak values, root mean squared errors (RMSE), and correlation coefficients were used for curve comparisons.

RESULTS AND DISCUSSION

RMSE (0.41±0.24 BW) and correlation coefficients (range 0.68 – 0.99) suggest similarly shaped JCF in the two limbs. Although not statistically significant at group level (t-test, p=0.38), differences larger than 7% between the mean JCF peaks (right: 5.5±0.7 BW, left: 5.5±1.2 BW) at the two ankles were observed in all cases, with the load on the affected joint being lower in six out of the nine cases.

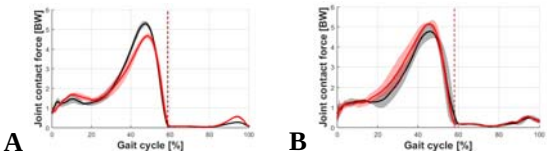

Figure 1: Asymmetric JCF (left in red) in two affected left ankles showing A) joint unloading and B) load increase.

CONCLUSIONS

This study represents the first attempt of using patient-specific MSK models of the lower limb to investigate the biomechanical response of the ankle joint in children affected by JIA. Due to the heterogeneity of the pathology, out of the 54 datasets collected so far, only nine could be used to investigate whether the ankle joint load would be reduced or increased due to joint involvement. The reported results suggest that the altered biomechanics leads preferentially to a protective strategy unloading the painful ankle joint. Ongoing processing of the collected dataset will allow to investigate alternative mechanisms by considering also other joints and changes over time of the disease status.

INTRODUCTION

Ankle sprain is one of the most common joint injuries in sport activities or in the daily life. About 10-20% acute ankle sprain patients are likely to develop chronic ankle instability symptoms, which result in sprain-instability-recurrent sprain loop. Therefore, patients would eventually get osteochondral lesions and osteoarthritis and their daily activities could be greatly restrained. A number of previous studies employed clinical comparison, cadaveric experiment, and finite element model to study the pathogenesis of ligamentous posttraumatic ankle osteoarthritis (PTOA), but a convincing conclusion is yet addressed. Since the ankle anatomy of mouse and that of human are comparable regarding to musculoskeletal structure [1, 2], the mouse might be the potential ideal animal model to study the pathogenesis of ankle osteoarthritis in higher clinical evidence level. In this study, we aimed to use a mouse model to explore ligamentous injury-induced PTOA by surgically transecting different lateral ligaments of mouse's hind foot and assessing both behavioral and histological results.

METHODS

In this study, 24 male C57BL/6J mice were randomly assigned into three groups. After training each mouse by beam walking, we transected different lateral collateral ligaments of 16 mice from two experimental groups under a microscope. SHAM group had no ligaments dissection operated; CFL-only group had calcaneofibular ligament (CFL) dissection operated to imitate moderate ankle sprain; ATFL+CFL group had both calcaneofibular ligament (CFL) and anterior talofibular ligament (ATFL) dissection operated to imitate the severe ankle sprain. Three days after surgery, we forced the mice to do wheel running six days per week for eight weeks in order to accelerate their OA formation. Elevated beam walking test (Figure 1) and foot print analysis were used to assess the balance ability of ankle. For beam walking test, the mice were subject to the duration to cross the beam and the times that the hind foot slips off the beam, which are recorded before and after surgery at different time intervals. For gait analysis, we measured elements of mice foot prints on white paper and obtained stride length asymmetry, paw overlap asymmetry, hind foot base width, forefoot base width, hind foot stance length and forefoot stance length. For histological analysis, ankle joint slices were stained by standard safranin O and fast green protocol.

RESULTS AND DISCUSSION

In elevated beam walking test, each test was proceeded three times to minimize random errors. Comparing to SHAM group, neither ATFL+CFL group nor CFL-only group shows significant difference of hind food slippery times on baseline (before the surgery). After the surgery, ATFL+CFL group shows significant difference ($p < 0.05$) from SHAM group on D3, W1, and W2. CFL-only group shows difference ($p < 0.1$) on W1 and significant difference ($p < 0.05$) on W2. Aside from the number of slips, the average time to cross the beam is also documented. In general, the duration is not affected by the transection of the lateral ankle ligaments statistically ($P > 0.05$). The asymmetry of stride length is affected by the transection of lateral ankle ligaments ($P < 0.05$). Comparing to SHAM group, ATFL+CFL group and CFL-only group had smaller left-stride lengths on D3 ($P < 0.05$). Left side stride lengths of CFL-only group is greater than that of SHAM group on W1 ($P < 0.05$). P-values are computed with ANOVA.

Figure 1: Elevated beam walking test to access mouse instability

Eight weeks after surgery, we analyzed the degree of injury of ankle histologically. In CFL-only and ATFL+CFL group, both the tibiotalar and the subtalar joints were remarkably degenerated and the degeneration of the tibiotalar joint was significantly worse. Moreover, the injury caused a worse consequence to CFL+ATFL group than CFL-only group. We have successfully established the mouse ankle OA model to evaluate surgical-induced joint instability.

CONCLUSIONS

The mouse could be an ideal animal model to explore mechanisms of ankle instability. The group of mice with worst ankle sprain (CFL+ATFL injury) provides less stability and has higher possibility to develop PTOA. This finding would benefit the understanding of chronic ankle instability and its progress mechanism, offer a theory to cure degeneration of cartilage injury, lead to better management of chronic ankle instability.

ALTERED MOVEMENT STRATEGY OF CHRONIC ANKLE INSTABILITY INDIVIDUALS WITH POSTURAL INSTABILITY CLASSIFIED BASED ON NYQUIST AND BODE ANALYSES

INTRODUCTION

Altered postural stability and movement patterns has been observed in patients with chronic ankle instability (CAI) [1], which is believed to lead to deteriorations in physical activity and health-related quality of life [2]. However, a limited understanding of this complex pathology still exists because of conflicting results among studies with similar outcome measures. The heterogeneity of CAI could explain the inconsistency of postural control strategies displayed during balance tasks. Existing evidence has emphasized that CAI is a multidimensional health condition that is associated with various insufficiencies [3], which helps to explain why CAI patients have variability in the types and combinations of measurable deficiencies related to this ankle pathology. For example, some patients with CAI may have insufficiencies in postural control, while others may not. Yet, clinical interventions, including movement strategy restoration, is often applied homogeneously. Therefore, identifying CAI patients with postural instability is critical prior to determining what movement strategies may be the contributing factors to altered postural control associated with CAI. This will allow more successful selection of the most appropriate interventions for CAI.

Novel engineering control theory techniques, such as Nyquist and Bode stability analyses [4], can classify the postural control system as stable or unstable. However, there is no previous study that has specifically examined movement strategies during a balance task in CAI patients with known postural instability using the Nyquist and Bode stability criteria. The purpose of this current study was to assess movement strategies during a single leg balance in CAI individuals with postural instability identified by Nyquist and Bode analyses and healthy controls.

METHODS

Ninteen participants with self-reported CAI (13M, 16F; 22.37±3.02yrs; 170.88±8.72cm; 72.57±13.66kg) and 15 healthy controls (4M, 11F; 21.07±3.88yrs; 165.82±6.76cm; 65.95±13.67kg) volunteered for this current study.

Participants performed single-leg eyes closed static balance trials. The sagittal and frontal plane kinematics at the ankle, knee, and hip as well as center of pressure (COP) trajectories were recorded during three, 20-second trials using a passive retroreflective marker motion capture system interfaced with a force platform. All kinematic and COP data were sampled at 100 Hz. The Nyquist and Bode stability analyses, which classify COP waveforms as stable or unstable based on the resulting gain and phase margins, were performed to identify the presence of postural instability. This verified that the CAI participants had a postural control deficit and that the healthy participants did not. Sample Entropy (SampEn) was implemented to analyze movement strategies during the postural control task. Mann-Whitney U tests were utilized to compare SampEn values between the CAI participants and healthy controls. Significance was set a *priori* at $P<0.05$.

RESULTS AND DISCUSSION

CAI participants with postural instability demonstrated a significantly lower SampEn value in frontal plane hip kinematics compared to the healthy controls (CAI=0.17±0.04, Control=0.21±0.08, $P=0.03$). No differences existed in other kinematic variability measures between CAI participants with postural instability and healthy controls. ($P>0.05$).

Sensorimotor insufficiencies following an initial ankle sprain have been hypothesized to contribute to altered postural control strategies associated with CAI [1], as evidenced by reweighted dominance on hip musculature strategies during a balance task in individuals with CAI [5]. In this current study, CAI participants with postural instability demonstrated less variability of the frontal plane hip kinematics during a single leg balance task compared to the control group. The findings of this current study indicate that CAI participants with postural instability may increase rigidity at the hip to maintain single leg stance by eliminating extra movement as a potential adaptive strategy. However, the rigid hip strategy in maintaining an upright posture may decrease flexibility to different perturbations and constraints [6], possibly having an association with the lingering issues observed in CAI patients. Thus, it is critical to explore how rehabilitation programs can develop proper postural control strategies to help these patients cope with their ankle pathology.

CONCLUSIONS

CAI participants with postural instability demonstrated less variability of frontal plane hip kinematics compared to healthy controls. The decline in SampEn values in participants with CAI reflects changes in the sensorimotor constraints on movement patterns during a single leg stance and indicates a less adaptable sensorimotor system below a healthy range to perturbation and environmental changes.

REFLECTIONS ON MUSCLE, TRUTH, SERENDIPITY, AND PARADIGMS

Walter Herzog

BACKGROUND

Two years ago, I participated in a workshop on neuro-muscular biomechanics, and at the very end of the discussion, a student asked all panelists: "what is the greatest impact you have made in your scientific life". I have thought about that question many more times since then, and in preparation for the Muybridge lecture, I did again. I came to the conclusion that it might be difficult to judge what findings may have made an impact in the field, while comparatively, it was much easier to identify findings and discoveries that formed my own thinking the most. I chose three findings that in very different ways affected the way I think about muscle contraction. They may be summarized as: (i) force enhancement above the plateau of the force-length relationship, (ii) passive force enhancement, and (iii) titin's ability to change its stiffness (and thus force contribution) in eccentric contractions. These three topics are important to me because the first one forced me to re-evaluate on a fundamental level my knowledge of muscle contraction; the second one came about by pure serendipity, unpredicted, unexpected, and I re-discovered that not everything in science can be planned; and the third one led me to the conclusion that maybe, 61 years after the last scientific revolution in muscle contraction, we need a new way of thinking, a new paradigm.

TRUTH

In 1982, Paul Edman, published a classic paper on residual force enhancement in skeletal muscles. A key question was if force in the enhanced state could exceed the maximal isometric force at optimal length. If yes, then factors other than cross-bridge mechanics would have to account for that extra force; if no, residual force enhancement could be explained exclusively within the existing frame work of the cross-bridge theory. Edman found the latter, forces in the enhanced state did not exceed the isometric force at the plateau of the force-length relationship.

18 years later, I asked one of my postdocs to stretch single frog fibres on the descending limb of the force-length relationship to test for stiffness properties. She found that for many experimental conditions, the residual force after stretching was 20-30% greater than the isometric plateau forces. We repeated the experiment, used other muscles and preparations, always with the same result. In that moment, a scientific truth – residual force enhancement can never exceed the isometric plateau forces – died, and with it all the theories associated with that thinking, and I realized first hand that scientific knowledge is a continuously changing quantity.

SERENDIPITY

In 2002, we published a paper on the so-called "passive force enhancement" property of skeletal muscle. The experiments that led to these findings had objectives unrelated to anything remotely associated with passive forces. For the longest time, I was convinced that we had made an experimental error, because we found something that did not exist, that COULD NOT exist. Only following further experimentation using other preparations and working on different structural levels did I dare to publish those results. We found the passive force enhancement property by accident in experiments aimed at solving a different set of questions. Serendipity provided us with findings that changed my thinking about muscle contraction, and this new thinking has dominated the past 15 years of our experimental work.

PARADIGM

In 2008, I gave a seminar on muscle contraction, and following that seminar, a student asked "how far can you stretch a sarcomere before it breaks?" I had no idea. So, I tasked one of my graduate students to pull myofibrils until they broke and record the sarcomere length at which they failed. "And while you are at it" I said "why don't you also stretch the myofibrils actively and compare them to the passive results. We found that sarcomeres break at about 7 µm in length independent if they were activated or not. We also found that the active failure force was about four times greater than the passive failure force. However, this could not be the case since actin-myosin filament overlap is lost at 3.9 µm, therefore even the activated myofibril could only use passive structural elements to produce force at 7 µm. Elimination of the structural protein titin abolished the differences in force between actively and passively stretched myofibrils. That is when we realized that titin may be a filamentous spring whose stiffness and force is controlled by muscle activation (calcium), and that our thinking of force production by actin and myosin exclusively may need revising. Further experimentation over the past nine years identified how force might be regulated by titin, and the question arose: "Do we need a new paradigm for muscle contraction? Do we need to replace the two-filament sarcomere model with a three filament model incorporating titin as an activatable spring element?

CONCLUSION

Scientific knowledge and truths are time-dependent properties that might come to you by serendipity, and a small remark at the end of a seminar may lead to experiments that challenge your thinking and may lead to changes in scientific paradigms. By being alert, listening carefully, having an open mind, and letting the data point the way, we might find the solutions we seek.

OPTIMAL LORDOTIC REINSTATEMENT FOR LUMBAR INTERBODY FUSION SURGERY

INTRODUCTION

The prevalence of low back pain is 80% in humans [1]. Spinal fusion, first reported in 1952 [2], is the primary standard treatment used to remedy intractable back pain unresponsive to nonsurgical treatment. It is designed to stabilise the spine by immobilising lumbar segments, effectively producing a biomechanically rigid environment at the same time preserving the original disc height. However, current spinal fusion surgery still presents unacceptable failure rates, requiring revision surgeries. One known contributing factor is ill-configured spinal lordosis, leading to an unnatural distribution of stress upon the lumbar segments.

Currently, surgeons rely on their 2D xray estimates and experienced to return the lumbar spine to its original lordosis estimated from sacral tilt. However this judgment is highly subjective especially since there is a lack of surgical guide devices, unlike in the knee and hip. This study aims to develop a computational framework as part of a surgical planning tool to assist orthopaedic spinal surgeons in rapidly planning the optimal degree of lordosis consistent with the state-of-the-art but also incorporating bone stress shielding.

METHODS

A semi-automated segmentation algorithm was developed for pre-surgical imaging data to allow rapid generation of patient specific lower lumbar finite element (FE) models. This semi-automated segmentation algorithm consists of vertebral localization via classification from annotations and model based segmentation to allow for accurate 3D reconstruction. Segmentation outcomes were then evaluated with Dice similarity coefficient against manual segmented ground truths. Generic intervertebral discs were then automatically tailored to patient specific lumbar vertebrae via a variant of free-form deformation known as “host mesh fitting [3].

An automated posture placement algorithm combining elements of computer vision and intervertebral disc biomechanical responses was then developed to allow for realistic manipulation of lumbar vertebrae. By modeling the intervertebral disc of each lumbar segment as a unique Cartesian stiffness matrix, realistic lumbar forces and moments dictate coupled lumbar segment movements. Utilising a Gilbert-Johnson-Keerthi (GJK) [4] collision detection algorithm, subject-specific lumbar segment movements are incorporated. A joint coordinate system (JCS) for each vertebra was then automatically determined in line with ISB JCS recommendations for spinal vertebra [5]. Realistically coupled lumbar segment motions along with a vertebra JCS were then applied to each lumbar segment using dual quaternions and then adjusted to patient specific vertebrae geometry via the incorporated GJK algorithm. The automated posture algorithm was then validated against MRI data of external validation subject in a variety of postures. A further correction of optimal lumbar lordosis was achieved by perturbations to the geometric solution in order to minimise intervertebral stress shielding.

RESULTS AND DISCUSSION

Figures 1 below demonstrates variation in lordosis obtained from the automated posture algorithm. External validation MRI data shows relatively accurate reconstruction of patient posture and lordosis with a maximum of ~10% error in posture prediction. Evaluation of predicted shape against manually segmented spines also produced a maximum of ~10% error in geometry.

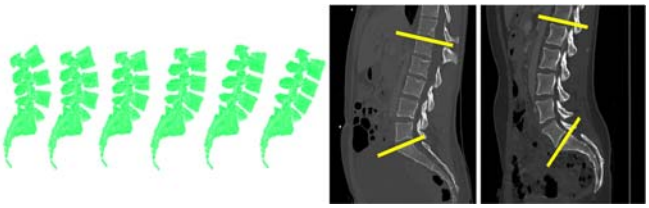

Figure 1: Variation in lordosis created by posture algorithm (left). 25º - 90º range of normal lordosis (right).

CONCLUSIONS

A computational framework was developed as part of a surgical planning tool to assist clinicians in rapid patient-specific lower lumbar FE model generation which is consequently used to inform the optimal lumbar lordosis recovery required for successful fusion surgery. This framework is currently being evaluated against retrospective surgical or revision cases to see if the lordosis predicted is consistent with clinical outcomes.

ACKNOWLEDGEMENTS

RADIOGRAPHIC, MECHANICAL AND HISTOLOGICAL EVALUATION OF FUSION IN AN OVINE MODEL: PEEK INTERBODY CAGES WITH AND WITHOUT A POROUS TITANIUM ALLOY COATING

[1,2,3]**Claire F Jones**, [2]William SP Robertson, [5]Stuart Callary, [1,3]Adnan Mulaibrahimovic, [1,3]Julia Kuliwaba, [6]Robert Gunzburg, [7]Christopher Colloca, [3]David Hall, [1,3,4]Brian JC Freeman

INTRODUCTION

Polyetheretherketone (PEEK) is a common material for spinal interbody cages, and has an elastic modulus more similar to bone than metal alloys [1], which may reduce graft stress shielding and endplate subsidence [2]. However, PEEK appears not to bond directly to bone whereas surface textured titanium and titanium alloy (Ti) implants can exhibit bony ingrowth or ongrowth [3]. PEEK interbody cages incorporating titanium or titanium alloy surfaces may promote early fusion and improve spinal fusion rates. The aim of this study was to compare radiographic, mechanical and histological indices of fusion in an ovine model for: (A) PEEK interbody cages; and, (B) PEEK interbody cages with nano-surfaced porous Ti coated endplates (PEEK+Ti) (Nanovis LLC, Columbia City, IN).

METHODS

14 skeletally mature Merino sheep (mean 69.6 kg) randomly received a PEEK or PEEK+Ti cage, with autologous bone graft, at L4/L5. Radiostereometric (RSA) assessments and CT scans were obtained at 0, 3, 6 and 12 mth post-surgery. Intervertebral range of motion (ROM) from flexion to extension position (mean error of rigid body fit <0.3 mm) was determined using UmRSA software (RSA Biomedical, Sweden). A linear mixed model (LMM) with Random effect of Sheep, and Fixed effects of Cage Type, Time Point and CageType*TimePoint, was used to determine if ROM was dependent on cage type or post-operative time point. Fusion was defined as the presence of ≥2 trabeculae passing between vertebral endplates in both the sagittal and coronal plane, and the absence of radiolucency around the cage, as viewed on CT scans by one senior spinal surgeon. Fusion rates were assessed using a Fisher's exact test at each time point. Lumbar spines were excised at 12 mth and L4-5 vertebral bodies prepared, embedded and subjected to quasi-static low load mechanical testing in flexion-extension (FE), lateral bending (LB), axial rotation (AR), anterior shear (ASh) and compression. Stiffness and ROM (mean of 3 cycles) for each testing mode were calculated, and compared using Mann-Whitney U-tests. Centre sagittal (0.8 mm thick) histological sections were prepared and stained with Toluidine blue. Fusion was defined as continuous bony bridging across the endplates either inside or outside of the cage, and difference in fusion was assessed using a Fisher's exact test. For all statistical comparisons, alpha=0.05.

RESULTS AND DISCUSSION

One animal died following 6 mth assessment and was excluded from 12 mth outcomes. The median flexion-extension intervertebral angle was slightly lower for the PEEK+Ti cage at each time point, but the LMM revealed ROM was not statistically dependent on Cage Type (PEEK vs. PEEK+Ti), or Time (0, 3, 6, 12 mth). Most relative rotations were ≤4°. There was no significant difference between the CT-derived fusion rates of the two cages at any time point. There was a trend for the PEEK+Ti group to have higher overall fusion rates at 3 (43 vs. 14%) and 6 mth (71 vs. 43%), higher central fusion rate at 3 mth (43 vs. 14%), and lower anterior fusion rate at 12 mth (29 vs. 67%), but none of these differences were statistically significant; this may be elucidated with larger sample size in future studies. 43% of animals in the PEEK, and 29% in the PEEK+Ti, group exhibited radiolucency at 3 mth; no radiolucency was observed at 6 and 12 mth. For the low loads tested, there was no significant difference in stiffness or ROM for between the PEEK and PEEK+Ti groups, for any loading direction (Table 1). Histology showed abundant trabecular bone inside the cage at 12 mth for all specimens except one in the PEEK+Ti group. In some cases there was a small cartilaginous-lined inclusion between the superior and inferior bony ingrowth in the centre of the cage. Overall fusion was present in 66% (4/6) PEEK, and 71% (5/7) PEEK+Ti, and central bridging bone was observed in 66% (4/6) PEEK, and 43% (4/7) PEEK+Ti. No differences in fusion rate observed via histology were significant.

CONCLUSIONS

PEEK and PEEK+Ti cages achieved intervertebral fusion in this ovine model. There was a non-significant tendency towards earlier fusion for PEEK+Ti. There was no significant difference in RSA, CT or histological measures of fusion, nor mechanical response, at 12 mth post-surgery.

INTRODUCTION

Current treatment for degenerative spinal disc disorder is by fusing the acetabular on either side of the degenerating disc through the use of an interbody fusion implant. Restoration of sagittal balance, through restoration of mono-segmental lordosis, is important to reduce back pain, avoid adjacent segment degeneration and prevent "flat-back" generation [1,2]. Factors associated with restoration of mono-segmental lordosis are the cage parameters (height, length and wedge angle) and surgical positioning. However, fusion device placement does not used guides, unlike the knee and hip, and rely on surgeon experience. Therefore spinal fusion has a relatively high failure rate (reportedly up to 40%), although only 25% of failures may be revised [3].

The aim of this study is to develop a population informed patient-specific finite element (FE) tool to evaluate the best fusion implant characteristics and location that would restore the required segmental lordosis for each lumbar segment.

METHODS

Three patients that received spinal fusion surgery underwent MRI and sagittal and frontal X-rays imaging pre-surgery followed by CT scan and 2 views X-rays imaging post-surgery. Full 3D reconstruction of each patient vertebrae were performed: 1) using 3D manual segmentation of the CT images and 2) using a statistical shape model scaled using key landmarks from patient's MRI images. Key landmarks chosen from patient's MRI images were first registered to the nearest neighbor correspondents on the statistical shape model, and the population based statistical shape model was subsequently transformed to best fit those landmarks using host-mesh fitting [4]. Each bone geometry resulting from the 3D reconstruction was exported into a FE model that included generic intervertebral discs.

The patient's spine model was then positioned in a standing posture based on the pre-operative sagittal and frontal X-rays. Pelvis incidence (PI), lumbar lordosis (LL), intervertebral and vertebral angles were then determined and the optimal segmental lordosis angle were calculated for each segment for surgery planning. Using these parameters the model could define the best fitting fusion implants characteristics and location on the acetabular bed to achieve each segmental lordosis angle to be restored. The customized fusion implants was modelled and evaluated with FE analyses. Multiple implant locations were simulated to evaluate the optimal location for implant placement.

RESULTS AND DISCUSSION

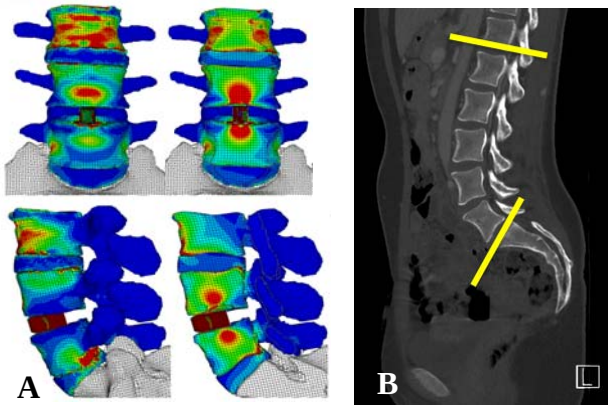

Figure 1: A) One possible solution for fusion device placement in both (up) anterior and (down) lateral views. B) Patient's standing X-ray with in yellow the lordosis angle

The population based lower lumbar model (Figure 1A) was able to be customised to patient MRI data using 12 strategically placed control points. Validation of this against manual segmentation produced a geometric RMS error of less than 3 mm. Each patient's model was fitted to their standing posture (Figure 1B) and optimized for the ideal implant placement that minimised ΔPILL (= PI-LL) and stress shielding in the anterior region of the spine encouraging more bone diffusion in the spinal fusion device. One solution is presented in Figure 1A from anterior and lateral views. Further work will focus on the automation of the 3D reconstruction from patient's MRI images along with the statistical shape model.

CONCLUSIONS

A population based modelling tool was developed to enable clinicians to rapidly generate patient-specific FE models of the lower lumbar. This in turn informed the ideal mono-segmental lordosis to be restored and location of the implant that can be used to aid implant placement decisions. This is currently being developed into an online web-based tool.

INTRODUCTION

Pedicle screws are well established and have been become an essential tool in spinal surgery. However, complications are common, especially in geriatric patients with poor bone quality [1]. Expandable screws are very promising to improve the osteoporotic bone anchorage. In own previous work a novel shape memory alloy (SMA) pedicle screw concept was developed that braces itself against the osseous environment after implantation by heating to body temperature. The aim of this study is to investigate first the influence of the actuator force on the primary stability of the pedicle screw in-vitro.

METHODS

Twenty-four lumbar and one thoracic vertebrae were taken from seven human cadavers for the in-vitro tests. Bone quality was determined from µCT using a self-made phantom. Pullout forces were determined with a biaxial testing device (DYNA-MESS, Aachen, Germany) in a climatic chamber at 39°C. The testing rate was 0.1 mm/s. Thirteen shape memory pedicle screws with two actuator sheets and twelve standard screws with continuous thread were analysed. The pullout forces were correlated to the Hounsfield values to minimize the influence of the bone quality. Additionally the heat-induced actuator force against resistance was evaluated.

RESULTS AND DISCUSSION

The mean actuator sheet compression force of the used SMA sheets was -7.4 N ± 0.6 N (n=19). Seven of the SMA screws were activated correctly after the implantation, four activated unilaterally only. Two SMA screws were not activated and therefore excluded from the analyses. The pullout force averaged 868 ± 392 N for the standard screws, ranging between 305 and 1391 N, and 828 ± 353 N for the SMA screw, ranging between 312 and 1254 N. The averaged mean HU value for all vertebrae with tested standard screws were 15 ± 101 HU (n = 10) and -24 ± 101 HU (n = 10) for the SMA screw tested vertebrae. The mean HU value for the SMA screws was lower so that the force values were standardised according to HU values. Three µCT-datasets was corrupted by artefacts and the corresponding tests were excluded. The mean standardised value for standard screws was -13 ± 19 N/HU and -6 ± 19 N/HU for the SMA screws. The mean value was minutely slower for the normal screw. However, the difference is not significant.

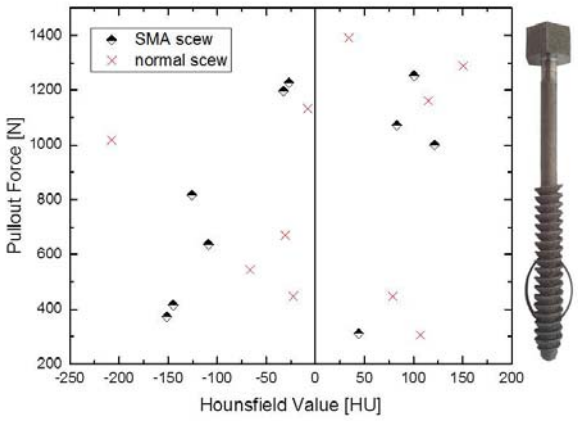

Figure 1: HU standardised pullout force of SMA and normal pedicle screw

CONCLUSIONS

The SMA screw has the same primary stability as the standard screw. Further, comparatively high pullout forces in cases of poor bone quality can be observed. It is to be noted, that the opposing notches within the treads for the SMA screws reduce the thread surface. In consequence it must currently be compensated by the actuators. In the future the surface of the actuator sheets should be structured like the missing parts of the thread. Thus, the primary stability can be increased. Subsequently, the long-term stability will be investigated.

Additionally the reliability of the activation of the actuator sheets must be improved and is e.g. affected by soft tissue, which winds around the screw.

To summarize, the results are promising and the implantation of the SMA screw could be done without additional effort.

HOW DEFUNCTIONING OF THE POSTERIOR ELEMENTS INFLUENCES THE SUSCEPTIBILITY OF THE INTERVERTEBRAL DISC TO HERNIATION

INTRODUCTION

In our earlier study of disc herniation, using fully intact ovine motion segments, we showed that under the combined loading of flexion and rapid compression, what tends to happen is that the outer annulus fibers fail first, followed by the mid-to-inner fibers, and then nuclear material protrusion [1]. This sequence of events in herniation was established from the detailed microstructural investigation, post mechanical testing, that was carried out.

In terms of the influence of the facets, it was noted that there were very few facet failures observed – 4 out of 72 segments tested. We proposed that these facet failures were a consequence of the sudden loss of disc height following herniation [1, 2]. Thus we hypothesized that the initiation of herniation, and its progression, is *relatively* facet-independent in healthy motion segments [2]. In this study we test this hypothesis.

METHODS

A total of 33 healthy ovine lumbar spine motion segments were obtained each containing an intact disc and posterior elements (two facets). However in 25 of these segments the superior vertebra pars interarticularis was sectioned and removed to effectively *defunction* the facets. All segments were flexed 10° and then compressed at a rate of 40mm/min. This combined loading follows exactly that used in our earlier study, and is found to induce herniation [1].

With the aid of video recording and the mechanical testing control system, loading was terminated by one of two indicators: first was the indication of external gross nuclear extrusion, and second the sudden drop in the load vs displacement curve. These two indicators were used to help understand the herniation/failure initiation and progression. Also from the video recordings measurements, anterior shear of the upper vertebra relative to the lower, and axial displacements were obtained from each test.

Following mechanical testing, all segments were fixed in formalin and decalcified to facilitate micro-sectioning and imaging of the disc-vertebrae, where layer by layer, the entire disc volume was analysed microscopically for the location and extent of structural damage.

RESULTS AND DISCUSSION

In all samples there was extrusion of nuclear material while none of the control motion segments displayed facet fracture following loading. The 25 motion segments with posterior elements removed had an initial failure stress of 14.8±3.3MPa compared to 23.6±5.8MPa for the controls. A student's t-test indicated a significant difference between these two groups (P=0.002) demonstrating that the disc is rendered more vulnerable to failure when the posterior elements were defunctioned.

Despite the significantly different failure loads between segments from the control group and experimental groups, there was no difference in the modes of structural failure observed for the two failure indicators used (Table 1).

Table 1: Mechanical and structural response to the two indicators of failure. *Significant ($p < 0.05$) difference between groups.

	1st Indicator	**2nd Indicator**
	Gross extrusion of nuclear material	Combined extrusion and endplate failure
Control Group Maximum Load (kN)	8.9 (n=6)	10 (n=2)
Posterior Elements Removed Maximum Load (kN)	*6.6 (n=14)	*7.4 (n=11)

Between the two groups, there was no significant difference between the extent of forward shear during loading, as well as the extent of axial displacement. Given the different maximum loads, this indicates a difference in the overall stiffness of the segment between groups.

CONCLUSIONS

From the data, under the combined loading of flexion and compression of ovine motion segments, it is concluded that the facets contributes to overall stiffness of the motion segment but is not critical in preventing herniation, other than requiring a higher load. The significance of this finding is in providing better understanding of the full mechanical role of the facets, especially in relation to our clinical interpretations and the development of biomechanical models of the lumbar spine.

INTRODUCTION

Bone formation and remodeling associated with altered strain changes as a consequence of inserting a higher modulus material is important as it can affect the long term performance of orthopaedic implants. Current analysis focuses on simulating the changes in bone density in the presence of a prosthesis to evaluate the performance and failure risk of implant design. The presence of extracortical bone formation around the collar of prosthesis has been demonstrated to increase the survivorship of endoprostheses for cancer patients from 75% to 98% [1]. Although static stages of extracortical bone growth have been studied using finite element (FE) analysis [2, 3], a time-dependent model that focuses on adventitious bone formation and external shape changes in three dimensions (3D) has not been implemented. This contribution proposes such an integrated bone formation and adaption model based on new algorithms for bone formation.

METHODS

Strain energy density (SED) was used as the criteria for bone remodeling, where the rate of bone growth is controlled by the difference in the current SED against a reference value [4]. Thereafter, osteoconduction and the modelling of external shape changes were achieved by building an osseo-connectivity matrix starting from the bone interface to account for neighbouring elements. The current level of remodeling and the connectivity matrix then control the rate of bone formation of adjoining elements. Physiological loading was applied to FE models of bone prosthesis to predict extracortical bone growth.

Parametric studies on the influence of initial density, spatial averaging function and threshold value (before the elements are permitted to remodel) were conducted. To ensure stable simulations and enable computation time to be minimized, guidelines for adaptive time steps were formulated. The algorithm was implemented using custom-written subroutines in a FE solver (Marc 2015) and applied to cylindrical models of porous titanium implants in cancellous bone.

RESULTS AND DISCUSSION

The FE results show good correspondence to experimental and clinical results for a plug model where a porous scaffold made of Ti6Al4 is implanted into trabecular bone (Fig. 1). Improved results using an averaging function to reduce the occurrence of local discontinuities in bone density were observed.

CONCLUSIONS

The developed model allows for the prediction of bone remodeling where parameter and geometrical influences can be investigated. The modelling approach has potential for further use in prosthesis design and where prediction of bone growth in addition to bone adaption is important.

PELVIC CONSTRUCT PREDICITON OF TRABECULAR AND CORTICAL STRUCTURAL ARCHITECTURE

INTRODUCTION

The pelvic construct is an important part of the musculoskeletal system as it facilitates the transfer of upper body weight to the lower limb and protects a number of organs and vessels in the lower abdomen. In addition, the importance of the pelvis is highlighted by the high mortality rates associated with soft tissue trauma caused by pelvic bone fracture [1]. Although computational models of the pelvis have been used to assess its structure or behaviour under loading, no attempt has been made to develop a model using a structural mechanics approach as opposed to a continuum mechanics approach. A model that can highlight the trajectories formed by trabecular bone could be used to gain a better understanding of pelvic fracture mechanisms and potentially prevent injuries by designing appropriate protective devices.

METHODS

This study presents a predictive mesoscale structural model of the pelvic construct and the joints and ligaments associated with it. Shell elements were used to model cortical bone, while truss elements were used to model trabecular bone. The sacroiliac and pubic joints were included along with the inguinal, sacrospinous and sacrotuberous ligaments which were all modelled using combinations of truss elements. The bone model was adapted to a number of common daily living activities (walking, stair ascent, stair descent, sit-to-stand and stand-to-sit) by applying muscle and hip joint reaction loads derived using a musculoskeletal modelling framework. Although the load cases representing each activity were subsampled to maintain computational efficiency, the hip joint loads were selected such that the resulting set of loads maintains the trend of the initial set of forces. The finite element model was subjected to an iterative optimisation process based on a strain driven bone adaptation algorithm [2].

RESULTS AND DISCUSSION

The cortical thickness distribution and trabecular architecture of the adapted model were compared qualitatively with computed tomography scans and models developed in previous studies showing good agreement. A thick cortex was found at the superior sacrum, along the gluteal surface, around the sacroiliac joint, superior pubic ramus, posterior iliac crest and greater sciatic notch. Clusters of trabecular elements with large radii were found at the superior sacrum, supra acetabular region, pubic tubercle and greater sciatic notch. In terms of structural architecture of the trabecular bone, several trajectories were formed. Figure 1 illustrates the trajectories formed in the ilium corresponding to the trabecular architecture observed by Macchiarelli [3].

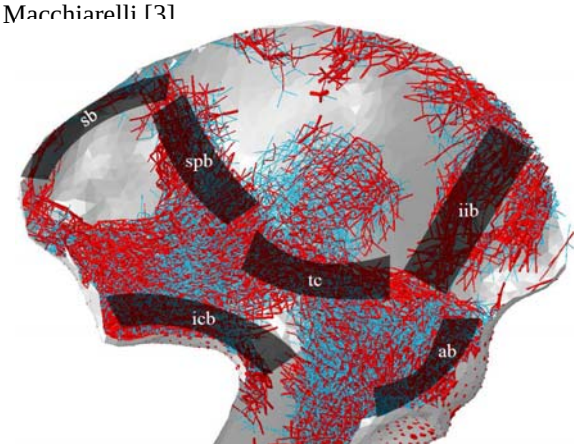

Figure 1: Trabecular trajectories formed in the ilium. The trajectories highlighted correspond to regions in the ilium with a higher trabecular density caused by walking observed in [3]: superior bundle (sb), anterior bundle (ab), sacropubic bundle (spb), iliocotyloid bundle (icb), ilioischial bundle (iib), trabecular chiasma (tc).

CONCLUSIONS

The resulting structure of the model shows good agreement with previous findings on pelvic bone architecture while the structural model model was found to be computationally efficient. Future work will include modelling the soft tissue within the pelvic construct and assessing the effect of bone fracture on organs and blood vessels. The developed structural model enables a number of applications such as fracture modelling, design and additive manufacturing of frangible surrogates. In addition, there is potential for the design and manufacture of massive endoprostheses and scaffolds to allow bone regeneration in specific areas of the pelvis affected by trauma or disease while preserving the mechanical properties.

ACKNOWLEDGEMENTS

FINITE ELEMENT INVESTIGATION OF MECHANICAL ROLES OF TISSUE GROWTH AND CONSTRICTION DURING OPTIC-CUP MORPHOGENESIS

[1]**Hironori Takeda**, [1]Yoshitaka Kameo and [1]Taiji Adachi
[1]Kyoto University
Corresponding author email: adachi@frontier.kyoto-u.ac.jp

INTRODUCTION

During morphogenesis, tissue-level deformation of multi-cellular tissues proceeds by coordinated cellular activities, such as growth and constriction. In this process, each cell has mechanical effect on surrounding tissues and regulates the tissue deformation. For example, during optic-cup formation, tissue growth and constriction depending on the stages of the morphogenesis induce the invagination of a spherical optic vesicle [1]. To understand the mechanism of morphogenesis, it is essential to understand how cellular activities mechanically influence the tissue deformation. However, it is difficult to investigate the mechanical state in multi-cellular tissues through experimental approach. In this study, therefore, we constructed a finite element model of tissue growth and constriction. To understand their mechanical role during optic-cup formation process, we performed computer simulation considering time-dependent growth and constriction.

METHODS

In order to clarify how cellular activities influence optic-cup morphogenesis, we constructed a finite element model for tissue growth and constriction based on nonlinear continuum mechanics. We adopted growth model [2] and active stress model [3] to describe volumetric growth and directional constriction of retinal tissues, respectively.

The optic vesicle, which consists of neural retina (NR) and retinal pigment epithelium (RPE), was modeled as a partial spherical shell. The retinal tissue was assumed to be a neo-Hookean hyperelastic material. The simulation of optic-cup morphogenesis was performed in the following steps. At first, the active constriction uniformly occurs on the inner surface. Second, the volume of RPE increases along the tangential direction. Third, the active constriction in NR ceases. Finally, the volume of NR increases.

RESULTS AND DISCUSSION

We simulated the formation of optic cup caused by time-dependent growth and constriction of retinal tissues (Fig. 1). The process of flattening of NR was reproduced by the in-plate expansion of RPE and the following relaxation of the constriction in NR (Fig. 1a). When RPE growth were insufficient, NR did not become flattened by relaxation of the constriction in NR. This result indicated that the well-timed relaxation of constriction with regard to RPE growth is necessary for the flattening process.

Then, we focused on the invagination process triggered by the expansion of NR. When NR expanded uniformly, the tissue deformed to the outside and failed to form an optic-cup structure (Fig. 1b), owing to the tensile stress on the inside and the compressive stress on the outside. When the flattened state was redefined as a stress-free configuration to assume stress relaxation, the uniform growth induced NR invagination (Fig. 1b). Thus, it was confirmed that the residual stress in the flattened state interferes with NR invagination.

To reproduce the invagination, we introduced a non-uniform growth, which can offset the effect of residual stress. Considering the previous study [1], which observed inter-kinetic nuclear migration and cell division in vitro, we assumed that NR growth rate is larger on the inner side than that on the outer side. The non-uniform growth induced NR invagination (Fig. 1b), suggesting that the spatial variation of NR growth with higher growth rate on the inner side is necessary for the invagination.

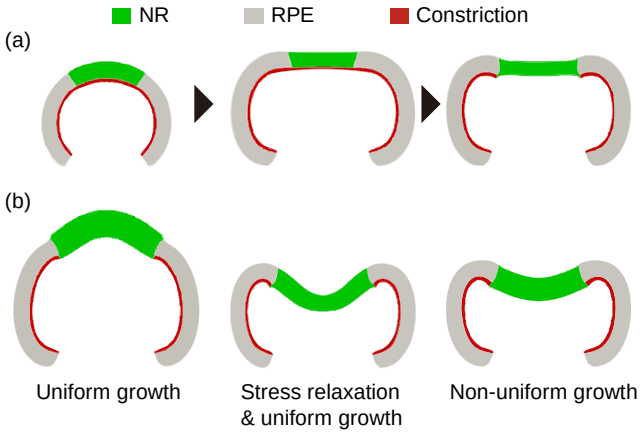

Figure 1: Simulation results of the optic-cup morphogenesis: (a) Representation of the flattening process. (b) Configurations after NR growth.

CONCLUSIONS

This study indicated that an optic-cup formation is caused by the time-dependent tissue growth and constriction, which mechanically affect their neighboring tissues. Simulation results showed that the relaxation of constriction in NR deforms NR to the flattened shape. The invagination process proceeds by radial non-uniform growth of NR, indicating that spatial variation of growth regulates the invagination process. Our study would help understand mechanical roles of tissue growth and constriction during the morphogenetic process.

INTRODUCTION

For the development of bone-replacement materials and for drug delivery applications, steps have been taken to quantify the form and property of fluid flow within bone. While there exists several excellent *ex vivo* studies which attempt to determine flow characteristics within bone, few have been utilized in the most concise form to accurately match the mass transport capabilities of natural bone.

In this study, a comprehensive framework is proposed to determine the diffusion and permeability characteristics of flow using fluid flow computations following microCT imaging. This framework is compared with literary studies and is validated through computational fluid dynamics modelling.

METHODS

We first scan four cylindrical bone samples and four sets of cylindrical ceramic bone-replacement scaffolds of varying porosities using a microCT scanner [1]. A cubic finite element mesh of each sample is then developed and imported into a multi-physics finite volume solver software package **arb** [2]. At the pore-scale, flow is characterized by governing numerical equations, i.e., Fick's First Law of Diffusion and Stokes' Equation [3].

For the flow to be characterized across the homogeneity of the specimens, the heterogeneous pore-scale properties are up-scaled to determine the macroscale permeability and the effective diffusivity across the cubic unit cell. For complete accuracy, a representative volume element and mesh refinement must be chosen.

To validate the framework, following the same methodology, we first take 1×1×1 mm^3 structured unit cells and apply various inclusions within. Extending this, we use the multi-physics modelling software COMSOL® to mimic these simulation conditions. Flow value outcomes are then compared with analytical solutions found in the literature [4,5].

RESULTS AND DISCUSSION

For both diffusivity and permeability, the validation study outcomes involving unit cells with spherical, ellipsoidal and gyroidal inclusions, matched well with the literary findings and analytical solutions, showing that both diffusivity and permeability increased with an increase in porosity.

Simulations run on a representative volume element greater than 2×2×2 mm^3, for a mesh resolution of 125,000 elements, under periodic boundary conditions, provided the most accurate representation of homogeneity and flow for both the bone and biomaterial samples.

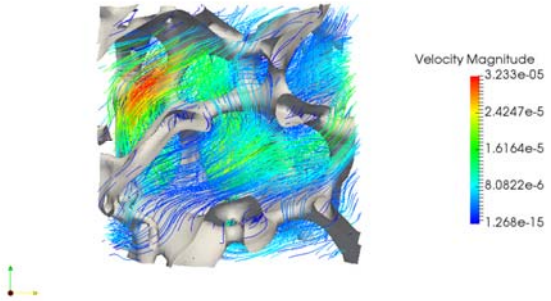

Figure 1: Pore-scale fluid flow simulation using **arb** software: velocity streamline profile across the unit cell (2x2x2 mm^3).

The finite volume solver **arb** was highly accurate and efficient, i.e., not computationally expensive, at performing fluid flow simulations. It showed equal effectiveness when dealing with complex geometries, and could produce outcomes that closely matched the physiological mass transport capabilities of natural bone.

CONCLUSIONS

We demonstrated that the proposed combined pore-scale simulations and numerical upscaling framework, is capable of accurately calculating the permeability and diffusion characteristics of bovine trabecular bone and biomaterials. The novel computational method used can be applied to porous materials containing complex geometries and biomaterials with random pore morphologies. This work allows for advancement of the field of biomaterial development and for drug delivery applications.

ACKNOWLEDGEMENTS

The authors are grateful to Prof. John Clement and Dr. Rita Hardiman from the Melbourne Dental School, University of Melbourne, for the in-kind use of the microCT facilities.

RATE AND AGE-DEPENDENT ELASTO-PLASTIC BONE MATERIAL FORMULATION FOR EFFICIENT FRACTURE SIMULATIONS

[1,2]**Claire C Villette**, [1,2]Andrew TM Phillips
[1]Structural Biomechanics, Imperial College London
[2]The Royal British Legion Centre for Blast Injury Studies at Imperial College London

INTRODUCTION

Prediction of bone fracture is beneficial in a range of clinical situations from screening and treatment of osteoporotic patients to assessment of protective equipment against trauma, and improved design of implants and prosthetics. There is a need for a considered trade-off between resolution and computational efficiency of models. Accounting for the variations introduced in bone material behaviour by tissue age or loading rate is crucial for the biofidelity of predictions.

The objectives of this study were to develop a strain-based failure model, with age and strain rate dependencies, able to efficiently predict fracture onset and development for generic loading conditions.

METHODS

Material model: A damage elasticity bone material formulation was developed to model an elasto-plastic (EP) constitutive behaviour. In the elastic regime, bone was modelled as a linear material with Poisson's ratio ν=0.3 and 'intact' Young's modulus E_{intact}=18 GPa. A plastic regime was defined for both compression and tension in the form of a plateau between the yield strains in compression $\varepsilon_{y,c}$ or tension $\varepsilon_{y,t}$ and the ultimate strains in compression $\varepsilon_{u,c}$ or tension $\varepsilon_{u,t}$. The 'effective' Young's modulus $E_{eff}(\varepsilon_n)$ to be assigned to the element section points varied with the normal strain measure ε_n as given below, with E_{fail} = 10 MPa.

$$E_{eff} = \begin{cases} E_{intact}, & if\ \varepsilon_{y,c} \le \varepsilon_n \le \varepsilon_{y,t} \\ E_{intact}\dfrac{\varepsilon_{y,c}}{\varepsilon_n}, & if\ \varepsilon_{u,c} \le \varepsilon_n < \varepsilon_{y,c} \\ E_{intact}\dfrac{\varepsilon_{y,t}}{\varepsilon_n}, & if\ \varepsilon_{y,t} < \varepsilon_n \le \varepsilon_{u,t} \\ E_{fail}, & if\ \varepsilon_n < \varepsilon_{u,c}\ or\ \varepsilon_n > \varepsilon_{u,t} \end{cases}$$

Rate and age dependency: Strain rate dependency was introduced by defining yield and ultimate strain values as polynomial functions of strain rate, based on mechanical tests results reported in the literature [1]. An age factor derived from further reported mechanical test results [2] was used to introduce age dependency in these relationships.

Fracture simulations: A mesoscale structural finite element model of the femur previously developed by the authors [3] was modified to simulate fractures under lateral compression, representative of side fall, for bone aged 30 and 75 years displaced at 2 mm.s^{-1} and 100 mm.s^{-1} (equivalent to strain rates of 0.01 s^{-1} and 0.5 s^{-1}). Cortical bone was represented as a layer of shell elements with varying thicknesses and trabecular bone as a lattice of truss elements with varying diameters. A side fall scenario was modelled via the application of a prescribed ramped displacement on the greater trochanter with the shaft at a 10° angle with the horizontal plane, and the femoral head in contact with a stiff plate fixed to the ground.

RESULTS AND DISCUSSION

Figure 1 displays the fracture progression and associated reaction force for a 75 year old femur in side fall at 2 mm.s^{-1}. At slow rate, side fall simulations resulted in type IV trochanteric fractures (Jensen's classification) for young (6.5 kN) and older bone (3.7 kN). At higher rate, young bone exhibited a type V trochanteric fracture (7.9 kN) while older bone fractured through the neck (5.5 kN).

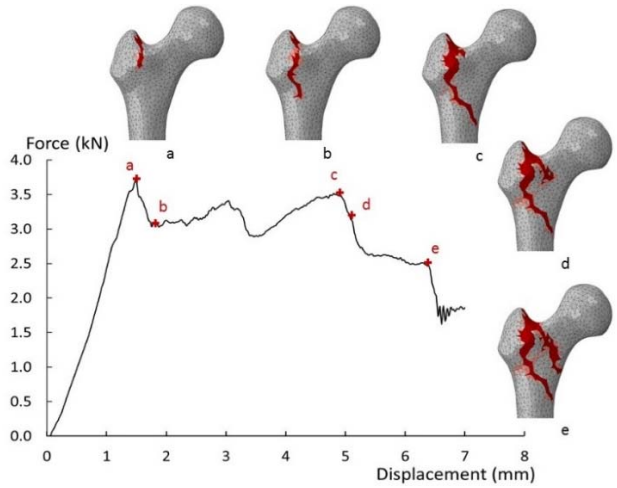

Figure 1: Side fall fracture of a 75 year old femur at 2mm.s^{-1}.

Fracture loads and types are in excellent agreement with both clinical and in-vitro studies [4,5]. The observed decrease in failure load with increasing age and to a lower extent with decreasing rate also compares well with clinical and in-vitro records [5]. The typical running time for the full fracture simulation is three hours on a standard desktop workstation.

CONCLUSIONS

A damage elasticity bone material formulation accounting for rate and age dependencies was developed which is capable of efficiently predicting bone fracture onset and progression in excellent agreement with clinical and in-vitro studies. Applications include investigations of the influence of activity regime and bone external morphology on fracture.

SPECIAL SESSION: LIFELONG CONTRIBUTIONS OF CARLO DE LUCA TO THE STUDY OF HUMAN MOVEMENT: MOTOR CONTROL INNOVATIONS

[1,2]Serge H. Roy

[1]Delsys Inc and Altec Inc, Natick USA
[2]Sargent College of Health and Rehabilitation Sciences, Boston University, Boston USA
Corresponding author email: sroy@delsys.com

Those of us who recognize the importance of the study of human movement, whether from the perspective of biomechanics and/or motor control, felt the loss from the untimely passing of one of its great pioneers, Prof. Carlo J. De Luca on July 20, 2016. This is particularly true of those of us who were fortunate enough to either be mentored by Prof. DeLuca or worked collaboratively with him during this period in history. Dr. Zev Rymer, who has kindly organized this session, my colleague Prof. Roberto Merletti, and I share this distinction, as well as countless others who have since become leaders in the field and could rightfully share this stage with us.

Every generation is allowed the luxury of thinking of their time as the most revolutionary or innovative, but not every individual can rightly be recognized as someone who led the way. Carlo contributed pivotal EMG innovations that have changed the way we currently study human movement. I have more than a 35 year story to tell on this topic, having worked alongside Carlo, first at the NeuroMuscular Research Lab (NMRL) at Harvard Medical School beginning in 1980, afterwards at the NeuroMuscular Research Center (NMRC) at Boston University in 1984, and currently at our research center at Delsys/Altec Inc; all of which were founded by Carlo. For the sake of time and the relevance of presenting this lecture at an international biomechanics conference my reflections will focus on Carlo's lifelong effort to understanding human movement from the perspective of measuring motor control strategies of the nervous system.

My earliest recollections were actually quite dramatic: Carlo and colleagues (most notably Mr. Don Gilmore), after having worked on developing the first myoelectric prosthetic elbow under the Liberty Mutual Insurance Co (the Boston Arm – still in use today), were embarking on a method and apparatus to interface the Boston Arm directly to peripheral nerves via EMG implants. Their first implant studies, before my time, were on a rabbit - having achieved 244 days of successful recording, a respectable achievement even by today's standards. Rabbits don't scare me but I was joining the group during the second generation of development on a primate – a baboon to be specific – which can kill a lion in the jungle and would therefore have no problem killing a lowly research assistant if given the opportunity. What is more noteworthy however is the fact that Carlo had the vision and tenacity of pursuing a technology, with some success I might add, that is has just recently re-emerged as one of the "new" high priority areas for DARPA and other agencies supporting a fully implantable prosthetic arm. This technology was patented under Carlo and Don's name and it is rewarding to see that some 138 patent applications since 1977 have cited this work; Carlo's very first of 26 patents.

Despite the importance of these implantations, Carlo is more widely known for his pioneering work in developing non-implantable motoneuron recording techniques. These *EMG decomposition* studies have a long and significant history of accomplishments, which can be found in over 100 publications, approximately 200 abstracts, over 20,000 citations (Google Scholar) he authored, and close to 40 Dissertations he advised; just in the area of MU studies and EMG decomposition.

The evolution of this technology and the motor control knowledge it imparted occurred in clearly defined stages. Carlo loved challenges and separating out individual MUAPTs from an EMG interference pattern represented among the most difficult at the time. His tenacity and resolve to meet this challenge was accomplished through the application of "good old fashioned engineering principals". His high-yield sEMG decomposition technique published in 2006[1] represents a transformative advancement in research capabilities. I vividly recall the graduate students in our lab prior to this development who needed to spend weeks to resolve 3-5 MUs from a single 20s isometric contraction from an invasive needle or fine wire recording. With the advances he pioneered in sEMG decomposition these same contractions today could be analyzed in a few minutes and yield an average of 30 – 40 MUs. Data from an entire doctoral dissertation could be batched processed in a day with 10X the yield rather than spend some 2 years of editing of decomposition files. Fifteen papers in high impact journals followed from his pen over the next decade using this technology, representing some of his most important findings in the field of motor control. Not satisfied with this breakthrough, he subsequently led our team to tackle and solve the problem of extracting neural firings from dynamic contractions such as gait and exercise[2]. This accomplishment has now raised the bar for all of us to embark on the next generation of biomechanics research: measure human movement characteristics while tracking the neural mechanisms that control this movement through wearable sensors. Carlo recognized the potential that this technology has on changing how we study human movement. His last few years, knowing full well of his impermanence, was spent reinforcing this concept at meetings, workshops and tutorials. This effort has culminated in the recently formed Motor Control and Biomechanics Section of ISB, which has sponsored a day and a half of symposiums devoted to this vision at ISB2017.

Corresponding author email: roberto.merletti@polito.it

I first met Carlo De Luca at the 4th ISEK conference he organized in Boston in 1979. Dr F. Felici joined the NMRC in 1985. Research in EMG was at its beginning, following the pioneer work of J. Basmajan, the mentor Carlo worshipped. At that time the Italian researcher B. Mambrito was programming a VAX computer, the size of half a room, for needle decomposition of the EMG and the idea of the quadrifilar electrode was being developed and tested. Decomposition time was measured in many hours. B. Mambrito, F. Stulen and R. LeFever were working on their MIT PhD thesis on EMG decompo-sition and monitoring of muscle fatigue. Prof. De Luca had done some work for Liberty Mutual Insurance Co. and devoted his compensation to setting up a research lab. There was a feeling of walking a few feet above ground, doing something that nobody had done before. The pioneer work "Physiology and mathematics of myoelectric signals" (1979) was fascinating to us because of its implications on biomechanics and motor control merging with math and physiology.

We felt like children looking in the window of a candy shop. A world was opening up, waiting to be discovered.

The idea of using the window provided by EMG mathematical processing to look into the CNS and unravel how it controls muscle force and movement did affect our research and motivated our students in later years when we had our respective labs. These students are now teaching these concepts across the world to engineers, MDs, PTs and trainers.

Many researchers joined Prof De Luca's NMRC, over the years, coming from many different countries: 41 in total, eight from Italy, three from my university. Mostly engineers but also a physical therapists (S. Roy) and a physiologist (F. Felici). Prof. De Luca had foreseen the importance of building a multicompetence team to cope with what he called "the challenge", the attempt to open the magic box of EMG to learn how to quantify fatigue and decode into numbers the central drive to muscles. This was the first and, perhaps, the most important lesson that we had from him. Besides, working with all of them, we learned a few things that we never learned in school: the importance of the weekly staff meetings with discussions of ideas and of the work done, the sharing of experience, the fights about disagreements, the preparation of the annual reports, the rigor in planning experiments and the severity in the writing, and rewriting, and rewriting of manuscripts: "your sentences are too long and convoluted, are you afraid to state your findings?".

Those of us who returned to their countries took with them and disseminated not only important innovative concepts (the common drive, the monitoring of muscle fatigue, the "onion skin" scheme) but, more important of all, they spread a way to approach science based on the interpretation of experimental evidence, not on opinions. Surface EMG is an excellent tool for monitoring, for quantifying the effectiveness of rehabilitation therapy and sport training, for preventing disorders. It seemed so easy and logical. Who could object? Not so.

"Be self-confident and present your evidence to the point of being biased". But "measurement" was not always welcome elsewhere: other issues were more relevant. "How can this help me in my practice and in my business? Can this increase my patients and my income?" We think there is no conflict between knowledge and business (as Carlo demonstrated) but there is a learning effort in between. Scientific and practical knowledge are not the same but the second is fed by the first that often challenges comfortable traditions or established practices and we all know that challenging tradition is neither easy nor appreciated.

For this reason the effort to transfer knowledge, experience and results, to different countries and in different societal settings has not been always successful. Even today, opinions and unquestioned traditions too often prevail over evidence. A quantitative approach is not always and not everywhere welcome and is often seen with suspicion and fear because of its potential challenge to established procedures. Therefore, we still have a long way to go. Nevertheless, researchers in neuromechanics settings are now accepting the technology and the interpretation originally proposed by the NMRC group for investigating neuromuscular system performance in a variety of different conditions.

We have come a long way in 40 years of research but problems are still open (e.g. dynamic contractions and other issues), for the modelling engineer as well as for the physiologist. In some environments, open issues to be addressed are blown up and interpreted as limitations.

We learned from Prof De Luca how to set up a proficient laboratory and to motivate students to unravel, understand and use the information contained in EMG. We now know so much more about its meaning and interpretation and we have transferred this approach and this knowledge to our students. He took strong positions, sometimes in contrast with tradition or with the positions of others. The challenge he left is the transfer of knowledge and technology to our students and to clinical movement scientists, physiotherapists and exercise specialists.

BACTERIAL CELLS DISTRIBUTION MIGRATING AROUND A CHEMICAL ATTRACTANT SOURCE

Tomonobu Goto, Mami Kajitani, Junpei Yoshino, Hiroki Mitsui and Tonau Nakai
Tottori University
Corresponding author email: goto@damp.tottori-u.ac.jp

INTRODUCTION

Bacterial cells swimming in a liquid medium migrate around a chemical attractant moving in a way of biased random walk. This chemotaxis should have relation to their colony formation or more complex biofilm formation, e.g. slime on waterways, rocks, and dead leafs in water. The capillary assay has been applied for studying the response of bacteria to attractant and repellent [1]. However, the process of migration has not been fully elucidated.

In this study, distributions of bacterial cells of *Salmonella Typhimurium* migrating around the tip of the capillary which contains L-serine were measured. The steady distributions approximated as exponential distributions were quantitatively compared to the results calculated by a mathematical biased random walk model.

METHODS

The strain of *Salmonella Typhimurium* SJW1103 was used. The cells were cultivated overnight in the LB medium. They were flashed and diluted in the motility buffer [1].

A thinned capillary containing 0.05M L-serine as an attractant was placed on a glass slide. A drop of the cell suspension was dribbled near the tip of the capillary, then a cover slip was placed to cover the drop and the tip of the capillary. The circumference of the cover slip was sealed by petroleum jelly. The thickness of the suspension was around 300-400 μm.

The process of bacterial migration around the tip of the capillary were observed through a microscope (IX71, Olympus) and recorded by a digital video camera (DP27, Olympus). The objective lens of 20x, or 40x coupled with the intermediate variable magnification lens of 0.5x was used. Four experiments were performed. The numbers of the cells within concentric circular bands whose center was the tip of the capillary were counted from the images after 12, 16, 20 min. The width of each band ΔR was 8 μm. The number density of the cells n(R) within each band was calculated (see the inset of Figure 1).

RESULTS AND DISCUSSION

Figure 1 shows examples the number density of the cells as functions of the distance from the tip of the capillary. The three distributions at different times are almost the same. The distribution seems to be steady in these time although the variation is quite large. The distribution in earlier time varies with time (data not shown).

The number densities are approximated well as a broken straight line in Figure 1 whose vertical axis is in logarithmic manner. This means that the cells migrating around the chemical source form an exponential distribution. We have calculated the slope of the lines among the four experimental data. The slope is in the range -0.035~-0.040.

According to a biased random walk model that is similar to the previously proposed [2], the number density is expressed in the form,

$$\log_{10}[n(R)] \approx -\log_{10}(1.3\alpha+1)\frac{\Delta R}{\Delta r}\frac{R}{\Delta R} + const.,$$

where Δr is the distance which a model cell moves during one time step, and α is the parameter indicating the strength of the chemotaxis; α =1 means the most intense bias, α =0 corresponds to the random walk resulting in diffusion. The value Δr which is assumed to be a constant in the model should be obtained through observation, and it is not determined yet. However, Δr ranges from several to several tens of times the cell size that is about a few μm. Therefore, it is plausible to assume that the order of Δr/ΔR is about one to one tenth. The α value is estimated as nearly 0.07 if Δr/ΔR=1, and 0.007 if Δr/ΔR=0.1.

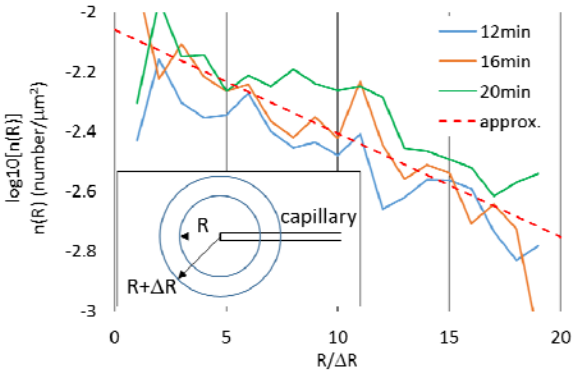

Figure 1: Examples of the distribution in number density of bacterial cells around the tip of the capillary containing chemical attractant.

CONCLUSIONS

Bacterial cells' distribution around the tip of the capillary containing chemical attractant was measured. Steady exponential distributions were observed 12-20 min after the tip was placed into the cell suspension. The chemotactic response is not so strong according to the previously proposed biased random walk model.

COLLECTIVE MOTION IN A DENSE SUSPENSION OF SWIMMING BACTERIA IN A CONFINED POOL

Tonau Nakai, Tomonobu Goto
Tottori University
Corresponding author email: nakai@damp.tottori-u.ac.jp

INTRODUCTION

Swimming bacteria living in an aqueous environment propel themselves by rotating their helical flagella. When the number density of cells is high, a collective motion occurs where cells in the neighbourhood swim toward a similar direction. This collective motion is a kind of synergetic effects caused by interacting "active matters" and has been studied recently [1].

The collective motion of bacteria has a vortex-like structure. Previously, we reported that the characteristic size of the vortex is of the order of 10 μm in the quasi-two-dimensional region [2]. On the other hand, there have been some reports that the vortex structure is spontaneously generated in a confined suspension [3,4]. These collective behaviours are considered to be dependent of the ratio of the sizes of the vortex and the confined region. In this study, we observed the individual cell's swimming and the collective motion by developing the experimental system, where we can control the size of pool confining bacteria.

METHODS

Bacillus subtilis cells were used for the observation. Cells were cultivated on a semi-fluid LB medium (0.6% agar) in a petri dish at 310 K. After 3 hours, the collective motion occurred. The thickness and length of the cell body was 0.7-0.8 μm and 5-10 μm, respectively.

Although the state of the collective motion varies with time due to evaporation, we managed to keep a circular pool on the agar medium by manipulating a fine glass needle. A glass rod (GD-1000, Narishige) was pulled by a puller (PC-20, Narishige) to make a fine needle whose diameter was a few μm at its end. The needle was operated by a micromanipulator (ON3-99D, Narishige) equipped on an inverted microscope (IX71, Olympus). When the tip of the needle touched on the surface of an agar medium, water gathered around the needle by the capillary force and a circular pool was formed. The size of the pool varied by a few μm depending on the angle of the needle to the agar surface. The circular pool was moved together with the needle by the manipulator. When the pool contacted the edge of a bacterial colony, the cells flowed into the pool and began to swim there. Cells were observed with an objective lens (LUCPlanFLX40, Olympus) and recorded with a digital camera (DP27, Olympus). In this bright-field observation, only the cell bodies were visualised; flagella could not be seen because of their fineness (~ 10 nm).

RESULTS AND DISCUSSION

Figure 1 shows *Bacillus subtilis* cells confined in a circular pool on an agar medium. Cells brought from a colony are aligned in the pool. Swimming directions are also aligned, along the edge of the pool. As shown in Fig. 1(b), vortex structure similar to that in Refs. [3][4] is observed. Cells in the pool do not cross each other, which shows that the thickness of the pool is on the order of the cell size (~ μm). When the pool filled with cells was carried by the manipulator, cells were gradually left on the medium and cell number density in the pool became lower, where no collective motion was observed. This means that the collective motion occurs due to the interaction between cells that swim straightforward in the free solution.

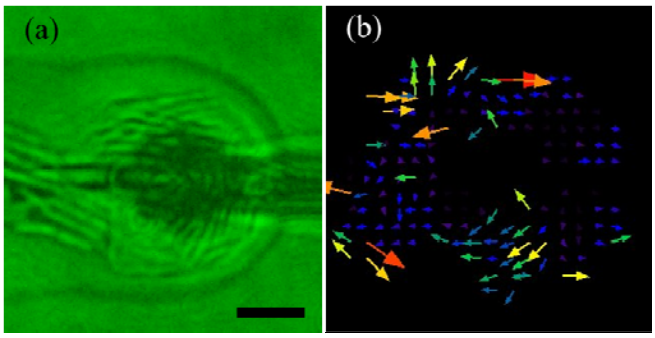

Figure 1: (a) *Bacillus subtilis* cells confined in a circular pool on an agar medium, (b) PIV result of (a). Cells are ordered and swim forming a clockwise vortex in the circular pool. The scale bar indicates 10 μm.

CONCLUSIONS

In order to investigate the condition under which the collective motion of bacterial cells occurs, we have developed experimental system to confine a certain bacterial group in a circular pool. It is found that decrease in the number density of identical cells produces the state of free swimming cells from the state of collective motion. Observed vortex motion in the circular pool is similar to that previously reported.

EFFECTS OF PACLITAXEL ON MICROTUBULE DISTRIBUTION AND ELASTCITY OF PC-12 CELLS

Chen Chou[1], **Ming-Shaung Ju**[1] and Chou-Ching K. Lin[2]
[1]Dept. of Mechanical Engineering
[2]Dept. of Neurology, College of Medicine and University Hospital
National Cheng Kung University, Tainan, Taiwan

INTRODUCTION

Paclitaxel is one of the drugs commonly used for chemotherapy of breast, ovarian and colorectal cancers. Paclitaxel can cause multipolar division of cancer cells and kill them [1]. However, about 50% of patients receiving paclitaxel suffer from chemotherapy-induced peripheral neuropathy and the associated acute pain syndrome [2, 3]. Most researches suggested that it induces hyperalgesia or mechanical allodynia due to the damages of some neural structures [4]. Only a few researches addressed on the influence of chemotherapy on mechanical properties of neuron cells. The Young's modulus of dorsal root ganglion cell decreases by 21%~45% with increasing dosage of vincristine [5]. Stretch of axon can amplify effects of paclitaxel on axonal transport [6]. The goal of this study was to investigate how paclitaxel affects microtubule distribution and elastic properties of PC-12 neuron-like cell.

METHODS

PC-12 cells planted in a 35-mm dish coated with type IV collagen were cultured in RPMI 1640 with 10% HS, 5% fetal serum, 5% FBS, 1% sodium pyruvate, 1% penicillin-streptomycin and 0.1% amphotericin B, and incubated at 37° C in a 5% CO_2 environment. Then differentiation was induced by nerve growth factor (NGF, 100 ng/mL) for 72 hours. After that the cells were separated into two groups, namely, control group that was treated with NFG and experimental groups that were treated with NGF and paclitaxel with a concentration level (1, 5, 10 μM, respectively) for 8 hours. Then all cells were taken out of the incubator and fixed by 3.7% PFA/PBS for 15 min.

Following the standard immune-fluorescence procedures, microtubules in PC-12 cells were stained using 0.2% Alexa Fluor 488. The immune-fluorescence images were acquired and analyzed using software *ImageJ*. To quantify the distribution of microtubules, dispersion ratio D defined as $D = (A_I/A) \times 100\%$ was computed, where A the whole cell area, and A_I the region surrounded the nucleus and having intensity of microtubules greater than a self-defined threshold.

Indentation on nucleus of the fixed cell was done using an atomic force microscope (Agilent 5500) to obtaine the force-indention data. The apparent Young's modulus E was estimated by fitting the data to the following equation [7]:

$$F = \frac{8Etan\theta\delta^2}{3\pi}\left\{1 + \frac{3.559tan\theta}{\pi^2}\frac{\delta}{h} + 16(1.7795tan\theta\frac{\delta}{h})^2\right\}$$

where θ is the half-opening angle of probe, δ the indentation depth, and h the height of the sample at indentation site.

RESULTS AND DISCUSSION

The mean dispersion ratio of microtubules for the experimental group is greater than that of the control group (Fig. 1). Among the experimental groups, the mean dispersion ratio increases with the increase of concentration of paclitaxel except the 10 μM group. When concentration of paclitaxel increased the microtubules surrounding nucleus are stabilized and becoming more dispersed. But when the dosage is too high the cell may shrink, leading to decrease of cell area, and so is D. One way analysis of variance shows that the effect of concentration of paclitaxel on D is significant ($p=0.009<0.05$). Although the sample size is only 3, the mean apparent Young's moduli of nucleus of experimental groups are greater than that of control group, 41.6 kPa (1 μM) and 35.3 kPa (5 μM) vs. 24.1 kPa (Fig. 1). The results reveal that paclitaxel might cause abnormal microtubule arrays and crystalline arrays around the nucleus and harden of the PC-12 cell [3]. It needs to be verified by further confocal microscopic or electro-microscopy images.

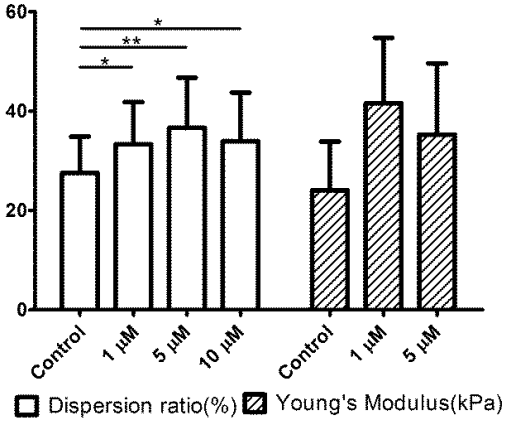

Figure 1: Dispersion ratio and Young's modulus of PC-12 cells for the control and those treated with paclitaxel with varied concentration. (* $p<0.05$, ** $p<0.01$)

CONCLUSIONS

For low dose of paclitaxel, the dispersion ratio of microtubule and apparent Young's modulus of PC-12 cell may increase with the increase of paclitaxel concentration. However, for high dose the dispersion ratio may decrease slightly but still greater than that of the control.

MOLECULAR DYNAMICS SIMULATION OF STRETCH-INDUCED PHASE TRANSITION IN PHOSPHOLIPID/CHOLESTEROL BILAYER: TOWARD UNDERSTANDING MECHANICAL RUPTURE OF CELL MEMBRANES

Taiki Shigematsu, Kenichiro Koshiyama and Shigeo Wada
Osaka University
Corresponding author email: shigematsu@me.es.osaka-u.ac.jp

INTRODUCTION

Fundamental structure of mammalian cell membranes is a phospholipid bilayer, which contains cholesterol molecules richly. The bilayer acts as a barrier to separate the inside of the cell from the outside. When exposed to excessive mechanical stresses, the bilayers are sometimes ruptured. Although the bilayer rupture is fatal to cells, the detailed mechanism of the bilayer rupture is still unclear. Our previous molecular dynamics (MD) simulation studies [1,2] clarified that, in stretched phospholipid/cholesterol bilayers, phase transition from liquid-ordered (*L*o) to interdigitated gel (*L*i) phase occurs. Additionally, the bilayers, where the transition to the *L*i phase occurs, can withstand larger areal strains without rupturing than those where the transition does not occur [1]. Thus, we suspected that the stretch-induced transition to the *L*i phase might prevent the bilayer rupture. However, there is no experimental observation of the stretch-induced phase transition to the *L*i phase and the mechanisms of the phase transition observed in MD simulations are unknown. In this study, to understand the mechanisms of the stretch-induced phase transition, we performed MD simulations of the *L*o and *L*i/*L*o coexisting phase bilayers under stretching and proposed a free energy model of the *L*i/*L*o coexisting phase bilayer.

METHODS

A phospholipid/cholesterol bilayer system was used. The bilayer was composed of 512 1,2-dipalmitoyl-*sn*-glycero-3-phosphochline (DPPC), 344 cholesterol, and 38,912 water molecules. The stretched bilayers were simulated by $NP_zA_{\parallel}T$ MD simulations at constant temperature (T = 323 K), constant pressure in the bilayer normal (P_z = 0.1 MPa), and various constant areas $A_{\parallel}$. The areal strain of the stretched bilayer ε_A was defined as $\varepsilon_A = A_{\parallel}/A_0 - 1$, where A_0 is a simulation box area at equilibrium. DPPC and cholesterol molecules in the *L*i phase were defined by using their occupied area on the bilayer plain. If the area is larger than a threshold value, the molecule is considered to be in the *L*i phase. If not, it is in the *L*o phase. The ratio of the total area in the *L*i phase to the whole bilayer area was defined as α. Also, the ratio of the number of the molecules in the *L*i phase to that in the whole bilayer was defined as β. We defined the free energy of the *L*i/*L*o coexisting phase bilayer U as

$$U(\varepsilon_A,\alpha,\beta)=U_e(\varepsilon_A,\alpha,\beta)+U_b(\varepsilon_A,\alpha)+U_h(\varepsilon_A,\alpha),$$

where U_e, U_b, and U_h are energies for elastic deformation, phase boundary, and surface tension in the *L*i phase, respectively. When the stretched bilayer is at equilibrium, U should be minimized. Under this condition, the optimal pair (α, β) for arbitrary ε_A was found by exhaustive search. α obtained from the model was compared to that from the MD simulation.

RESULTS AND DISCUSSION

Figure 1 shows the relationships between α and ε_A obtained from the MD simulations and the free energy model. Insets in Figure 1 show representative snapshots of the *L*o and *L*i/*L*o coexisting phase bilayers. Before stretching, DPPC and cholesterol molecules are ordered and form a bilayer structure, i.e., the *L*o phase (Figure 1*A*). When ε_A exceeds a critical areal strain ε_C, which is estimated to be in the range 0.073–0.101, some DPPC and cholesterol molecules penetrate into the opposite leaflet of the bilayer and form a *L*i phase locally (Figure 1*B*). α obtained from the MD simulations keeps around 0 below ε_C, but sharply increases around ε_C (Figure 1 circle). The change in α obtained from MD simulations can be reproduced by the free energy model (Figure 1 dashed line). This means that the stretch-induced phase transition to the *L*i phase can be explained by the balances among the energies for elastic deformation, phase boundary, and surface tension in *L*i phase.

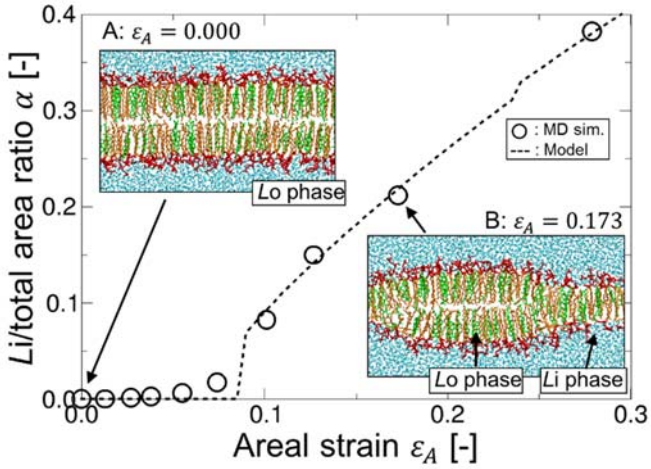

Figure 1: Relationship between *L*i/total area ratio α and areal strain ε_A. Insets *A* and *B* are representative snapshots of *L*o and *L*i/*L*o coexisting phase bilayers, respectively. DPPCs are shown in red and orange, cholesterols in green, and water in blue.

CONCLUSIONS

To understand the mechanisms of the stretch-induced phase transition to the *L*i phase, we performed MD simulations of the stretched DPPC/cholesterol bilayers and proposed the free energy model of the *L*i/*L*o coexisting phase bilayer. In the MD simulations, the phase transition occurred when the applied areal strain exceeded a critical value. Our free energy model successfully reproduced such the phase transition behavior observed in the MD simulations. As the results, we found that the stretch-induced phase transition can be explained by the balances among the energies for elastic deformation, phase boundary, and surface tension in the *L*i phase.

INTRODUCTION

Human-induced pluripotent stem cell-derived cardiomyocytes (hiPSC-CM) have been increasingly used as *in-vitro* model for pharmacological studies and are also being investigated in terms of the treatment of damaged or diseased heart tissue [1]. For the analysis of hiPSC-CM a device called *CellDrum* was developed in our institute [2,3]. The *CellDrum* is a well with a bottom formed by an only 3µm thick silicone membrane on which hiPSC-CM are cultivated. Clamped in a fixed ring the auto-contractile tissue construct is inflated by a syringe pump and beating characteristics, e.g. frequency and amplitude of the contractions can be measured using a laser triangulation sensor.

HiPSC based cell lines differ in the content of specialized cardiomyocytes and the amount of fibroblasts. Fibroblasts can couple to cardiomyocytes and are known to affect their electrophysiological properties which may lead to arrhythmias [4,5]. Mechanical processes, i.e. the contraction, depend on the electrophysiology and a computer simulations showed that the active stress during contraction decreases in the presence of fibroblasts [5]. However, apart from that little is known on how fibroblasts affect the mechanics.

Our study aims to gain a deeper understanding on the electromechanical interaction between fibroblasts and cardiomyocytes using experiments with hiPSC based cell lines and an electromechanically coupled tissue model.

METHODS

A hiPSC based cell line of 60% ventricular, 22% atrial, and 18% nodal cardiomyocytes is used (Cor.4U®, Axiogenesis AG, Germany). Fibroblasts (Fibro.Cor.4U®, Axiogenesis AG, Germany) are added so that their relative cell content varies from 0 to 50%. For every mixture the central deflection during contraction is measured.

The Finite Element Method (FEM) is used to model the tissue construct based on the continuum approach which maps the average properties of many homogenously distributed cells rather than describing each cell separately. Cardiomyocyte electrophysiology is computed by a set of ordinary differential equations which are embedded elementwise in the FEM framework. Electrical stimulation is considered in the center of the tissue with a frequency taken from the experiments and electrical propagation over the tissue is modelled by the reaction-diffusion type monodomain equation [6]. Controlled by the membrane potential in a given cardiomyocyte its calcium (Ca^{2+}) concentration varies with time. Contraction models relate the calcium concentration to the active stress. However, no Ca^{2+} currents have been identified in fibroblasts yet. Mechanically the tissue construct is characterized as a hyperelastic and nearly incompressible material with a nonlinear stress-strain relation. Both mechanically and electrically the tissue is furthermore assumed to be isotropic because the cells are not specifically orientated in the tissue. Active stress arising during contraction is added to the passive stress in the force balance that determines the deformation. Passive stress of the tissue construct is described by the neo-Hookean strain energy function as in previous models [7]. Inflation measurements with the *CellDrum* are performed for its parametrization and the determination of the reference stress in the contraction model.

Fibroblast electrophysiology is represented by the active model published by MacCannel et al. [8] which include four membrane currents. One cardiomyocyte is coupled to a variable number of homogenous fibroblasts via an intercellular conductance.

RESULTS AND DISCUSSION

Up to a relative fibroblast content of 25% the tissue deflection in the center increased and decreased again up to 50%. This is in contrasts to the computer simulation study [5]. However, in [5] the number of fibroblasts connected to one cardiomyocyte was not varied, model data were not adapted from hiPSC-CM but from multiple species and different from our experiments only ventricular cardiomyocytes were considered.

The electromechanical interaction between fibroblasts and ventricular cardiomyocytes will come to the focus in the next step of the study. This is made possible by a recently developed cell line which contains 90% ventricular and 10% atrial and nodal cardiomyocytes (vCor.4U®, Axiogenesis AG, Germany). So far, there is a lack of hiPSC-CM cell models. Based on new experiments they will be developed in order to finish the computer model.

CONCLUSIONS

The *CellDrum* is a promising tool to investigate the electromechanical effects of fibroblast on hiPSC-CM. Combined with a computer model it may be capable to explain variations in the tissue deflection depending on the relative fibroblast content.

THE INFLUENCE OF ADDED MASS ON TENDON STRETCH & MOVEMENT STRATEGY IN JUMPING

Logan Wade, Glen Lichtwark and Dominic James Farris
The University of Queensland
Corresponding author email: l.wade@uq.edu.au

INTRODUCTION

Previous studies have shown an important contribution of elastic energy stored within the Achilles tendon (AT) to jumping power [1]. As this energy is stored against the resistance of bodyweight [2], it may influence how we generate work and power for jumping. Previously, we found that increasing the mechanical work required for jumping via additional body mass resulted in an ankle centred movement strategy, while increasing work due to additional jump height resulted in a hip and knee centred strategy [3]. We believe this ankle centred strategy preference is a result of using additional energy stored within the AT. To ascertain if this is the case, we examined if additional body mass increased the stretch of the AT during jumping, indicating additional energy storage. We hypothesised that there would be additional stretch of the AT when jumping with increased body mass but not when matching the same increase in work via increasing jump height.

METHODS

Male participants (N = 13, Height = 179.8 ± 5.4 cm, Mass = 73.4 ± 6.3 kg) performed maximal and submaximal countermovement jumps with 100%, 120%, 140% and 160% body mass. Work was controlled by having participants jump to pre-set heights wearing weight vests loaded at 1kg intervals to increase body mass. Two paradigms were compared; Body Mass Paradigm (BMP): increasing work by increasing body mass while jumping to a constant height and Jump Height Paradigm (JHP): match the increasing total work outputs of the BMP by increasing jump height at a constant body mass (100% body mass).

Kinematic data were recorded using 3D motion capture (200Hz) and analysed using standard inverse kinematic techniques in OpenSim, from which soleus muscle-tendon unit (MTU) length was obtained. Images of soleus muscle fascicles (MF) were recorded using B-Mode ultrasound (80Hz) and their lengths tracked throughout all jumps. Series elastic element (SEE) length was calculated from: MTU – (MF * cos(pennation angle)).

Statistical analysis of MTU, MF and SEE length changes were split into two phases. Phase 1 started at the point where SEE began to lengthen until maximum SEE length. Phase 2 was from SEE maximum length until toe off. Statistical differences were tested for using two-way repeat measure ANOVA's with work and experimental paradigms as factors. A significant main or interaction effect highlighted a change in length of the MTU, MF or SEE, and if found a post hoc analysis using a one way ANOVA with a Bonferroni adjusted alpha level ($\alpha = 0.025$) was performed.

RESULTS AND DISCUSSION

There was a significant main effect of increasing work ($P = 0.0246$) on the SEE length changes in phase 1. Post hoc analysis identified that there was a significant increase in the length of the SEE under the BMP ($P = 0.0087$) but not the JHP ($P = 0.5015$). The SEE demonstrated no significant changes during phase 2

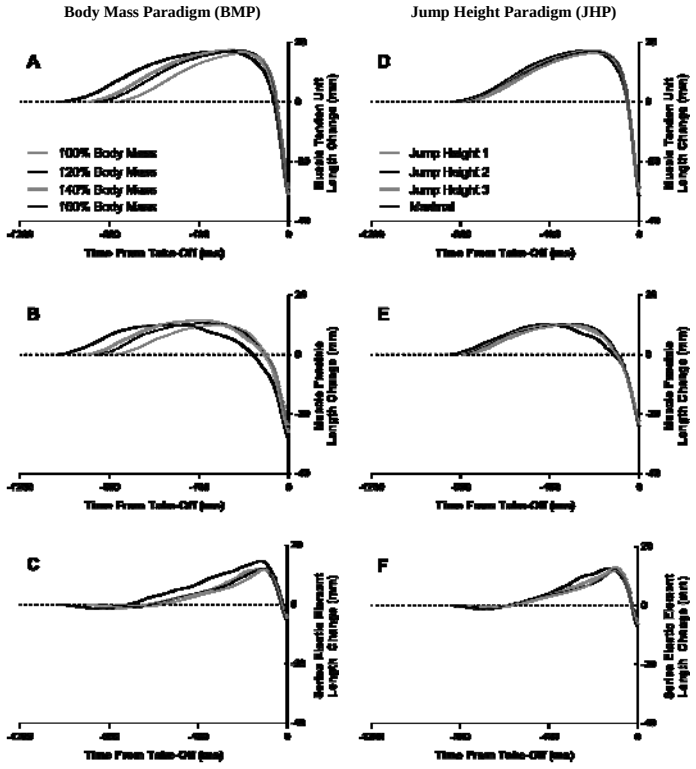

Figure 1: Time series data of Soleus length changes during the BMP and JHP. Time point 0 ms is synchronised to toe off. Graphs; A & D represent MTU length change. B & E represent MF length change. C & F represent SEE length change.

These results suggest that with additional body mass the soleus SEE stretch significantly increased, which may enable additional elastic energy storage. This extra stretch may explain the preferred ankle centred strategy with added bodymass that was previously observed [3]. There was no change in SEE length under the JHP, further supporting our hypothesis that energy stored in the AT is primarily done against the resistance of body mass during jumping.

CONCLUSIONS

We believe that the work produced at the ankle joint is heavily influenced by the amount of elastic energy stored within the AT - due to body mass. Once energy is stored within elastic structures it must either be used or absorbed and therefore the amount of elastic energy stored will likely influence our movement strategy.

INTRODUCTION

In rowing it has been conventionally assumed that a high boat velocity is achieved through the production of large, symmetrical forces, efficiently delivered through the feet, up the human kinetic chain to the oar handles [1]. Despite this, recent advances in laboratory research have demonstrated preliminary evidence of lower limb asymmetries for different biomechanical variables [2]. Such evidence of asymmetries in on-water rowing is more limited. Difficulties in building a conclusive evidence base on asymmetries in rowing are partly due to the measures used to quantify asymmetry, which tend to be discrete values or indices [2]. Understanding the potentially functional role of asymmetry patterns across the *entire* stroke cycle would be useful from a technical perspective and more practically insightful.

As such the purpose of this study was to explore the role of asymmetry patterns in on-water single sculling using analytical techniques from *Functional Data Analysis* (FDA). Patterns of asymmetry were explored relative to level of competitive representation.

METHODS

Twenty seven female rowers voluntarily consented to participate (age = 25.60 + 4.88 years; height = 1.74 + 0.04 cm; mass = 75.62 + 4.61 kg). At the time of testing, competitive performance was used to categorize participants as either 'national' (n = 14) or 'international' level (n = 13) rowers. Participants were instructed to row a total of 1000m, composed of 250m at four ascending pre-selected stroke rates (i.e., 20, 24, 28 and 32 stokes per minute). For this study, only the 32 strokes/min data was analyzed. Data was obtained using ROWSYS instrumentation [3]. Ten strokes were retained for further analysis.

A *difference* time-series (or profile) was created for each individual stroke and ensemble average profiles were created for each participant. The difference time-series was created by subtracting stroke-side (right hand) force from bow-side (left hand) force across the entire drive phase (see Figure 1). Functional principal components analysis (*f*PCA) was then applied to these time series. For *f*PCA, B-spline basis functions were used to fit each of the difference time-series. A smoothing parameter was also selected using generalized cross validation (GCV) and from these new functions, functional principal components (*f*PCs) were derived. Each difference function was weighted by each of the first five *f*PCs, with resulting scalar averages referred to as *f*PC scores. *f*PC scores were assessed using univariate ANOVAs ($p < .05$) for competition level differences.

RESULTS AND DISCUSSION

Four of the five retained *f*PCs demonstrated statistical significance ($p < .05$) between national and international rowers. The combination of these four *f*PCs demonstrated a trend for international rowers to lead force production with the stroke-side from the start of the drive phase until approximately half way through the movement cycle, before reversing through the second half of the drive phase. The opposite was true for national level rowers. This asymmetrical offset is likely the result of international athletes modifying their movement strategies relative to mechanical offsets in boat rigging [3].

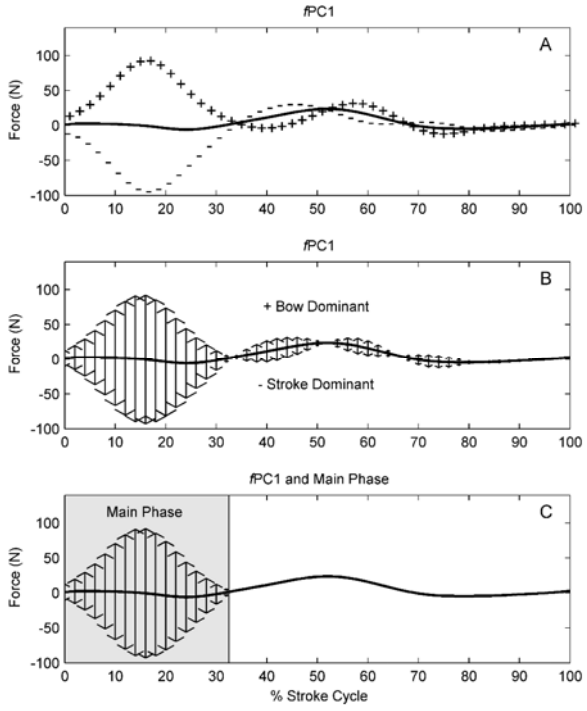

Figure 1: A: Example *f*PC of difference time-series, B: direction of asymmetries reported by *f*PCs, C: Main phase of asymmetry.

CONCLUSIONS

Results from this study, thus suggest it is possible that asymmetries in sculling may have a functional role in successful execution of the rowing stroke, and rather than asymmetries be dismissed as a potential problem and detractor of performance, they are treated similarly to other coordination structures that are explored in biomechanics and human movement research.

INTRODUCTION

Rowing performance is defined as the average shell velocity over 2000 meter. In order to maximize average velocity rowers need to optimize their aerobic and anaerobic physical capacities. To achieve this, training sessions at different intensities are highly important [e.g.1]. Nowadays, on-water training intensity is controlled by parameters that are affected by external factors such as the weather and the state of the rower (e.g. boat velocity, stroke rate, rowers' subjective feeling and heart rate) [e.g.2]. Mechanical power output (PO), instead, is a direct parameter for training intensity since it is strongly related to metabolic power production [3].

Recent technological developments allow for a valid calculation of mechanical PO [4] and for real-time feedback of this quantity while rowing. In order to use PO as a parameter to control training intensity, it is important to understand whether rowers are capable to adjust mechanical PO based on feedback.

The primary aim of the study was to examine whether rowers are better able to comply to PO targets when they are provided with real-time feedback on PO compared to traditional feedback. Subsequently, it was tested whether rowers' PO was less variable between strokes when they got real-time feedback on PO compared to traditional feedback.

METHODS

Eighteen Dutch rowers (minimum experience of 2.5 years of intensive rowing) rowed three identical training sessions in crewed boats. In all training sessions the rowers were instructed to row blocks at low- and medium-high intensity. Related target power outputs, based on earlier determined ergometer scores were given. In the first two sessions the rowers were provided with traditional feedback on training intensity (subjective feeling, stroke rate, and/or heart rate), while during the last session they also got real-time feedback on mechanical power output. Training sessions were adjusted to the rowers' normal training sessions and consisted of at least a warming up, 3 times 2km of low intensity rowing and 1.5 km of medium-high intensive rowing.

Forces at the oar pin as well as oar angle in the horizontal plane were measured (Peach Innovations Ltd., Cambridge, United Kingdom; 100Hz) and stored on a SD card. Mechanical power output was calculated using the algorithm described in [4] and provided to the rowers using a custom made android application that was running on Samsung S5 Smartphones.

RESULTS AND DISCUSSION

Multilevel analyses revealed that rowers complied better to their power output targets when they were provided with feedback on power output compared to the traditional feedback parameters ($F(180.25)=30.04$, $p<.001$) (figure 1). In addition, on average, their real PO fluctuated less between strokes in the different intensity blocks during the training session with real-time feedback on PO compared to the training sessions with traditional feedback ($F(180.21) = 6.02$), $p=.003$).

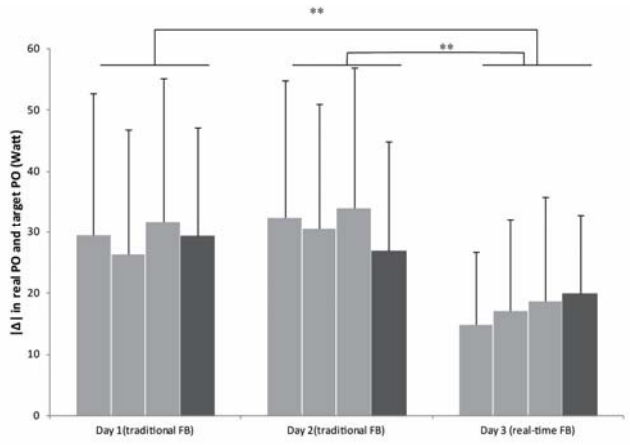

Figure 1: Absolute difference (|Δ|) between real PO and target PO during the light intensity blocks (light grey) and the medium-high intensity (dark grey) block with traditional feedback and with real-time feedback on PO.

CONCLUSIONS

The results suggest that rowers are more capable to adjust mechanical PO based on feedback on PO compared to traditional feedback. Since mechanical PO is strongly related to metabolic PO [3], mechanical PO seems, therefore, an important parameter to control and monitor training intensity.

ACKNOWLEDGEMENTS

This study is part of the project " optimizing propulsion in rowing" and funded by the " Stichting Techniek en Wetenschap" under Grant 12868.

ACCELERATION ATTENUATION IN DROP LANDING AND DROP JUMPING: A SPECTRAL ANALYSIS

Stuart McErlain-Naylor, Sam Allen and Mark King
School of Sport, Exercise and Health Sciences, Loughborough University, Loughborough, UK

INTRODUCTION

Impacts form an inevitable aspect of many human activities; kinetic energy must be lost without musculoskeletal injury or damage to vital organs. Major contributors to this loss include compliance within joint structures, as well as soft tissue movement and voluntary joint actions. Numerous studies have shown a reduction in impact accelerations from the tibia to the head [1,2]; however it is important to quantify the relative contributions of various structures to this attenuation. Thus the purpose of the present study was to quantify the progressive reduction in impact acceleration and hence kinetic energy by the human body.

METHODS

One male subject (19 years, 1.82 m, 70.1 kg) performed two single leg drop landings (SLDL) and two male subjects (26 ± 4 years, 1.90 ± 0.06 m, 87.4 ± 1.8 kg) performed two double leg drop landings (DLDL) and two double leg drop jumps (DLDJ) from each of 0.30, 0.45, 0.60, and 0.75 m. Lightweight Dytran triaxial accelerometers were positioned over the first metatarsophalangeal (MTP) joint, the distal and proximal anteromedial aspects of the tibia, the lateral femoral epicondyle, the L5 vertebra, and the C6 vertebra. Magnitude and timing of the peak resultant accelerations were identified, and power spectral densities for the signals at each drop height were averaged for individual subjects. Transfer functions were determined as the signal gain or attenuation between two positions. A two-way ANOVA for repeated measures and a Tukey-Kramer pairwise comparison were used to detect significant differences. Partial eta-squared (η^2) provided a measure of effect size.

RESULTS AND DISCUSSION

For peak resultant accelerations, significant main effects were observed for accelerometer position in all three tasks ($p < 0.001$; $0.97 < \eta^2 < 0.98$). For SLDL and DLDL, significant main effects for drop height ($p < 0.05$; $0.86 < \eta^2 < 0.94$), and drop height-position interaction effects ($p < 0.05$; $0.71 < \eta^2 < 0.72$) were also observed. Peak resultant accelerations tended to increase with increasing drop height and decrease with increasing distance from ground (Figure 1). A further significant main effect was observed between accelerometer position and timing of peak resultant acceleration for SLDL and DLDJ ($p < 0.01$; $0.71 < \eta^2 < 0.94$), which increased with height on the body. A significant drop height-position interaction was observed for SLDL peak acceleration timing ($p < 0.001$; $\eta^2 = 0.77$).

On average, the peak resultant MTP acceleration was already reduced by 27 ± 17% at the distal tibia (55 ± 13% SLDL; 25 ± 5% DLDL; 15 ± 8% DLDJ) and by 82 ± 9% (91 ± 2% SLDL; 73 ± 9% DLDL; 85 ± 3% DLDJ) and 90 ± 4% (96 ± 2% SLDL; 89 ± 4% DLDL; 89 ± 1% DLDJ) at the L5 and C6 vertebra respectively. Power spectra contained two major components corresponding to the active (2-16 Hz) and impact (18-36 Hz) phases of the time-domain signals. Transfer functions quantified progressive attenuation from the MTP towards the C6 vertebra within the 18-36 Hz range, even where there had been no significant reduction in overall peak resultant acceleration.

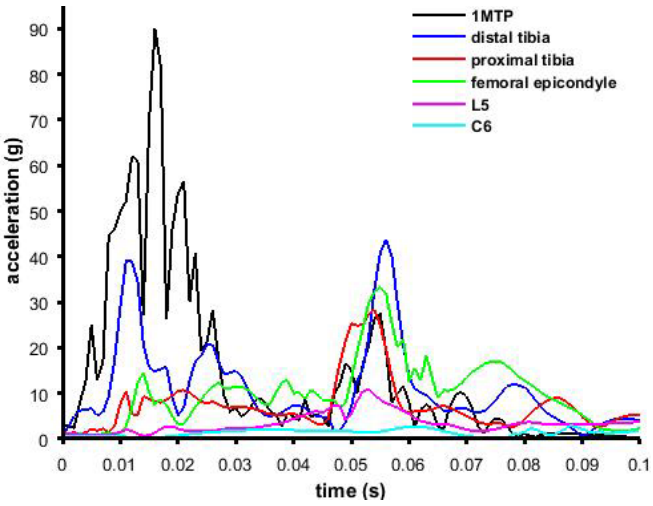

Figure 1: A typical 0.60 m time-domain acceleration signal.

Peak accelerations were greater following drops from higher heights and tended to decrease progressively, with increasing time delays, up the body. This ensured that the peak accelerations close to vital organs were less than 20% of those at the MTP joint, with even lower accelerations measured at the neck. Whilst the resultant accelerations included active joint motion, the impact component of the power spectra revealed stepwise attenuations even where there had been no reduction in peak acceleration. This emphasises the importance of spectral analyses in human impact investigations.

The observed attenuation of impact accelerations across joint structures has implications for both experimental and theoretical investigations. The assumption that the distal end of one body segment shares a common point with the proximal end of the connecting segment neglects the influence of compliance within joint structures and the subsequent effects on the kinetics and kinematics within the human musculoskeletal system.

CONCLUSIONS

This study demonstrated a progressive reduction in accelerations in the human body with distance from the point of impact, as well as an amplifying effect of greater drop heights on peak accelerations. Such effects of compliance within joint structures should be considered when representing the connection between adjacent body segments.

VISION-BASED AUTOMATIC PADDLER DETECTION AND TRACKING OF UPSTREAM GATE NEGOTIATION IN CANOE/KAYAK SLALOM FROM OVERHEAD VIDEO

[1] **Ami Drory**
[1]College of Engineering and Computer Science, Australian National University (ANU), Australia
Corresponding author email: Ami.Drory@anu.edu.au

INTRODUCTION

Upstream gate negotiation is a fundamental skill and key determinant of overall performance in competitive Canoe / Kayak (CK) Slalom. To date, only one study attempted characterisation of the gate negotiation strategy [1]. However, it employed tedious and time consuming manual digitisation of marker locations in images with low repeatability to extract data, which restricts its adoptability.

In this work, we describe a computer vision based automatic method for detection and tracking of a CK Slalom paddler negotiating an upstream gate from overhead video that doesn't suffer from these limitations. Our technique facilitates subsequent trajectory analysis, real-time feedback and inter-trial and inter-athlete comparisons.

Human detection and tracking remain open problems in computer vision due to significant variations in human location, shape and appearance. Using a supervised machine learning approach, we train a prior paddler appearance model comprised of a rich discriminative cascade classifier [2] that we employ for paddler detection and tracking.

METHODS

Given an input image, we construct a rejection cascade. A cascade classifier forms a degenerate decision tree that uses a sequence of node classifiers to distinguish paddlers from non-paddlers and simultaneously selects weak features to form strong ensemble classifiers using Adaptive Boosting (AdaBoost). At each stage a classifier is trained on the examples that were evaluated as positives in all preceding stages. A positive classification is passed on for evaluation at the subsequent classifier. A negative classification of an image patch results in rejection of the patch. Due to the scarcity of the paddler relative to the background, efficient detection is achieved by early rejection of most easily classified negative features (Figure 1). Consequently, the classifier's complexity and discriminative power increases as stages increase due to the escalating task difficulty.

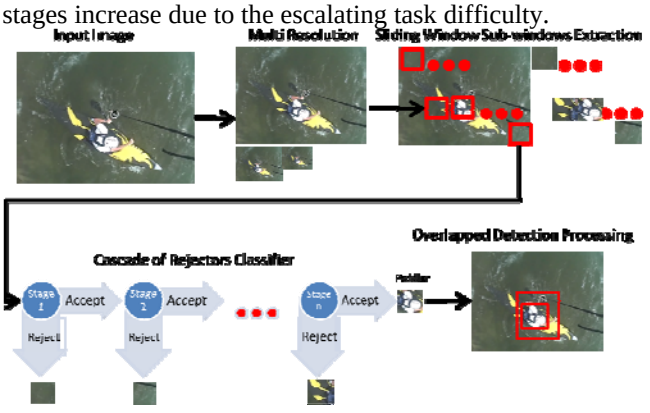

Figure 1: Efficient detection is achieved by early rejection of most easily classified negative features.

Cascade classification can be used with any feature descriptors. For selection of detector feature type and number of cascade stages, and to separately evaluate the performance of our paddler detection, we empirically tested the detector on 3 levels of features. Specifically, we experiment with low level Haar features due to their low computational cost, as well as with rich mid-level Histogram of Oriented Gradients (HOG) and Linear Binary Patterns (LBP) feature descriptors. Likewise we experiment with 3 levels of number of cascade stages (15, 20 and 30). The image test set that was used for these experiments consisted of 350 images randomly extracted from 20 image sequences in our dataset that were manually annotated for the paddler's ground truth location with a bounding box.

Our classifier training dataset contains 240 manually annotated overhead images. To train our detection models, we have split this dataset into a standard 60%, 20% and 20% for model learning, cross-validation and testing sets, respectively. Our negative set is comprised of 1694 images from the INRIA Person and Parse datasets, which contain background scenery images, as well as people to ensure that our paddler model discriminates well between people displaying a variety of activities and paddlers.

RESULTS AND DISCUSSION

Our experiments indicate that compared to using rich mid-level feature descriptors (HOG and LBP), Haar features resulted in higher number of detections, precision and recall. Further, our results show that 20 cascade stages perform superiorly to 15 and 30 stages on standard criteria of the number of detections, precision, and recall (Table 1), and are comparable with the state-of-the-art. Our detector can be readily combined with efficient online tracking algorithms.

Table 1. Paddler Detection Results (350 test images)

	Feature Type			# Cascade Stages		
	Haar	LBP	HOG	15	20	30
Detections	**322**	215	244	251	**302**	275
Precision	**0.89**	0.87	0.86	0.81	**0.88**	0.87
Recall	**0.74**	0.45	0.59	0.55	**0.63**	0.56

CONCLUSIONS

We present an automatic supervised learning method for detection and tracking of CK Slalom paddlers negotiating an upstream gate. Our technique yields accurate paddler localisations at low computational cost. The robust tracking information forms a crucial evidence base pre-requisite to feedback-driven technical or tactical amendments aimed to optimise technique and performance.

EFFECTS OF WOBBLE BOARD TRAINING ON INTERLIMB COORDINATION DURING WALKING

[1]Uwe G. Kersting, [1]Priscila de Brito Silva, [2]Anderson S.C. Oliveira, [1]Natalie Mrachacz-Kersting

INTRODUCTION

The use of multimodal neuromuscular training programs has repeatedly been shown to reduce injury risk or re-injury incidences of ankle sprains. Balance training on inherently unstable surfaces, such as foam pads or wobble boards (WB), are important components of such training programs. It appears that standing on unstable surfaces requires different mechanisms to maintain balance, which allow for a transfer to high-risk movements in sport (Silva 2016, Oliveira 2014). The underlying neural control processes are currently unknown. Crossed responses have recently been described (Mrachacz-Kersting et al. 2011) as a possible mechanism directly related to interlimb coordination.

The goal of this study was to determine if interlimb communication pathways are affected by isolated balance training on a wobble board. It was hypothesized that the crossed reflex would be downregulated for a better control of counter-movements which are the main mechanical factors controlling balance in dynamic situations.

METHODS

Twelve sports practitioners (5 females) with no prior wobble board training experience were recruited (23.4 +/- 1.5 years, 73.8 +/- 7.2 kg, 1.73 +/- 0.09 m; mean +/- SD). Six of them were randomly selected and subjected to unilateral WB training 3 times weekly (30 min sessions with progressing difficulty) for 4 weeks on their left leg (TG) while the others served as controls (CG), continuing their regular training. Participants provided informed consent prior to data acquisition and training.

Interlimb coordination was assessed during self-paced treadmill walking by providing 30 unexpected plantar-flexion perturbations (amplitude: 6°, velocity 300°/s) to the left ankle joint during the stance phase using a custom-built ankle stretch device (Andersen, 1995) and 30 control trials. The activation of the left, ipsilateral soleus (iSOL) and right, contralateral biceps femoris (cBF) were monitored using electromyography (EMG) while goniometers traced the ankle movement. WB performance was assessed by timing the standing time without losing balance

EMG data were bandpass filtered (10-500 Hz), rectified and lowpass filtered (40 Hz). The typical unloading response in the iSOL was observed in all subjects ranging (61±8) ms. The individual onset times of the cBF response and the duration were established by comparison to the unperturbed trials. The magnitude was calculated separately for reflex (onset to 120 ms) and voluntary components (120 ms to offset) and expressed as a percentage of the unperturbed magnitudes. Paired t-tests were employed to assess differences between the pre and post training responses ($P<0.05$).

RESULTS AND DISCUSSION

The TG improved their WB standing time significantly (45%) while CG showed only small improvements, which were likely a training effect caused by the exposure during the actual test session.

The comparison of unperturbed and perturbed walking trials showed no changes for the CG while the training group demonstrated significant reductions in magnitude ($P=0.02$) (Figure 1) and duration ($P=0.03$) (234 vs. 182 ms) of the voluntary component of the response.

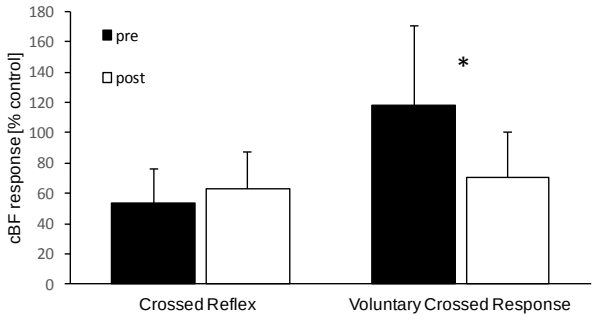

Figure 1: Crossed reflex and voluntary responses for TG (mean +/- SE).

These preliminary results provide a basis for discussing potential mechanisms behind the effect of balance training on unstable supports. It may remain questionable if the stretch reflex of ipsilateral lower leg muscles can contribute to the prevention of ankle inversion trauma. The observed alterations in crossed communication of iSOL and cBF muscles indicate that WB training alters the integration of afferent inputs within multi-joint intermuscular coordination. It is likely that other muscle groups are also involved. Future studies should further investigate these interactions and their role in functional tasks, especially in high-risk movements such as landing and cutting.

CONCLUSIONS

Crossed responses are significantly affected by balance training on a WB. The demonstrated relationships support the role afferent feedback may play in the control of complex tasks. It is a potential mechanism for how the transfer from isolated balancing exercises may contribute to improved motor control in risky situations. Further, a new perspective for investigating training programs and functional effects is provided.

INTRODUCTION

Unstable shoes are proposed to strengthen the lower limb muscles and enhance balance. Yet, recent studies report conflicting results in muscle activations during gait [1, 2] and postural balance tests after regular wear [3]. This may be due to adaptations learnt to reduce the initially increased movement variability to a similar level as a regular shoe [2]. Perhaps a more challenging, less predictable stimulus, such as an irregular surface (IS), would create the greater and continuous instability likely required to train the neuromuscular system. It was hypothesized ankle strength and balance would improve in a training group after 6-weeks of repeatedly walking on an IS compared to a control group.

METHODS

Fifteen, healthy participants were randomly assigned to a training (n = 8) and a control group (n = 7) which completed pre and post-training test sessions. After the pre-tests, the training group completed a 6-week training program consisting of 3, 1-hour sessions per week walking on an IS treadmill at their preferred speed (Mean (SD): 3.8 (0.5) km/hour). To create the IS, loop Velcro was attached to the belt of a regular treadmill (LOKO S55, Woodway GmbH, Germany) and 4 types of EVA dome shaped inserts (Ø: 140mm) of different height (10 and 15 mm) and hardness (40 and 70 Asker C) were attached by hook Velcro [4].

Concentric ankle muscle strength of the right leg was determined from an isokinetic dynamometer (System 3, Biodex Medical Systems, Inc., NY, USA) at 100 Hz. After a 3 repetition warm-up, 5 maximal repetitions for plantarflexion, dorsiflexion, eversion and inversion were performed at 60deg/sec. The highest 3 peak torques were averaged from each test. Postural balance was assessed using a standard, static 1-legged barefoot stance test on the right leg [5]. Ground reaction forces were recorded by a force plate (Kistler 9281B, Amherst, NY, US) for two trials of 30 seconds. Sway area, centre of pressure range and standard deviation of the velocity in the antero-posterior (AP) and medio-lateral (ML) directions were calculated. Results were compared statistically by a two-way mixed ANOVA ($p<.05$).

RESULTS AND DISCUSSION

Results showed no significant interactions or differences between the training and control group. Both groups showed significantly increased dorsiflexion ($p= .017$) and eversion ($p = .005$) peak torques, and reduced postural sway area ($p = .010$), ML centre of pressure range ($p = .011$) and velocity variability ($p = .046$) in the post-test (Table 1). The training group displayed greater post-test strength increases and postural sway decreases than the control group, although not significantly for: dorsiflexion peak torque (training group: +42%, control: +8%), eversion peak torque (+24%, +13%), sway area (-36%, -27%) medio-lateral range (-19%, -12%) and variability of velocity (-19%, -14%).

The control group post-test improvements suggest a learning effect occurred. A thorough familiarization session to the testing procedures or a midway test would help distinguish if ankle strength or balance improved as a result of the IS training alone. The lack of significant group differences could also be due to a limit on the amount of postural balance improvement in young, healthy adults [6]. Moreover, participants with reduced ankle strength and greater postural sway at pre-test, made larger post-test improvement. Alternatively, a more de-stabilising IS may be required to train the neuromuscular system.

Table 1: Mean (SD) joint torques and centre of pressure results across groups and test session. All results were significant between pre and post-tests ($p<.05$).

	Training group		Control group	
	pre	post	pre	post
Dorsiflexion [Nm/Kg]	.28 (.07)	.40 (.12)	.38 (.12)	.41 (.11)
Eversion [Nm/Kg]	.27 (.06)	.34 (.07)	.32 (.13)	.36 (.13)
Sway area [mm^2]	97.7 (45.0)	62.2 (12.8)	107.0 (41.0)	78.2 (26.1)
ML range [mm]	23.8 (4.5)	19.3 (3.5)	24.4 (4.3)	21.4 (3.8)
ML Velocity SD [mm/s]	26.0 (6.0)	21.1 (4.5)	30.2 (10.0)	26.0 (3.2)

CONCLUSIONS

Findings indicate regular IS walking may improve aspects of ankle strength and balance. Further research should include a larger sample size and familiarisation session. Testing participants with reduced preconditioned ankles, such as those in rehab, or developing a more demanding IS is recommended.

EFFECTS OF TRICEPS SURAE FATIGUE ON PELVIS TO HEAD ACCELERATION ATTENUATION IN YOUNG WOMEN AS PRACTITIONERS AND NON-PRACTITIONERS OF STRENGTH TRAINING

[1]**Georgia Cristina Lehnen**, [1]Gustavo Souto de Sá e Souza, [1]Rina Márcia Magnani, [1]Fábio Barbosa Rodrigues, [1]Marcus Fraga Vieira

INTRODUCTION

The measurement of body accelerations is a useful technique to assess walking patterns [1]. Accelerometry has been used to evaluate gait spatiotemporal parameters on different walking surfaces, and effects of ageing [2,3]. Localized muscle fatigue may alter conscious joint awareness. Then, the proprioception can be altered during walking due to triceps surae fatigue, which is important for posture and gait [4]. Strength training can improve muscle condition [5], and may result in changes in movement.

The aim of this study was to assess the effects of triceps surae fatigue on pelvis to head acceleration attenuation in young women as practitioners and non-practitioners of strength training.

METHODS

Tri-axial accelerometers (sampled at 1000 Hz) were used at the head and pelvis in 19 young women who were strength-training practitioners (Practitioners Group - 22.00 ± 3.27 y.o.) and 21 who were not practitioners (Non-practitioners Group - 21.76 ± 3.01 y.o.). They did not have any functional impairments or pain within the past six months. The local ethical committee approved the study.

They walked for 4 min at preferred walking speed pre-fatigue (PreF), performed the fatigue protocol and walked 4 min (0-PostF), rested 2 min, walked 4 min (6-PostF), rested 2 min and a third 4 min (12-PostF). Muscle fatigue was induced with a unilateral functional protocol (without weights) in triceps surae of dominant leg. In a standing position, the participants were instructed performed as many repetitions as she could and rested for 30 sec. This process was repeated until the number of repetitions amounted to only half of the number achieved in the first series.

Attenuation was calculated as ATT (%) = $((1 - RMS_{Head}/RMS_{Pelvis})*100)$ to study the ability to dissipate accelerations from pelvis to head. Data was processed with a custom-written code (Matlab, Mathworks Inc.). For statistical analysis was used Shapiro-Wilk test, repeated measures ANOVA with one factor - Bonferroni correction, and t-test for independent groups ($p<0.05$).

RESULTS AND DISCUSSION

It was observed a decrease of the attenuation in the ML direction for both groups in relation to the PreF, but only the PG presented a recovery trend. In the AP direction, only the PG presented significant differences, with a recovery trend. There were no differences between groups (Table 1).

After the triceps sural fatigue (mainly in the 0-PosF), the gait became more challenging in terms on pelvis to head acceleration attenuation, however the PG presented a possible greater coordination or ability to attenuate the accelerations (mainly in ML direction), bringing greater safety to the walk.

Table 1. Attenuation (ATT, %) in each direction.

Direction	ATT	Practitioners	Non-practitioners
ML	PreF	61.16 (16.40)[a]	55.57 (20.11)[a]
	0-PostF	58.78 (16.35)	51.93 (17.08)
	6-PostF	56.93 (18.73)[a]	49.56 (20.32)[a]
	12-PostF	57.29 (18.73)	49.82 (19.32)[a]
AP	PreF	0.95 (1.09)[b]	1.25 (1.88)
	0-PostF	0.68 (1.27)	1.36 (2.11)
	6-PostF	0.57 (1.24)[b]	1.32 (1.95)
	12-PostF	0.64 (1.22)	1.11 (1.97)
V	PreF	70.30 (7.86)	63.07 (20.99)
	0-PostF	65.92 (10.94)	54.37 (23.74)
	6-PostF	68.41 (10.44)	55.81 (24.00)
	12-PostF	67.57 (13.96)	59.80 (18.63)

[a, b] Significant differences between instants (pairwise comparison $p<0.05$). Medial-lateral (ML), anterior-posterior (AP) and V (vertical).

The trunk has a role in attenuating accelerations at the head, providing a stabilization necessary to optimize conditions for the visual apparatus and for the vestibular systems. This may be one of the most fundamental tasks of the body's postural control system when walking [1,3]. Maintaining stability when walking primarily requires controlling the motion of the center of mass. During walking stabilizing the head is also likely to be important. Thus, assessing accelerations of the pelvis and the head simultaneously may allow a more elaborate study of walking stability and pattern [1].

CONCLUSIONS

Fatigue of triceps sural provided a challenging task in terms of pelvis to head attenuation, regardless of the training condition, but, overall, with recovery after 12 minutes.

POSTURAL CONTROL STRATEGIES DURING DIFFERENT BALANCE TASKS

Glen M Blenkinsop, Michael J Hiley, and Matthew TG Pain
Loughborough University, UK
Corresponding author email: G.Blenkinsop@lboro.ac.uk

INTRODUCTION

Insights into sensorimotor control of balance can be achieved by studying how subjects respond to controlled disturbances; however, this may not be representative of balance during unperturbed conditions. Examining various postures during multiple tasks and discovering invariant traits in the way control strategies are implemented can aid understanding of how the CNS attempts to control balance.

The aim of this study was to determine the percentage of time spent in different control strategies during perturbed and unperturbed balance in standing and handstand postures.

METHODS

Twelve injury free national level gymnasts experienced at balancing in handstand gave written informed consent as approved by the University Ethical Advisory Committee.

Perturbed and unperturbed balance was assessed in two separate sessions one week apart. The four unperturbed conditions were handstand and standing postures with eyes open and eyes closed. The eight perturbed conditions were standing and handstand postures each with small (5 cm at ±10 cm s^{-1}) and large (10 cm at ±20 cm s^{-1}) perturbations in the forwards and backwards directions.

Trials were completed on a CAREN system (Motek Medical). Kinetic data were collected with two 0.4 m by 0.6 m force plates (Bertec FP4060-07) and kinematic data were collected with nine T20 Vicon cameras (Vicon, Oxford Metrics Group) operating at 200 Hz. Joint torques were obtained using inverse dynamics calculated from quaternions and wrenches [1] and using the inertia model of Yeadon [2].

Ankle strategies in standing, and wrist strategies in handstand, were identified by positive correlations between all adjacent joint torques (Figure 1). Other control strategies in standing were identified by a negative correlation between: ankle and knee (knee strategy), or knee and hip (hip strategy), and in handstand between: wrist and elbow (elbow strategy), elbow and shoulder (shoulder strategy), and shoulder and hip (hip strategy). The amount of time spent using each control strategies was determined by performing multiple correlations with a moving one second window.

RESULTS AND DISCUSSION

During unperturbed standing the percentage of time spent in each control strategy was: 95.2% ankle, 0.4% knee, 1.4% hip, 0% mixed, and 3.0% non-significant. During unperturbed handstand the percentage of time spent in each control strategy was: 88.3% wrist, 4.2% elbow, 0.6% shoulder, 0.2% hip, 2.0% mixed, and 4.8% non-significant. Findings are similar to previous research which showed wrist joint torque is used to control COM displacement and velocity together with synergistic torques at the shoulder and hip during handstand balance [3].

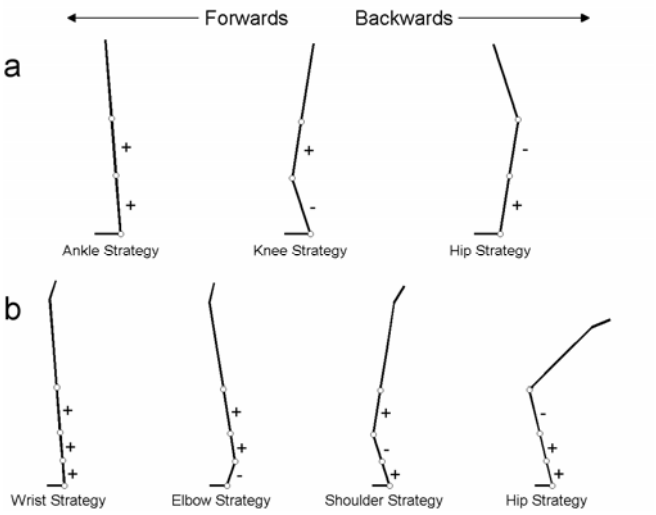

Figure 1: Examples of control strategies in a) standing and b) handstand, identified by positive and negative correlations of adjacent joint torques.

During perturbed standing the percentage of time spent in each control strategy was: 90.6% ankle, 0.9% knee, 2.2% hip, 0.2% mixed, and 6.0% non-significant. During perturbed handstand the percentage of time spent in each control strategy was: 75.8% wrist, 10.8% elbow, 1.0% shoulder, 0.9% hip, 1.5% mixed, and 10.1% non-significant. Statistical analysis revealed there were no significant differences between perturbation directions or magnitudes for the percentage of time spent in any control strategy in standing. However, in handstand significant differences can be attributed to the direction rather than the magnitude of the perturbation. Findings suggest that the conditions imposed by the direction of the perturbation interact with the biomechanical constraints of balancing in the handstand, but not standing posture. One example would be the position of the wrist joint at the end of the hand, allowing torque in only one direction, whereas the ankle is positioned several centimeters in from the heel allowing some torque in both directions.

CONCLUSIONS

The primary control strategy for both perturbed and unperturbed conditions was an ankle strategy during stance and a wrist strategy during handstand. Findings reveal that the CNS maintains balance during a variety of tasks and postures by employing a single control strategy. The multi-segment system is controlled by torque about the most inferior joint with compensatory torques about all superior joints acting in the same direction to maintain a fixed orientation between segments.

ACTION DIRECTION OF MUSCLE SYNERGY IN MULTI-DIRECTIONAL POSTURAL CONTROL

INTRODUCTION

Humans maintain bipedal standing by controlling center of foot pressure (COP) to keep the center of gravity within the base of support. In order to accomplish multi-directional shift of COP, humans co-activate several muscles that have different but limited action directions (AD), which is the endpoint force vector of each muscles [1]. Such a postural task, however, is so redundant in musculoskeletal control that previous study has been proposed the necessity of modular organization, i.e., muscle synergies, simplifying the redundancy [2]. Therefore, it is important to quantify the mechanical contribution of muscle synergies to postural control. In this study, we investigated the AD of muscle synergies using the EMG-weighted averaging (EWA) method [3] based on a cross-correlation between the fluctuations in activation coefficients of muscle synergies and COP. This means that EWA method clarifies the AD of each muscle synergy during multi-directional control of COP. Our goal was to show coordinative structure of muscles which contribute to postural control.

METHODS

Six healthy males participated in this study. During multi-directional postural control, each subject was instructed to shift his COP from the original position to the target point by leaning his body around the ankle joint and then to hold the target COP position as precisely as possible for 10 s. The target directions include 12 different directions distributed equally over the horizontal plane at 30° increments. For each trial, they viewed the desired COP position as a target on a visual display in front of them. Surface EMGs were recorded from 18 muscles spanning ankle, knee and hip joints and trunk in the right side. We extracted muscle synergies from the data matrix of the EMGs using non-negative matrix factorization (NMF) [4]. We measured the similarity of muscle synergies among subjects by calculating their scalar product [5]. In each trial, EWA was quantified using cross-correlation between the fluctuations in activation coefficients of muscle synergies and COP based on a time lag from 50 to 150 ms, during which the EWA trajectory reached its first peak magnitude. We determined the time lag and corresponding spatial direction as EWA direction which shows EWA peak. We then estimated the AD of each muscle synergy by averaging EWA directions across all subjects and all trials.

RESULTS AND DISCUSSION

The result of ADs given by EWA analysis showed that ADs of lower thigh muscles were distributed between 60° and 120° except tibialis anterior (274.9°), while those of muscles in thigh and trunk were relatively dispersed. In this study, entire muscle activities were accounted for by 5.5 ± 1.52 global synergies, which were extracted from the entire data set across each subject. The muscle synergies across each subjects were grouped into 8 clusters (S1~S8). S1, S2 and S7 were mainly constructed by lower thigh muscle and contributed to forward movement of COP. These synergies were consistent with ankle strategy. On the other hand, S3, S5, S6 and S8 tended to have more dispersed ADs and were comprised both lower thigh muscles and muscles of the thigh or trunk. These synergies were considered to be mixture of ankle and hip strategy. S4 was composed of vastus lateralis and gluteus medius, which generate torque at knee and hip joint, respectively. As a result, we extracted muscle synergies comprised muscles which contribute to different strategies and have various ADs. Previous study [2] has disclosed that we use ankle, hip, and even knee strategy as distinct muscle synergies to deal with multi-directional perturbation. Our results imply that the synergy corresponding to mixture of several strategies aided to keep COP precisely around the target by generating force which flexibly match the desired direction and magnitude.

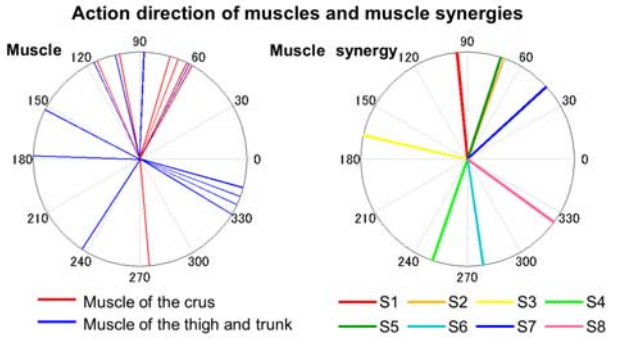

Figure: Action directions (ADs) calculated by EWA direction across all subjects and all trials.

CONCLUSIONS

In multi-directional postural control, some of the muscle synergies included muscles which contribute to different strategy and have various ADs, which considered to bear flexible force to keep COP precisely around the target.

A NOVEL FOUR-AXIS PARSING OF SHOULDER NET JOINT MOMENT IN MANUAL WHEELCHAIR PROPULSION

[1] **Ian M Russell**, [1]EV Wagner, [2]PS Requejo, [2]S Mulroy, [3]C Muller-Karger, [4]MM Rodgers, [1]JL McNitt-Gray

INTRODUCTION

Clinicians and researchers have suggested the repetitive mechanical loading of the shoulder during manual wheelchair (WC) propulsion may be a factor contributing to the high prevalence of shoulder pain among the spinal cord injury population. A detailed understanding of the upper extremity demand during propulsion is necessary for describing an individual's interaction with their WC and identifying how to maintain shoulder health [1]. The Net Joint Moment (NJM) represented as a vector can be used to describe mechanical demand on the shoulder. By parsing the vector into four axes, we can decouple the mechanical demand imposed on the shoulder more accurately using an anatomically relevant reference system [2]. The aim of this study was to use this novel method of parsing the shoulder NJM into four axes to better understand the mechanical demand imposed on the shoulder during manual WC propulsion.

METHODS

One hundred ninety six experienced manual WC users with paraplegia (9 ± 6 yrs post SCI) from the Rancho Los Amigos National Rehabilitation Center outpatient clinics volunteered to participate in accordance with the local Institutional Review Board. Individuals were excluded from participation if they reported a history of shoulder pain that altered performance of daily activities. Upper extremity kinematics (VICON, 50Hz) and pushrim reaction forces (SmartWheel, 200Hz) were collected during manual WC propulsion on a stationary ergometer at self-selected fast condition. Upper extremity joint kinetics were calculated using custom MATLAB code.

The NJM vector ($\vec{\tau}$) was calculated and projected into the longitudinal axis of the upper arm ($\vec{x}_{UA}$) to find the degree of internal/external (IE) moment about the upper arm. ($\vec{\tau}$) and ($\vec{x}_{UA}$) are expressed in the torso reference frame:

$$\vec{\tau}_{IE} = \vec{x}_{UA}(\vec{x}_{UA} \cdot \vec{\tau})$$

Next the $\vec{\tau}_{IE}$ component is subtracted from $\vec{\tau}$. The remaining torque describes the NJM vector perpendicular to the upper arm's longitudinal axis.

$$\vec{\tau}_{XYZ} = \vec{\tau} - \vec{\tau}_{IE}$$

By expressing $\vec{\tau}_{XYZ}$ in the torso reference frame, the components in the $\hat{\imath}$, $\hat{\jmath}$, and $\hat{k}$ directions correspond to the moments about abduction/adduction (AbAd), horizontal abduction/adduction (HAbAd), and flexion/extension (FE) axes respectively:

$$\vec{\tau}_{XYZ} = (\tau_X)\hat{\imath} + (\tau_Y)\hat{\jmath} + (\tau_Z)\hat{k}$$

We now have the components of the shoulder NJM in four independent axes ($\vec{\tau}_{IE}, \vec{\tau}_{AbAd}, \vec{\tau}_{HAbHAd}, \vec{\tau}_{FE}$).

RESULTS AND DISCUSSION

Parsed shoulder NJM profiles for multiple push cycles during the fast propulsion condition show a variety of control strategies. Resulting profile plots show a mixture of single axis dominant techniques (Fig.1 top row), with NJM about the FE axis being the most common. Other subjects employ an even split between two or three axes (Fig.1 bottom row), where the NJM vector aligns equally between anatomical axes, as opposed to aligning along one of the anatomical axes as seen in the single axis dominant profiles.

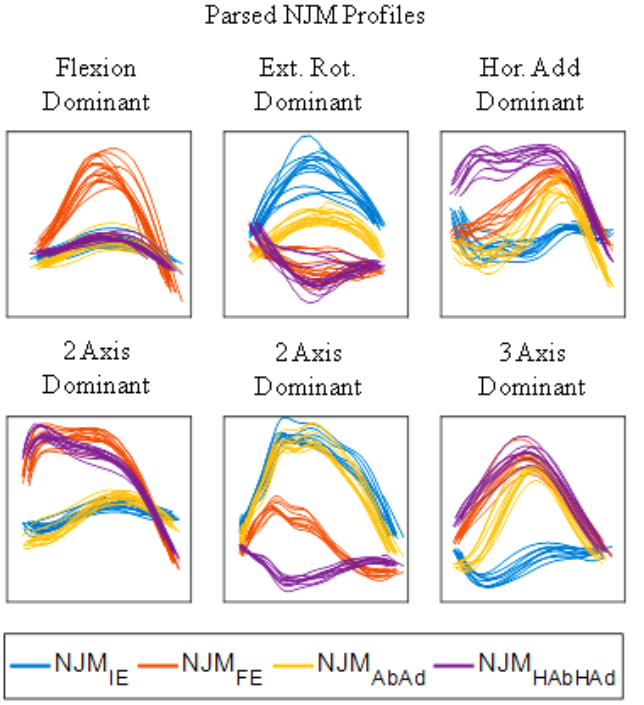

Figure 1: Shoulder NJM vector of multiple fast push cycles parsed into 4 axes components for six example subjects. Moment magnitude about each anatomical axis IE(blue), FE(red), AbAd(yellow), and HAbAd(purple). Independent axis is the hand position on the pushrim.

CONCLUSIONS

This novel method of NJM parsing provides an effective means to characterize the mechanical demand imposed on the shoulder during physical demanding activities. Future work will look into how these NJM profiles change within and across subjects under varying conditions as well as its potential relationship to shoulder pain.

PROACTIVE BALANCE STRATEGIES DURING NORMAL WALKING AMONG INDIVIDUALS WITH INCOMPLETE SPINAL CORD INJURY

[1] **Tarun Arora**, [1,2] Kristin E Musselman, [1]Joel L Lanovaz and [1]Alison R Oates
[1]University of Saskatchewan
[2] Toronto Rehabilitation Institute, University of Toronto

INTRODUCTION

Balance impairments are common among individuals with incomplete spinal cord injuries (iSCI), causing at least one fall in 75% of this population [1]. Falls can lead to injuries, lower balance confidence, and subsequently restrict activities and community participation [2].

Proactive balance strategies have been shown to prevent the occurrence of hazardous slips (defined below) [3] among able bodied (AB) individuals. Unexpected slip perturbations in high functioning individuals with iSCI elicit reactive responses similar to that in AB individuals as measured by electromyography (EMG) [4]. One explanation could be that greater proactive strategies are present among individuals with iSCI, which leads to lower slip intensity. This study: (1) compared proactive balance strategies between individuals with iSCI and AB individuals, and (2) compared proactive balance strategies between individuals who have hazardous (HZ) and non-hazardous (NHZ) slips. We hypothesized that (1) individuals with iSCI will show greater proactive strategies during normal walking than AB, and (2) when exposed to an unexpected perturbation, individuals with iSCI with more effective proactive strategies will have a less HZ slip.

METHODS

Fourteen individuals with iSCI, and 11 age- and sex-matched AB individuals were tested. Participants walked along a 10m walkway at a self-selected speed for at least three normal walk (NW) trials followed by an unexpected slip trial induced using low friction steel rollers (coefficient of friction~0.09). Peak slip velocity (PSV) of the the slipping heel within 50 ms of the heel strike was calculated. Slips were categorized as HZ (PSV ≥ 1m/s) or NHZ (PSV < 1m/s) [3].

Ground reaction forces (GRF) (fs = 2000 Hz) were obtained using two force plates (OR6-7, Advanced Mechanical Technology, Inc., Watertown, MA) embedded in the walkway – one under the slip device. Kinematics (fs = 100Hz) were obtained using a motion capture system (Nexus, Vicon, Centennial, CO). Surface EMG (fs = 2000 Hz) were collected bilaterally from the tibialis anterior (TA), soleus (SOL), and gluteus medius (GM) muscles (2400GT2, Noraxon Inc, Scottsdale, AZ).

An integrated co-contraction index (CCI) was calculated at the ankle joint using normalized EMG activity in the slip leg TA and SOL muscles [3]. CCI values were integrated from -20% to +20% of the stance duration with 0% being heel contact [3]. The required coefficient of friction (RCOF) was calculated as the ratio of the maximum antero-posterior GRF and the corresponding vertical GRF from a NW trial [5].

Antero-posterior margin of stability (MOS_{AP}) was determined for the slip trial at the time of slip heel contact. MOS_{AP} was calculated as the distance of the extrapolated centre of mass (XCOM) from the heel of the slip foot in the anterior direction such that a positive value would place the XCOM in front of the lead heel [6].

Mixed ANOVA's were used for statistical analysis (SPSS v.24) with each variable used as the dependent variable and iSCI/AB groups and NHZ/HZ groups as fixed factors. Significance was set at $\alpha = 0.05$.

RESULTS AND DISCUSSION

Ankle CCI main effects and interactions were not significant ($p > 0.05$) indicating TA and SOL muscle co-contraction was not different between iSCI/AB groups and it did not affect the occurrence of HZ slips in either of the groups.

For RCOF, the interaction between iSCI/AB group and NHZ/HZ group was found to be significant (F (1,20) = 7.15, p = 0.015). Individuals with iSCI who had a HZ slip were found to have higher RCOF values during NW (0.140 +/- 0.008) as compared to those individuals with iSCI who had NHZ slip (0.100 +/- 0.008). AB individuals who had HZ and NHZ slips had similar RCOF values (0.141 +/- 0.008 vs 0.150 +/- 0.013, respectively). This indicates reducing the RCOF is a proactive measure used by individuals with iSCI to potentially reduce the occurrence of a HZ slip.

A significant interaction between iSCI/AB groups and NHZ/HZ groups was found for MOS_{AP} (F (1,20) =4.71, p =0.04). The iSCI group had their XCOM 96.09% farther in front of the slipping heel at the heel strike during HZ slip than NHZ slip, whereas AB group had their XCOM 32.23% farther in front of the slipping heel during NHZ slip as compared to HZ slip.

CONCLUSIONS

Individuals with iSCI show a greater proactive responses during NW, which appear to be effective in reducing the occurrence of HZ slips.

INTRODUCTION

Hereditary Spastic Paraplegia (HSP) is generally characterised by progressive spasticity and weakness of the lower limbs[1]. Patients with HSP have several common spatio-temporal[2] and kinematic[3] deviations in their gait.

Currently, spasticity management options for these deviations are limited. A clearer understanding of gait disturbances and their contributing factors will assist in determining appropriate management and treatment options in patients with HSP. The ability to classify common and prevalent gait deviations in HSP patients may assist in developing more appropriate interventions and improve monitoring of disease progression. Therefore, the aim of this study was to use a classification system[4] to classify HSP gait based on graphical data, and determine if a difference exists in kinematic data variables. research[4] it was hypothesised that sagittal plane kinematics could successfully be used to classify gait.

METHODS

This study was a retrospective observational audit and was approved by the relevant Human Research Ethics Committee. Eighteen retroreflective markers were placed based on the VICON Plug-in-Gait model (VICON, Oxford, UK). Participants were instructed to walk along a 10m walkway barefoot at their preferred walking speed. Kinematic data were normalised to 100%. Sagittal plane kinematic data were extracted. Two physiotherapists experienced in CGA independently reviewed the sagittal plane gait kinematics of each patient and categorised each limb as: crouch, recurvatum, stiff-knee, and jump-knee[4]. Differences were reviewed and an agreement reached. A one-way between-groups MANOVA was performed to investigate differences in sagittal plane hip, knee and ankle kinematics across each gait classification. A Bonferroni correction was performed and alpha level was set at 0.005.

RESULTS AND DISCUSSION

Fifty participants with HSP were recruited (age=49±13.88years; height=1.70±1.05m; weight=75± 19.38kg). 24% had a different classification between limbs. 20% (n=208) of data were identified with an extreme outlier in one or more variables and therefore removed prior to the final analysis. The results were consistent with previous research[4,5] (Table 1). Crouch gait supported the classification showing increased hip flexion at initial contact against recurvatum and stiff groups. Recurvatum gait was classified as having increased knee extension and reduced ankle dorsiflexion during stance, and this was supported by the data across all groups. Stiff knee gait supported the classification by showing reduced hip and knee ROM in stance, and reduced knee flexion during swing. Jump gait classification was verified by increased ankle ROM compared to the crouch, recurvatum and stiff groups, increased knee flexion in early stance between the recurvatum group, and increased hip ROM between crouch and stiff groups.

Table 1. Sagittal plan kinematic summary

Mean kinematic angles (degrees)	Crouch (n=8)	Recurvatum (n=40)	Stiff (n=28)	Jump (n=18)	Normal-like (n=6)
Hip flexion at initial contact	37.56b,c,e	34.45a,c,d	32.70a,b,d	36.26b,c	34.41
Peak hip flexion	40.11b,c,e	37.30a,b	35.74a,b,d	38.04c,e	35.43
Hip flexion/extension ROM	43.22b,c,d	47.61a,c,e	39.79a,b,d,e	47.53a,c,e	43.51
Peak knee flexion at early-stance	23.19	19.32	24.57	26.65b,e	19.39
Peak knee extension at mid-stance	2.36b,e	-2.81a,c,d,e	4.75a,b,d,e	-0.14	-2.10
Peak knee flexion in swing	47.82	48.63	41.68a,b,d,e	51.35	39.03
Knee flexion/extension ROM	50.50	49.03c	36.26a,b,d,e,	49.81c	53.48
Peak ankle dorsiflexion in stance	15.86b	8.94a,c,d,e	14.79b	13.97b	15.34
Ankle dorsi/plantarflexion ROM	21.90d	22.16d,e	21.14d,e	24.86a,b,c	24.95

[a] = different compared to crouch, [b] = different compared to recurvatum, [c] = different compared to stiff, [d] = different compared to jump, [e] = different compared to normal-like; ROM = range of motion.

CONCLUSIONS

Subjective categorisation of HSP gait based on kinematic graphs can be done successfully. Objectively examining treatment options within each gait classification may ultimately assist clinicians in rapidly identifying the most pertinent treatment option in this group of patients.

DOES MUSCLE COACTIVACTION INCREASE WITH SPEED IN PATIENTS WITH MULTIPLE SCLEROSIS?

INTRODUCTION

Recent studies have shown that patients with multiple sclerosis (PwMS) exhibit increased coactivation of agonist/antagonist lower limb musculature when walking overground and on a treadmill[1]. This gait deterioration is not observable with current clinical tools such as the expanded disability status scale (EDSS) especially in PwMS with low scores (≤3.0: no evident gait deterioration) [2]. Increased coactivation is thought to be associated with slower walking speed, the most common sign of gait impairment [3]. Although coactivation has been shown to increase with speed [4], it is not known whether this pattern is also present in PwMS. Coactivation speed-dependency is relevant when studying sub-clinical gait deterioration in PwMS since it may be a confounder when comparing patients with controls. Therefore, the aim of this study was to determine the effect of speed on ankle muscle coactivation in PwMS when walking at different controlled speeds on a treadmill.

METHODS

Ten PwMS with EDSS≤3.0 (42±8 yrs) participated in this study. Each participant walked on a BIODEX-RTM600 treadmill (Shirley, NY, USA) at 3 different speeds (1.0 m/s, 1.2m/s and 1.4m/s) for 20 seconds. An 8–camera VICON system (Oxford, UK) was used to determine heel contact and toe-off from foot marker positions (200Hz). A wireless 6-channel Cometa system (Milano, Italy) was used to record electromyographic (EMG) signals (1000Hz) from bilateral leg musculature: tibialis anterior (TA), lateral gastrocnemius (LG) and soleus (SO). Muscle coactivation was measured using the coactivation index (COI) for the LG/TA and SO/TA muscles pairs using the method described by Chow et al [5]. COIs were calculated for the stance (ST) and swing (SW) phases of the gait cycle (GC) separately. The mean COIs for 10 left and 10 right GCs was used for statistical analysis. Multivariate ANOVA was performed for each muscle pair to determine group differences in each GC phase (p<.05).

RESULTS AND DISCUSSION

Descriptive statistics are shown in Figure 1. Overall, no significant effects of speed were found for any of the agonist/antagonist muscle pairs analyzed during ST nor during SW phases (p>.05). However, small increases in COI during ST but not during SW phases were observed as speed increases. These results differ from those of previous studies in older adults and young populations in whom speed significantly increased coactivation of lower limb musculature during walking [4]. It is noteworthy, nonetheless, that the relatively constant levels of coactivation observed in our sample of PwMS may be a reflection of motor adaption elicited by the underlying neurodegeneration caused by the disease that affects, amongst other signs and symptoms, the sensorimotor system [2]. Therefore, it is most likely that the effects of the disease per se are more relevant than those elicited by changes in gait speed. Furthermore, the mean COI found in the present study are greater than those exhibited by healthy controls walking at 1.2m/s [6]. Taken together, differences in COIs found in previous studies and no speed effect on COIs found in the current investigation, indicate that further studies exploring the effect of disease progression or interventions in PwMS may not need to utilize different speed conditions when using treadmill walking. However, research involving between group comparisons should still use matched speeds due to the known effect of speed on most gait biomechanical measures [3].

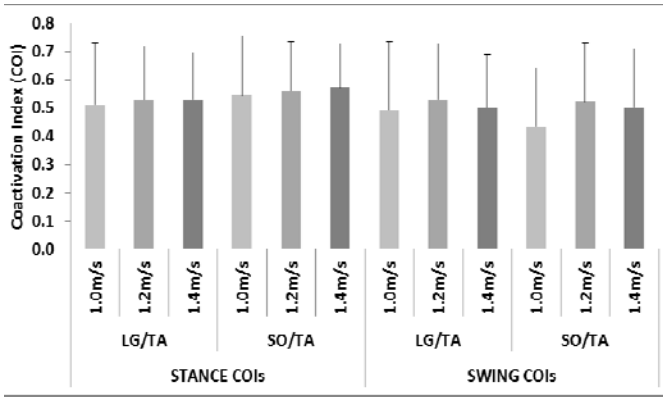

Figure 1: Mean coactivation indices (COI) for each muscle pairs at each speed and for both stance and swing gait cycle phases

CONCLUSIONS

Coactivation of ankle plantar/dorsi flexors muscles in patients with multiple sclerosis at early stages of the disease is not significantly affected by speed when walking on a treadmill.

WALKING SPEED INFLUENCES ON GAIT CHARACTERISTICS IN ADULTS WITH AUTISM SPECTRUM DISORDER

[1] **Hiroshi Kurumadani**, [2] Mieko Shinomiya, [2] Natsumi Kobayashi, [1] Toru Sunagawa, and [2] Reiko Fukatsu

INTRODUCTION

Children and adults with autism spectrum disorders (ASD) often develop motor dysfunctions: impairments in motor coordination and gait [1]. In the studies of children with ASD, many studies have indicated that the gait characteristics; stride interval, ankle joint angle, and upper body acceleration; differ between ASD children and typical developmental children [2,3]. However, fewer reports have shown whether the gait characteristics of adults with ASD differed from those of healthy adults.

In most studies of the gait of individuals with ASD, subjects walked at a self-selected or comfortable speed. As a walking speed affects the gait cycle and characteristic, we have to compare the gait data at the various walking speed. However, it is still unclear whether the gait characteristics at different walking speeds differ between ASD adults and healthy adults. The purpose of this study was to evaluate the gait characteristics of adults with ASD at different walking speeds during treadmill walking.

METHODS

Eight male adults with ASD and twelve healthy male adults participated in our study. Four of these ASD participants were classified as Asperger syndrome subjects and the remaining four, Pervasive Developmental Disorder Not Otherwise Specified subjects according to DSM-IV-TR criteria. The score of Autism-Spectrum Quotient in ASD was significantly higher than that in healthy adults.

All participants performed treadmill walking, and its speed was increased 0.25m/s every minute from 0.5m/s to 1.5m/s: 0.5m/s, 0.75m/s, 1.0m/s, 1.25m/s, and 1.5m/s. They walked on a treadmill for one minute per each walking velocity.

We measured the gait characteristics using three wearable inertial sensors (LP-WS0904, LOGICAL PROSUCT Inc.), which contain a triaxial accelerometer and gyro sensor. Two sensors were attached to the right shin and foot using double-sided tapes and elastic bandages, and one sensor was fixed at lower back at the area of the third lumbar spinous process using an elastic belt. We obtained five gait characteristics: the stride interval, stride count, trunk acceleration [3], and ankle angular change.

We compared the gait characteristics using two-way ANOVA with the factor groups (ASD and healthy adults) and walking speeds (0.5m/s, 0.75m/s, 1.0m/s, 1.25m/s, and 1.5m/s) with the significant level of 5%.

RESULTS AND DISCUSSION

There were significant differences between the groups (ASD and healthy adult) in the stride interval, stride count, trunk acceleration, and ankle angular change.

There were also significant differences among walking speeds in the stride interval, stride count, trunk acceleration, and ankle angular change. With the increase in the walking speed, the stride count, trunk acceleration, and ankle angular change of both ASD and healthy adults significantly increased, and the stride interval of them significantly decreased (Figure 1).

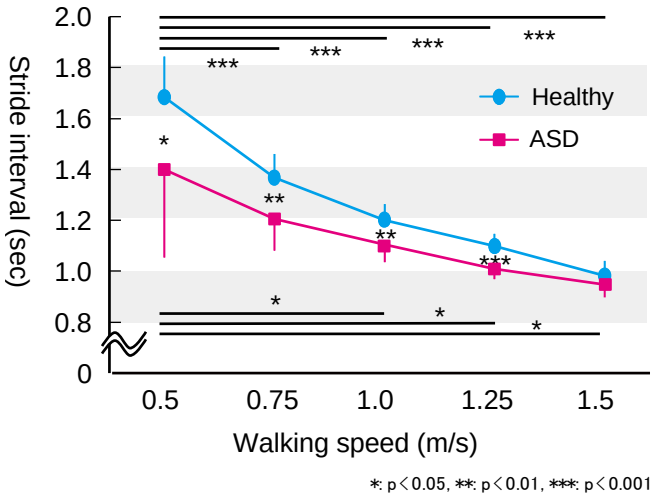

Figure 1: Stride interval for ASD and healthy participants at different walking speeds.

The gait characteristic of adults with ASD differed from that of healthy subjects [4]. Our finding shows that the gait characteristic of the adult with ASD significantly differs from that of the healthy adult at the most walking speeds. Regardless of walking speeds, persons with ASD have a different gait characteristic from healthy ones.

CONCLUSIONS

At the most walking speeds, the gait characteristics of ASD adults significantly differed from those of healthy adults. With increased walking speeds, the gait characteristics of ASD adults were similar with those of healthy adults.

THE ASSOCIATION BETWEEN ESTIMATED VERTEBRAL LOADING AND SPINAL CURVATURE USING SUBJECT-SPECIFIC MUSCULOSKELETAL MODELS OF THORACOLUMBAR SPINE

[1,2]**Hossein Mokhtarzadeh**, [1,3]Alexander G. Bruno, [1]Brett T. Allaire, [1]Kelsey R. Velie, [1]M. Clara De Paolis Kaluza, [1,2]Dennis E. Anderson and [1,2,3]Mary L. Bouxsein

INTRODUCTION

Musculoskeletal models of the thoracolumbar spine are emerging that can predict spinal loading across the whole thoracolumbar spine for a variety of activities [1]. We have recently shown that incorporating subject-specific variations in spine curvature and trunk muscle morphology into such models can affect estimated vertebral compressive and shear loads [1]. However, it is unclear to what extent these effects can be explained by overall anatomic measurements, such as lumbar lordosis (LL) and thoracic kyphosis (TK). Thus, we aim to evaluate predictors of differences in vertebral loading between the baseline model (only adjusted for height and weight, Ht/Wt) and subject-specific models using multiple regression analyses. We hypothesized that higher TK (more curvature compared to the baseline model) and lower LL (less curvature compared to the baseline model) will result in higher loads compared to the baseline Ht/Wt model.

METHODS

We selected 125 men (57.1 ± 11.8yrs, 175.7 ± 6.9cm, 89.7 ± 15.7kg) from the Framingham Heart Study (FHS) Multidetector CT Study, a community-based cohort study. We created three different thoracolumbar spine models by measuring spine curvature and trunk muscle morphology using spine CT scans for each person: 1) height and weight adjusted (Ht/Wt models, with TK = 42° and LL = 25°); 2) height, weight and spine curvature adjusted (+C models); and 3) height, weight, spine curvature, and muscle morphology adjusted (+CM models) [1,2]. Using OpenSim, we used static optimization to predict muscle forces and then intervertebral joint reaction forces at T8, T12, L3 in four different activities: 1) neutral standing, 2) standing with a 10 kg weight in each hand and elbows flexed 90°, 3) 40° trunk flexion while holding a 5 kg weight in each hand, and 4) 10° trunk lateral bending to the right while holding a 5 kg weight in the right hand. Multiple regression analyses were performed to find the relationship between spinal curvature (TK and LL) as independent variables and differences in intervertebral joint reaction forces from Ht/Wt model as dependent variables. Full model R^2 and regression coefficients i.e. β (95% CI) were calculated for TK and LL. Analyses were performed using Stata/IC version 14.2. The study was approved by the BIDMC Institutional Review Board.

RESULTS AND DISCUSSION

The mean (+SD) TK and LL in our sample were 33.6° ± 9.0° and 15.3° ± 8.0°, respectively. The results of multiple regression analyses relating differences in thoracic kyphosis and lumbar lordosis (+C models vs. Ht/Wt models and +C/M models vs. Ht/Wt models) to vertebral loading differences varied by activity and level. For instance, β-coefficients for thoracic kyphosis difference ranged from +5 to -5 N/deg; and β-coefficients for lumbar lordosis ranged from -2 to -15 N/deg), generally showing weak to moderate associations (Figure 1). The change in LL was more often a significant predictor of loading differences (23/24 β's) than the change in TK (11/24 β's). There was a general trend that lower LL (less curvature compared to the baseline model) resulted in higher loads compared to the baseline Ht/Wt model.

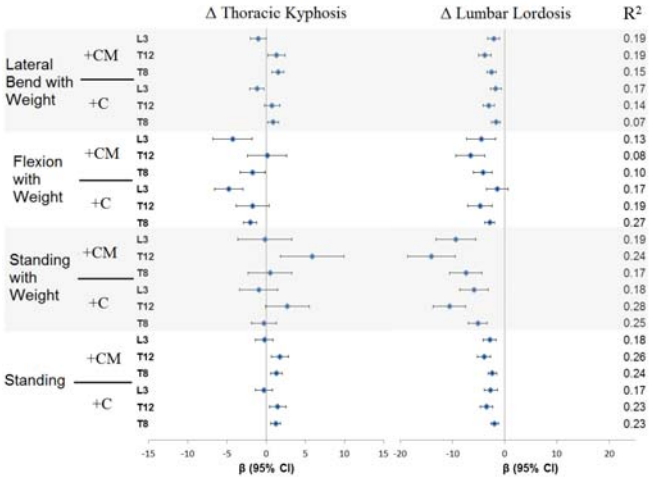

Figure 1: Multiple regression analysis was used to determine whether the subject-specific difference in TK and LL between the +C and +C/M models and the baseline Ht/Wt model is associated with the difference in vertebral loading estimated by the models.

CONCLUSIONS

These results indicate that the contribution of subject-specific spinal curvature measurements to differences in vertebral loading varies with activity and spinal level. Overall, measures of kyphosis and lordosis explained about 10–25% of the variance introduced by subject-specific modeling, and less lumbar lordosis is associated with greater compressive vertebral loading. These findings can provide insights into the role of subject-specific spinal curvature on predicting vertebral loading, which has implications for spine conditions such as back pain and vertebral fracture.

LUMBAR MUSCLE STRUCTURE PREDICTS OPERATIONAL POSTURES IN ACTIVE DUTY MARINES

[1]**David B Berry**, [1]Bahar Shahidi, [1]Ana E Rodriguez-Soto, [2]Karen R. Kelly, and [1]Samuel R Ward
[1]University of California, San Diego, [2]Naval Health Research Center
Corresponding author email: srward@ucsd.edu

INTRODUCTION

Upright MRI has been used to study the effect of load magnitude, distribution, and position on the lumbar spine in active duty Marines [1-3]. Advanced 3D MRI (supine) has been used to measure whole muscle volume, fat fraction, muscle microstructure, and T2 relaxation of the intervertebral disc (IVD) in the same cohort of Marines [4]. However, the relationship between lumbar spine posture and muscle structure is not well understood. Therefore, the purpose of this study was to investigate the predictive capacity of muscle structure on lumbar spine posture in active duty Marines.

METHODS

Under an IRB-approved protocol, Marines (n=31) were scanned using an upright 0.6T MRI scanner. T2-weighted images were collected in the following positions: standing without load (St.U.), standing with body armor (St.L.), sitting with body armor (Si.L.), and prone on elbows with body armor (P.L.). A load magnitude of 11.3 kg was chosen based on body armor mass, which is the minimum protective equipment Marines are required to wear during military operations/training. Sagittal Cobb angle, angle with respect to horizontal, and sacral angle were measured to assess lordosis, flexion/extension, and sacral tilt, respectively, using a previously validated algorithm [5]. Differences between St.U. and St.L. (Δload) and between Si.L. and P.L. (Δposition) were calculated to determine lumbar spine kinematics in response to load and position, respectively.

Additionally, Marines were scanned using a 3T supine MRI scanner. The imaging protocol consisted of: 1) standard anatomical, 2) fat-water separation, 3) diffusion tensor imaging (DTI), and 4) T2 mapping of each lumbar IVD. These images were used to estimate muscle volume, fat fraction, and restricted diffusion profiles in: multifidus, erector spinae (ES), psoas, and quadratus lumborum. IVD T2 values were used to quantify disc hydration.

Independent variables were grouped into 3 separate domains: muscle physiology (volume, fat fraction, fractional anisotropy (FA), mean diffusivity, λ_{1-3}); IVD health (T2 relaxation of each disc); and anthropometric measures (age, weight, height). Domain groupings were further verified with hierarchical cluster analysis. Dependent variables were global postural measurements for all positions, Δload, and Δposition. Principle component analysis was then used to sort like variables into weighted groups (eigenvectors). Within each eigenvector, Pearson's correlation was used to remove collinear variables ($r>0.8$, or variance inflation factor>10). For collinear variables, the one with the smallest eigenvector value was removed. Remaining variables were entered into a stepwise multiple linear regression model to identify physiologic measures predictive of lumbar spine posture. Statistical analyses were performed using SPSS statistical software.

RESULTS AND DISCUSSION

After initial grouping of independent variables, collinearity resulted in the removal of 7/25 independent variables from the model. The multiple regression model demonstrated that FA of the ES was a significant predictor of lumbar posture for 7/18 dependent variables measured and explained 20–35% of the variance in each model (Table 1). Additionally, weight was a significant predictor of lumbar lordosis when P.L. and hydration of the L4L5 IVD was a predictor of lumbar flexion when St.U.

Table 1: Stepwise multiple linear regression results.

Dependent variable	Position	Independent variable(s)	β	R^2	p
Cobb angle	St.L.	ES FA	.45	.21	.020
	P.L.	Weight	.47	.22	.016
Angle with respect to horizontal	St.U.	T2-L4L5	-.44	.19	.025
	St.L.	ES FA	.51	.26	.007
	P.L.	ES FA	-.48	.23	.013
	Δposition	ES FA	.46	.21	.020
Sacral angle	St.U.	ES FA	.44	.20	.024
	St.L.	ES FA	.59	.35	.002
	P.L.	ES FA	.56	.32	.003

CONCLUSIONS

In this study, we combined *in vivo*, functional imaging of active duty Marines with high resolution imaging of the paraspinal muscles to investigate the relationship between lumbar posture and muscle physiology. FA, a key measurement of DTI, was shown to predict posture in several different loading conditions and positions. FA is thought to be inversely related to muscle fiber size, which is directly related to force generating capacity [6]. Therefore, this model suggests that muscle structural features (e.g., estimates of fiber size) in the ES have 20–35% predictive capacity for a more straight, upright lumbar posture in Marines.

INTRODUCTION

Low back pain (LBP) is a complex condition that affects 65-85% of the general population during their lifetime (1). Recent evidence suggests that a high proportion of individuals go on to develop recurrent symptoms leading to functional disability over time. Muscle tissue has been shown to be relatively unresponsive to traditional rehabilitative efforts in individuals with recurring symptoms, suggesting that injured muscle is not recovering appropriately in this population (2). Muscle architectural and energetic features at the cellular level, such as atrophy and fatty infiltration are predictors of muscle performance, and are altered in individuals with LBP. However, studies in humans are limited by poor tissue localization procedures and qualitative analyses. As a result, quantitative histological and cell-level changes in the lumbar musculature in chronic LBP have not been well characterized. The purpose of this study is to provide quantitative measures of lumbar multifidus tissue composition, muscle fiber type and area, vascularity and inflammation, and degeneration in individuals with lumbar spine pathology.

METHODS

Human multifidus biopsies were acquired from 22 patients undergoing surgery for chronic lumbar spine pathology. All patients consented to MRI and biopsy procedures under approval of the local institutional review board. Patients were classified based on pre-operative clinical MRI's according to muscle fatty infiltration levels (Kjaer grades) with grade 0 corresponding to <10% fatty infiltration, grade 1 corresponding to 10-50% fatty infiltration, and grade 2 corresponding to >50% fatty infiltration (Figure 1A). Relative fractions of muscle, adipose, and extracellular matrix were quantified based on staining color and intensity and manual tracing from hematoxylin and eosin and Gomori trichrome stains. Muscle fiber type was quantified using silver-stain gels for myosin heavy chain (MHC) isoforms I, IIa, and IIx. Muscle fiber cross-sectional area (CSA) and number of centrally nucleated fibers were quantified for each biopsy cross section stained for laminin-111 and 4'6-diamidino-2-phenylindole (DAPI). Inflammatory cells were quantified as number of CD68-positive macrophages per square millimeter of tissue in the whole biopsy cross section. Similarly, vascularity was quantified as number of Von Willebrand Factor positive vessels/mm^2. Muscle degeneration was quantified as the number of 1mm^2 quadrants within the cross-section containing degenerating muscle fibers divided by the total number of muscle-containing quadrants. One-way Analysis of Variance procedures were used to compare variables of interest across Kjaer grades.

RESULTS AND DISCUSSION

The majority (59.1%) of patients were categorized as Kjaer grade I (10%-50% 10-50% fatty infiltration) pre-operatively. On average, multifidus biopsies contained 48.5% ± 14.8 muscle, 11.7% ± 9.7 adipose tissue, and 26.1% ± 9.5 collagen tissue with no differences in tissue composition across Kjaer grades (p=0.43). Increased inflammatory cell counts (48.5 ± 30.0 macrophages/mm^2) were observed as compared to reported norms (5.0 macrophages/mm^2), with a trend toward higher densities in the Kjaer grade I group (p=0.08). Vascularization was decreased (275.6 ± 69.4 vessels/mm^2) as compared to reported normative values (389 vessels/mm^2, range (342-413)) for healthy multifidus muscles, but no differences in vascularity were observed across Kjaer grades. Increased fiber CSA (3,996.0 ± 1,909.2 um^2) and a predominance of type I fibers (61.8 ± 18.0%) were observed in addition to evidence of pathological degeneration-regeneration cycling (18.8 ± 9.4% centrally nucleated fibers, and 55.2 ± 24.2% of muscle containing regions showing active degeneration) (Figure1B). There were no differences in these variables across Kjaer grades.

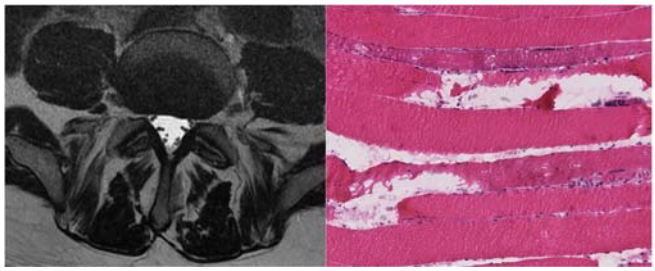

Figure 1: Axial MRI image of lumbar multifidus muscles with (Kjaer grade 1) fatty infiltration (A). H&E stained longitudinal section demonstrating areas of muscle degeneration with cellular infiltration (B).

CONCLUSIONS

Individuals with chronic lumbar spine pathology demonstrate profound levels of muscle loss via imbalanced degeneration/regeneration, increased inflammation, and decreased vascularity. Additionally, the multifidus muscle contains large proportions of adipose and connective tissue, larger fiber size, and is predominantly composed of type I fibers. The higher rates of degeneration compared to regeneration without concurrent evidence of fiber atrophy suggests that rehabilitation paradigms aimed at restoring muscle function through hypertrophy may not be appropriate in this population.

ACKNOWLEDGEMENTS

INTRODUCTION

Low back pain has been recognized as a major public health problem and creates disability, work loss and socio-economic burden. The health of the spine depends on the integrities and proper functions of structural components**.** It has been generally accepted that paraspinal muscle dysfunction including muscle weakness is related to the spinal degeneration such as intervertebral disc (IVD) failure, because paraspinal muscles and spine are mutually dependent in a functional manner [1-3]. Most of previous studies for investigating the muscle weakness effect on spine degeneration have been conducted using an *in vitro* experiment due to the difficulty of *in vivo* experiment. The purpose of this study was to investigate the effects of Botox induced paraspinal muscle weakness on the degeneration of the lumbar spine in an *in-vivo* lapine model.

METHODS

New Zealand white rabbit were obtained (N= 8, average age = 19 months) and were grouped according to the experimental group with botox injection (N=6) and the sham control group with saline injection (N=2). Rabbits in the experimental group were anesthetized for receiving intramuscular botox injections at left and right sides of paraspinal muscles at thoracic 12, lumbar 1 and lumbar 2. Botox injections were conducted 6 times during 28 weeks of the experiment period to keep the amount of muscle atrophy (average 3.2 Unit/kg-animal weight). The saline injections in the shame control group were conducted according to the injection protocol for the experimental group. This study was approved by ethical committee. MRIs were taken before and at 28 weeks after the botox injection (Siemens.,1.5 T) for quantifying paraspinal muscle atrophy and integrity, and the conditions of lumbar disc and spine alignment. Bone mineral density of the lumbar vertebrae was measured by dual X-ray absorptiometry (InAlzyer, Medikors, Korea). Histology analysis conducted for exam muscle integrity. A paired T-test was used for statistical analysis. The level of significance for all tests was set at α=0.05. Results are shown as means standard ± deviations.

RESULTS AND DISCUSSION

Botox injections produced paraspinal muscle atrophy (Figure. 1a). The cross-section areas of paraspinal muscle at T12-L1, L1-L2 and L2-L3 decreased by 17.6 ± 8.3 %, 19.6 ± 5.7 % and 19.5± 8.0 % at 28 weeks after the botox injection, respectively. In terms of muscle integrity, MRIs showed grey colour structure increased within the muscle areas which could be passive elements of muscle, such as fat infiltration or collagenous structure (Figure 1b). As a consequence of the decrease of the paraspinal muscle at 28 weeks after the botox injection, the lumbar spinal discs showed symptoms of disc degenerations. The disc thickness at T12-L1, L1-L2 and L2-L3 decreased by 10.4 ± 9.0 %, 16.8 ± 14.0 % and 15.7 ± 11.1 % at 28 weeks after the botox injection, respectively (Figure 1c). In addition, MRIs showed that the spinal discs at 28 weeks after the botox injection have the partial loss of nucleus pulposus, and the degeneration of spinal alignment (Figure 1d). The average bone mineral density of the lumbar vertebrae in the botox injected group (0.061 g/cm^3) decreased by 51% compared to that in the shame control group (0.125 g/cm^3). MRI and histology showed that there is no muscle atrophy and integrity change in the shame control group.

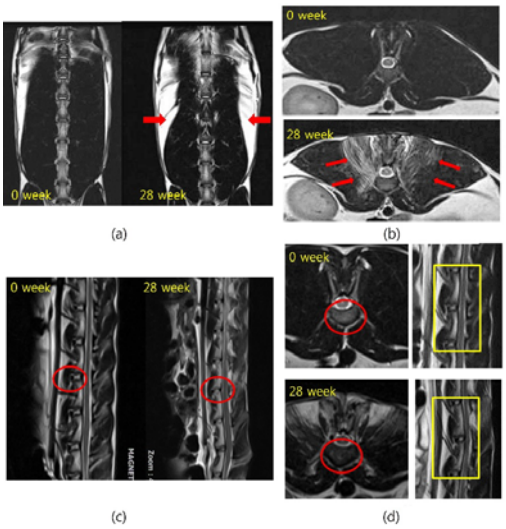

Figure 1: Comparison of muscle, IVDs and spine integrity before and 28 weeks after botox injection: (a) muscle atrophy, (b) the increase of passive elements of muscle, (c) the decrease of dis thickness, (d) the alteration of spine alignment.

CONCLUSIONS

We developed an *in-vivo* animal model for understanding the effect of paraspinal muscle weakness on the degeneration of lumbar spine. Based on the results of this study, chronic paraspinal muscle weakness caused severe disc degenerations, such as disc thickness decreases and bone mineral density loss in lumbar vertebrae.

ASSESSMENT OF THE SOFT TISSUE ARTEFACT WITH SURFACE MEASURES FOR LUMBAR SPINAL MOTION USING ULTRASOUND IMAGING.

INTRODUCTION

Surface markers are used to measure lumbar posture and movement, but there has been limited quantification of the error associated with changes in the relationship between skin marker position and the underlying spinous processes (soft tissue artefact) during movement. Ultrasound imaging has been validated against MRI to measure interspinous distances with changes in lumbar curve[1], and skin surface position can be related to image position with an acoustic shadow[2]. This study quantified changes in skin marker position relative to bony landmarks and soft tissue depth changes from L1-S1 between prone lying, standing and slumped sitting. We also confirmed the reliability of our ultrasound measure of surface position relative to spinous processes in each posture.

METHODS

An acoustic shadow (induced by placing a piece of string in the field of ultrasound image) was aligned to the midpoint of each lumbar spinous process, and a mark was placed on the skin overlying this landmark with the participant positioned in prone lying, standing and slumped sitting, for 23 healthy participants (11 males). Skin movement artefact was quantified as the difference between the skin marks made in prone lying, relative to the skin marks that were similarly made to reflect the midpoint of the spinous process in slumped sitting and in standing (Figure 1).

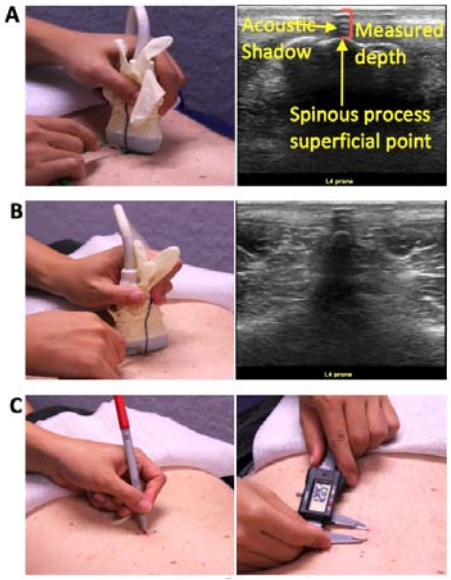

Figure 1 A: Sagittal view to mark skin beside the acoustic shadow. **B**: Transverse view. **C**: Marking the centre of lines A and B, then measuring between marks in each posture.

To assess reliability of ultrasound-guided marking of the skin (cranio-caudal displacement) and images captured (soft tissue depth), an invisible ink pen was used before re-marking with a visible pen (n=11). Participants remained in each posture for the process of re-marking for reliability.

RESULTS AND DISCUSSION

The smallest cranio-caudal skin artefact occurred at S1 in slumped sitting relative to prone, with median(quartile range) of 1.4(-5.2 to 4.6) mm caudal displacement. The largest cranio-caudal artefact occurred at L5 in standing relative to prone, with 19.1(15.1 to 22.9) mm cranial displacement. In general, from L1-L5 the skin was displaced cranially ~5 to 20 mm with changes from prone lying to slumped sitting or to standing. Depth of spinous processes varied from 4.8(3.8 to 6.4) mm at L3 in slumped sitting to 18.1(16.1 to 22.7) mm at S1 in standing. With changes in posture, spinous process depth change was largest at the L5 spinal level, increasing 7.7(6.5 to 10.3) mm from slumped sitting to standing.

Single operator reliability for marking and re-marking the skin in three postures was good with small errors in cranio-caudal skin orientation (ICC 95%CI: 0.80-0.95, SEM: 0.55-0.62 mm); and spinous process depth (ICC: 0.77-0.97, SEM: 0.21 mm). Remarking of the skin was responsible for a mean(SD) error in measurement of cranio-caudal skin displacement between sitting and prone of 0.3(4.4) mm, and between standing and prone of 0.7(5.0) mm. Mean error with repeatedly identifying the centre of a spinous process, capturing an image and measuring soft tissue depth on both images in sitting was 0.9(1.7) mm, in prone was 1.2(1.7) mm, and in standing was 1.5(1.8) mm. Thus, we are confident in the sensitivity of this method to quantify cranio-caudal artefact >5 mm and soft tissue depth changes >2 mm.

CONCLUSIONS

With large changes in lumbar and hip posture, the relationship between skin markers and spinous processes can change by up to 22.9 mm between two postures, and compression of the soft tissue over the spinous process can change the depth by up to 10.3 mm. This magnitude of error may be modest relative to the amplitude of regional spinal motion (e.g. L1-S1), but large relative to the motion of a single spinal segment (e.g. L5-S1). In some experimental tasks error might be minimized if surface markers are applied in the position that posture/motion will be measured.

EFFECT OF SPINO-PELVIC MISALIGNMENT ON STANDING BALANCE IN PATIENTS WITH SYMPTOMATIC SPINAL DEFORMITIES

[1] **Monica Paliwal**, [1]Laura Frey-Law and [2]Sergio Mendoza-Lattes
[1]University of Iowa
[2]Duke University

INTRODUCTION

Aging of the spine results in alterations in the normal spino-pelvic alignment, such as reduction of thoracic kyphosis, loss of lumbar lordosis, and increased pelvic tilt. While reduction of thoracic kyphosis and loss of lumbar lordosis contribute to increasing sagittal spinal imbalance, spinal deformities can lead to impaired function and pain beyond normal age-related changes. Increased pelvic tilt is a compensatory mechanism that may be utilized to reduce the consequences of spinal deformity [1]. Clinically, spinal deformity and compensation through pelvic retroversion are quantified using radiographic parameters: Sagittal vertical alignment (SVA) and pelvic tilt (PT) respectively [2].

Since the spine plays a pivotal role in maintenance of stable upright posture by transferring upper body loads to pelvis and lower extremities, increased spino-pelvic misalignment as observed in patients with spinal deformities may pose challenges to neuromuscular balance systems. However, the effects of spinal deformities on standing balance are unclear. Accordingly, the purpose of this study was to examine the relationships between radiographic spinal misalignment, compensatory mechanism and standing balance in patients with symptomatic spinal deformities.

METHODS

Ninety-seven patients with spinal deformities and 58 age- and sex-matched controls participated. Lateral spine radiographs were taken, from which the radiographic parameters, SVA and PT, were calculated. Patient subgroups were operationally defined as having mild (SVA $\leq$ 5 cm), moderate (5 cm < SVA $\leq$ 10 cm), or severe (SVA > 10 cm) sagittal imbalance, with compensatory pelvic tilt classified as low (PT < 25°) or high (PT $\geq$ 25°).

Subjects were asked to stand independently on a Wii Balance Board to record Center of Pressure (COP) measurements for 30 seconds. Path length (total vector sum of the distance covered by the COP signal) was calculated.
One-way analysis of variance (ANOVA) was used to evaluate differences in path length between spinal patients and healthy controls. Two-way multivariate ANOVA was performed to assess how path length varied with sagittal imbalance (mild, moderate, and severe SVA) and compensation (low, high PT) in patients only. Significance was set at $p \leq 0.05$ for all analyses (SPSS statistics v23).

RESULTS AND DISCUSSION

The patient cohort consisted of 82 females and 15 male; mean age: 60.0 ± 14.2 years; BMI: 28.8 ± 6.3 kg/m^2; 44 with mild SVA, 32 moderate SVA, and 21 severe SVA. The control group consisted of 48 females and 10 males, mean age: 53.8 ± 16.5 years and BMI: 27.8 ± 7.3 kg/m^2. Standing balance worsened with greater sagittal spinal imbalance. Specifically, path lengths for patients with severe and moderate SVA were approximately 64% and 33% greater than healthy adults, respectively (Figure 1A). There were no significant differences in standing balance based on use of PT compensation or any interaction between sagittal imbalance and PT compensation (Figure 1B). Thus, compensation through greater PT did not improve standing balance as measured by path length.

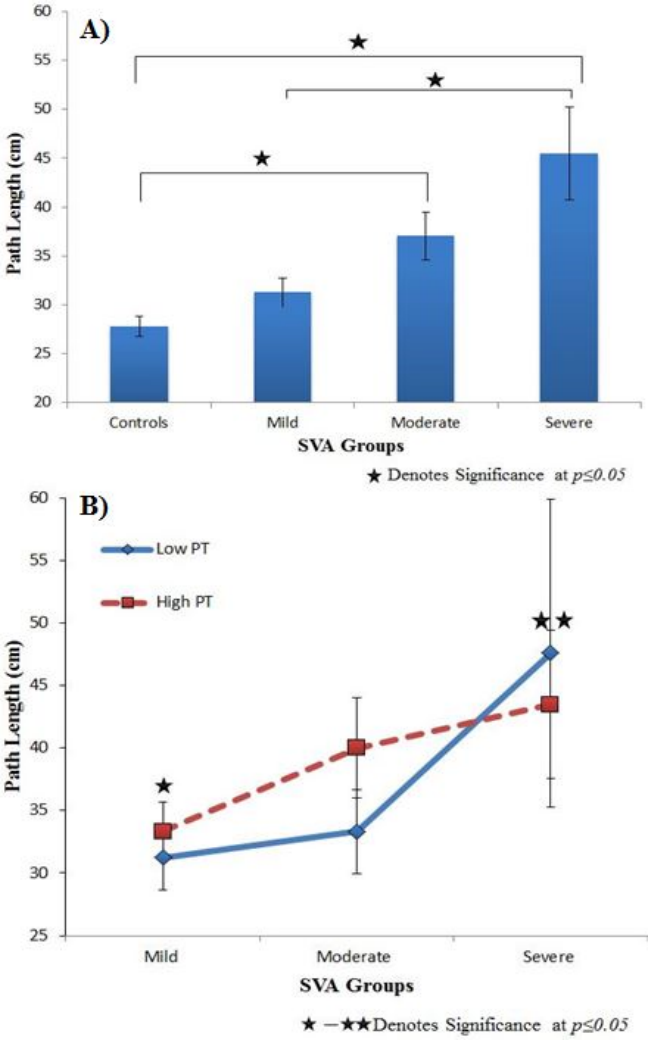

Figure 1: Mean (SE) path length (cm) for A) healthy controls and patients sub-grouped by SVA (mild < 5cm; moderate ≥ 5cm & < 10cm; severe ≥ 10cm) and B) in SVA patient groups separated by level of PT compensation.

CONCLUSIONS

Standing balance worsens with increasing radiographic sagittal imbalance (SVA) and does not improve with the use of PT compensation. This suggests that although compensation through pelvic retroversion may correct for positive SVA, the resulting posture does not appear to improve standing balance stability.

A NEW APPROACH TO CONSIDER 3D ANGLES IN EVA

[1] **Geneviève A Dumas**, [2]Philippe Corbeil and [3]André Plamondon

INTRODUCTION

The development of new wireless sensors such as IMUs now allows the monitoring of workers' posture in the field giving precious information on their postural exposure. Time series of postural angles can be recorded in 3D with unprecedented accuracy [1]. Exposure Variation Analysis (EVA) adds information on how much time is spent within a given range of angle and duration. In the case of the trunk, it is widely accepted that trunk asymmetry combined with flexion increases risk of injury to the spine. However current methods such as EVA consider only one angle at the time, while the three angle time series provide the 3D posture at each instant. Therefore, the question raised in this abstract is: how can we better represent the 3D postural exposure of workers, and create summary indices of postural exposure that take into account coupling between angles.

METHODS

Data were collected from 14 daycare workers, looking after infants or toddlers, during the morning of their shift (~3 hours). A dosimeter with two IMU sensors located on the spine at T1 and S1(sacrum) levels was used and the three relative angles between these two levels –flexion-extension, lateral bending and torsion- were calculated for the duration of the collection[2].

Illustration of asymmetry: Asymmetry was considered to exist when either trunk lateral bending or torsion were larger than a given threshold. After considering several EVA options, the consensus went to the following. A modified EVA flexion graph was created in which: a) the classes for posture (angles) and duration were taken from the flexion EVA graph, b) the bars height was split into two colours, the upper part of which representing the percent time spent in asymmetry for the data in this bar, the lower part the time spent in symmetric posture (Fig. 1).

Postural exposures indices. Our reflection was based on the following considerations: a) the range of trunk flexion is large, and its magnitude directly related to spinal loads, b) static postures, particularly awkward ones, increase risk of spinal damage, c) asymmetric postures also increase risk of damage, but c) ranges of lateral bending and torsion are smaller and more difficult to measure than range of flexion and there are no accepted thresholds for them.

We chose to summarize postural exposure using three dimensions: amplitude of flexion, duration that postures are maintained, and percentage of time spent in asymmetry. Thus we propose the following measures: Pos and Dur indices (X and Y coordinates of the "center of mass" of the EVA) for Flexion with or without asymmetry (lateral bending or torsion > 20º), and percent time spent in asymmetry.

RESULTS AND DISCUSSION

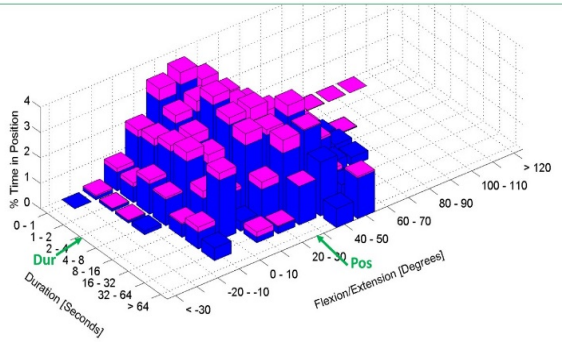

Figure 1: Percent of total time with (pink) or without (blue) asymmetry (lateral bending or torsion > 20º) at various flexion angles and durations for one subject (infants), Pos =6.7 (20º - 30º), Dur =3.0 (2 - 4 s) and 12% of total time spent in asymmetry.

Pos and Dur indices were used by previous studies for postural data and showed they could discriminate between conditions [3]. Here, percent of time spent in asymmetry had mean values of 7.7% (SD 4.5%) for the infant group (n=5) and of 18.9% (SD 16.5%) for the toddler group (n=7). This suggests that workers looking after toddlers spend a larger percentage of their time in asymmetric posture than those working with infants, and should be confirmed on more subjects. Results also showed that time spent in torsion > 20º was smaller than time spent in lateral bending > 20º for most subjects.

CONCLUSIONS

This paper proposes a novel approach to take asymmetry and coupling of angles in different planes in consideration in evaluating postural exposure. More field research is necessary to determine meaningful thresholds of risk for these indices.

THE CONTRIBUTION OF HIP ABDUCTOR MUSCLES DURING TWO-STEPS BALANCE RECOVERY

Soheil Bajelan, Pazit levinger, Hanatsu Nagano, Calum Downie, Rezaul Begg.
Institute of Sport, Exercise and Active Living (ISEAL), Victoria University, Melbourne, Australia. Corresponding author email: soheil.bajelan@live.vu.edu.au

INTRODUCTION

Falls could become a crucial event for older adults that often end their independent lifestyles [1]. Tripping is the leading cause of falls mostly leading to forward balance loss [2]. Therefore, it is important to establish an effective recovery strategy from forward balance loss. Single or multi rapid steps are required to restore centre of mass balance within the base of support [3]. Graham et al. recently revealed the important contribution of Hip Abductors (HA) for balance recovery in addition to other lower limb muscles [4]. They, however, examined balance recovery action just for the initial recovery step during the period from toe off to foot contact of the stepping leg.

In this study, a musculoskeletal model has been developed for two-steps strategy to advance our understanding about multi-steps balance recovery. We compared the lead limb's HA muscular kinetics between the first and second recovery steps in detail, using AnyBody simulation software.

METHODS

Balance recovery data of four healthy older participants (75.2 (3.3) years, 50% females) were analysed for two-steps strategy from a Tether-release method (Figure 1). To capture two-steps balance recovery movement, Vicon motion capture system (VICON, Oxford Metrics) was used to record 3D kinematic data of the whole body motion based on Plug-in gait model at 100Hz. Three AMTI force plates were placed next to each other to obtain ground reaction forces (GRF) sampled at 1000Hz. The subject initially stood on the first plate and the first recovery step landed completely on the second force plate while the second recovery step landed on the third plate. All the participants completed their balance recovery within two steps.

Acquired data were processed in Visual 3D (C-motion) and further modelled using AnyBody musculoskeletal modelling software (Anybody Technology, Aalborg, Denmark). The simulation was performed using min/max optimisation method [5] to compute time-histories of forces of HA muscles in detail: Gluteus Medius (GMed) (Anterior, Posterior), Gluteus Minimus (GMin) (Anterior, Medius, Posterior) and Tensor Fascia Latae (TFL). Recovery step was defined from toe-off to 0.1 second after maximum knee flexion. During each recovery step, the mean muscle force was obtained for each subject (normalized to body mass).

RESULTS AND DISCUSSION

Table 1 presents mean normalised hip abductors' forces of the first and second steps of each muscle's head. Mean forces in anterior, medius and posterior heads of GMin and anterior head of GMed increased in the second step for all subjects while GMed posterior head and TFL did not show the consistent trend.

As shown in table 1, GMin increases from the first to second recovery step across all subjects. Combining all locations together (anterior/medius/posterior), increases were 260% on average (ranging from 16% to 1200%). GMin anterior head performs opposite function compared to posterior head in many movements such as hip flexion and external rotation [6]. However, when all muscle fibers are activated simultaneously, they act together to stabilise the femoral head by pulling it into the acetabulum [6]. Thus, it appears that GMin muscles may possibly play an important role in completing balance recovery action through its contribution to hip stabilisation.

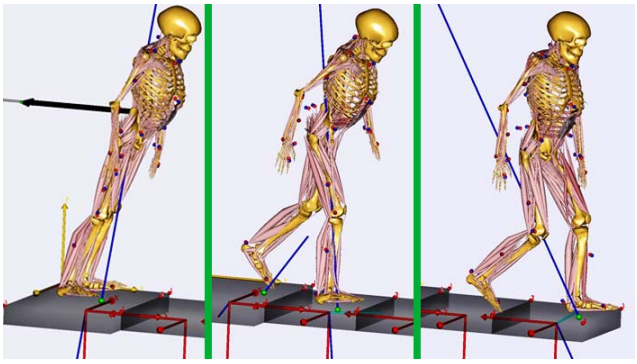

Figure 1: Balance recovery model developed using AnyBody.

CONCLUSIONS

The simulation results implied that the final recovery step might require increased GMin activation to complete balance recovery. Further investigations are necessary to test this hypothesis.

MECHANICAL PERTURBATION OF SPINAL POSTURAL CONTROL WITH SUDDEN AXIAL LOAD DEMONSTRATES DIFFERENT TIMING OF TRUNK MUSCLES IN SITTING VERSUS STANDING.

INTRODUCTION

Sudden application of load along a sagittal or a coronal axis has been used to examine muscular responses that maintain postural control of the trunk, but this is the first study to use sudden application of (vertical) axial load. Previous validation of the methods for axial loading have demonstrated effective stiffness over the first 200 ms after onset of force input to be 12.0 (SD 4.3) N/mm in sitting and 13.3 (4.2) N/mm in standing [1]. The aims of this study were to i) identify the timing of superficial paraspinal and abdominal muscle onsets relative to peak forces applied with a sudden axial load, ii) describe and compare the relative sequence of muscle responses to sudden axial load in sitting and in standing.

METHODS

Load equivalent to 20% of body weight was released from light contact onto the shoulders of ten healthy participants (4 males) as shown in Figure 1. System identification (2^{nd}-order mass-spring-damper system with a delay term) was used to fit data from the time of load release to time of peak load displacement.

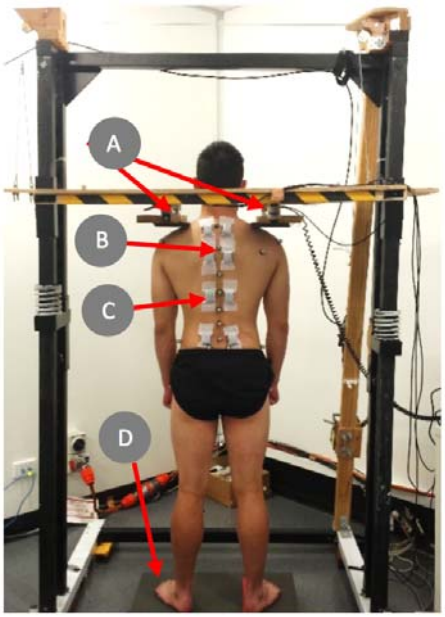

Figure 1: A: Force transducers (recording input force), B: 3-D reflective marker (to assess 3-D kinematics from 7 spinal levels), C: Wireless EMG electrode (T11 L side at arrow, EMG was recorded bilaterally at 4 spinal levels), D: Force plate (recording output force).

Force input was measured via force transducers at shoulders, force output was measured via a force plate below the participant, and spine kinematics was determined using 3-D motion capture. Surface electromyography of spinal extensor muscles adjacent to the 7^{th} cervical (C7), 5^{th} thoracic (T5), 11^{th} thoracic (T11) and 5^{th} lumbar (L5) vertebrae; gluteal muscles (glute); and obliquus exterior (OE) and obliquus interior (OI) muscles were recorded bilaterally. Analysis of variance compared muscle onset following axial loading, between the 7 muscle regions and between the sitting and standing postures.

RESULTS AND DISCUSSION

Effective stiffness was 9.56 (3.4) N/mm in sitting, and 10.1 (3.5) N/mm in standing. Peak input and output forces occurred from 80-130 ms, but activation of extensor muscles at T5, T11, L5 and glutes was between 140-300 ms.

In response to the onset of sudden force input at the shoulders, muscles adjacent to C7 showed a burst of activity at 103 (2) ms in sitting and 107 (3) ms in standing. In sitting, the onsets of muscle activity at T5, T11, L5, gluteal, OE and OI and abdominals were not statistically different, and occurred between 72-106 ms after that observed at C7 (P<0.01). In standing, the onset of OE and OI muscles were similar to C7 muscles (P>0.27), and for the spinal extensor muscles a trend for cephalad-caudad sequence of muscle onsets occurred. Electrodes adjacent to C7 recorded muscle onset 60-80 ms earlier than those at T11, L5 and glutes (P<0.01). At T5 the onset was 60 (6) ms before glutes (P=0.037).

CONCLUSIONS

This study provides new insight into the specificity of muscle function for trunk control in standing relative to sitting. Muscle onsets after peak forces suggest that the initial mechanical behaviour measured represented the system in sitting and standing prior to any responses that occur with sudden axial load. Muscle activation in sitting, caudal to C7 occurred in an *en bloc* manner. In standing, activation of muscles caudal to C7 demonstrated greater specificity than sitting, with relatively early activation of OE, and a general top-down sequence for spinal and hip extensor muscles.

HOW DO WE RECOVER FROM FALLING IN A HOLE? A JOINT LEVEL ANALYSIS

Taylor J.M. Dick, Laksh K. Punith, Gregory S. Sawicki
Joint Department of Biomedical Engineering, North Carolina State University and University of North Carolina-Chapel Hill
Corresponding author email: tjdick@ncsu.edu

INTRODUCTION

In our everyday lives, we continuously negotiate complex environments and unpredictable terrain. Our ability to stay upright in the face of obstacles, such as a hole in the ground, is quite remarkable. Yet, we understand relatively little about how humans adjust limb behaviour to recover from an unexpected perturbation. Previous studies in birds running over an unexpected drop in terrain height suggest that stability is maintained via adjustments in limb contact angle as well as energy absorption in lower limb joints [1,2].

Moreover, the ability for biologically inspired devices to both augment intact and restore impaired neuromuscular systems is rapidly enhancing the locomotor possibilities in healthy and diseased populations. Despite the impressive ability for these devices to emulate the biological behaviour of lower limb muscle-tendon units during bouncing [3] and walking gaits [4], designing exoskeletons and prosthetics capable of rapidly responding to unexpected perturbations remains a challenge.

How does the lower limb recover from falling in a hole during steady state hopping? In this study, we begin to tackle this question by determining how lower limb joint power is redistributed in response to an unexpected perturbation (via a drop in substrate height) during hopping.

METHODS

We asked subjects to perform steady state hopping at their preferred frequency while we collected kinematic and kinetic data. Subjects began hopping on a platform elevated above the level ground; between the 10th and the 20th hop we elicited an unexpected perturbation via removal of the platform. The subjects continued to hop following the perturbation. We tested two different perturbation heights (platform heights of 10 cm and 20 cm). An eight-camera motion analysis system (Vicon, Oxford, UK) was used to capture the three-dimensional (3D) positions of 36 reflective markers attached to the pelvis and lower limbs. Joint angles for the ankle, knee and hip were computed from a scaled musculoskeletal model and the motion capture data [5]. 3D ground reaction forces applied to the left and right legs were computed during hopping using a static split belt instrumented treadmill (Bertec, OH, USA). Inverse dynamics analyses were then used to compute the net joint moments. We calculated the time-varying net joint powers at the right ankle, knee, and hip by multiplying the net joint moments by the joint angular velocities.

RESULTS AND DISCUSSION

Within the lower limb, joint power is redistributed to recover from the unexpected perturbation. The ankle provides majority of the total limb mechanical power in hops before and after the perturbation while the contribution of the knee changes to absorb a large portion of the added energy during the initial contact after the fall (Fig. 1). Similar to previous hopping studies [6], the contribution of the hip to the overall mechanical power is minimal, and like birds [2], the hip appears to maintain relatively the same mechanical role in normal versus perturbed hopping. Joint level responses were similar, although smaller in magnitude, for the 10 cm drop height in comparison to the 20 cm drop height.

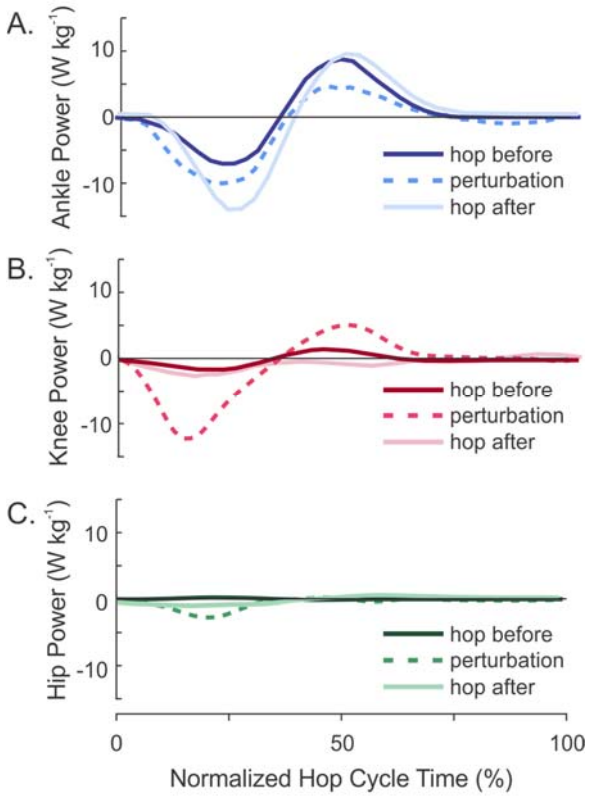

Figure 1. Joint power for the ankle (A), knee (B), and hip (C) over 3 hopping cycles for one subject at a 20 cm perturbation drop height. Data is shown for the hop prior to the perturbation (hop before), the hop when the platform was removed and the subject landed on level ground (perturbation), and the hop immediately following the perturbation (hop after).

CONCLUSIONS

Further investigations into the muscle-tendon mechanics underlying these joint level responses will likely provide insight into the control strategies used to recover from perturbations and help provide biological inspiration for future designs of wearable exoskeleton and prosthetic devices.

DOES KINESIO-TAPING ALTER THE STIFFNESS OF UNDERLYING SOFT-TISSUE IN THE THORACOLUMBAR AREA?

INTRODUCTION

Thoracolumbar fascia (TLF) biomechanics are a current research focus for understanding lumbar pathology and treatment mechanisms for people with low back pain. Kinesio-Taping (KT) is a popular taping approach used to treat musculoskeletal pain. Peolple LBP have reduced relative movement between skin and muscle during passive lumbar flexion and a consequently reduced TLF deformation [1]. Our previous work indicated similarly reduced TLF deformation during lumbar flexion when KT was applied in asymptomatic subjects [2].

These conflicting findings result in a lack of clarity concerning the importance of TLF shear deformation or its therapeutic potential. A recent study reported that taping, applied to unload muscles, affects muscle shear elasticity at rest and during contraction [3], albeit using a non-elastic tape type but giving indications that taping can alter tissue biomechanical characteristics.

The aim of our study was to investigate the effect of K-tape on TLF deformation during active lumbar flexion, in order to inform efforts to understand taping mechanisms and ultimately target treatment better. Our null hypothesis was that taping would not affect tissue measurements.

METHODS

After ethical approval and gaining consent, 14 healthy volunteers participated. Tissue stiffness was evaluated by measuring shear wave velocity (SWV) dispersion [4]. An Aixplorer ultrasonic scanner (V6.0; Supersonic Imagine, Aix-en-Provence, France) coupled with a linear transducer array (4-15 MHz, SL15-4), was used in elastography mode to measure soft tissue SWV. SWV of two regions of the TLF were compared: the subcutaneous and deep fascial zones.

Three taping conditions (no KT, KT and sham tape) were examined. Sham tape was applied as two small pieces of KT on the top and bottom of area of interest. After taping, volunteers were asked to adopt three postures (0°, 45° and 90° of lumbar flexion) in a randomised order.

A two-way repeated-measure ANOVA was used to test the effects of taping condition and subject posture, with dependent variables being SWV of the subcutaneous and deep fascial zones. Post hoc least significance difference tests were used when significant main effects were observed, and $\eta 2$ effect sizes noted. Significance was defined as an alpha of < 5%.

RESULTS AND DISCUSSION

SWV increased in both the subcutaneous ($F = 17.30$, $p < 0.01$, $\eta 2 = 0.57$) and deep fascial zones ($F = 7.59$, $p < 0.01$, $\eta 2 = 0.37$) when lumbar flexion degree increased, irrespective of tape condition. This is indicative of increased TLF stiffness with flexion.

When KT was applied, there was a trend towards reduced SWV across the TLF, with a significant stiffness reduction at 90° of lumbar flexion in both the subcutaneous ($T = 2.06$, $p = 0.03$) and the deep facial zone ($T = 2.30$, $p = 0.02$). Sham taping showed no differences from no taping, but a significant increase in SWV at 90° of flexion was found in comparison with KT ($T = 1.79$, $p = 0.048$).

A particularly interesting finding was the significant interaction between posture and taping on SWV ($F = 4.36$, $p = 0.04$, $\eta 2 = 0.25$). Which implies that fascia stiffness is no longer positively correlated with tissue length when KT is applied.

CONCLUSIONS

This is the first study to investigate the mechanical effects of KT in the TLF using elastography. Results showed that KT significantly reduced TLF stiffness in flexion, providing a potential explanation for taping effects reported in clinical practice (reduced pain; improved movement). Further investigation is needed to test if results differ in a symptomatic cohort.

SELF-ORGANIZING MAPS FOR CLUSTER ANALYSIS OF SACROILIAC INVOLVEMENT IN LOW BACK PAIN PATIENTS

[1] **Melanie D Bussey PhD**, and [1] Peter Lamb PhD

INTRODUCTION

Artificial neural networks are a powerful artificial intelligence technique currently employed in the medical field to aid in difficult subcategorization of patient populations.[1] Self-organizing maps (SOMs) are a special class of artificial neural networks, trained using unsupervised learning to provide a low-dimensional visualization and clustering of high-dimensional data. The purpose of this study was to identify and characterize clusters in a heterogeneous low back pain sample of high-dimensional kinematic data collected during a modified Trendelenburg task. Identification of subgroups within the database could help elucidate aberrant movement functionality and facilitate future diagnostic model building.

METHODS

117 participants gave informed consent to take part in this study. 79 were healthy controls with no history of low back pain. 19 of these were diagnosed with pain arising from the SIJ as per current guideline recommendations.2 A further 19 diagnosed with LBP symptoms located in the lumbar spine
and had fewer than 3 positive tests for SIJ (7 had one positive test, 2 had two positive tests and the remaining participants had no positive SIJ tests).

Participants performed the standing hip flexion test to auditory signal 40 times for each leg. Three-dimensional kinematic analysis of the spine, pelvis and lower limb, defined by a fifty-two retroreflective marker model, were conducted during the modified Trendelenburg clinical test using Ten Vicon© MX T20 cameras capturing at 200Hz.

SOMs, were used to characterize the movement patterns of low back pain participants and health controls. The dataset used for training the SOM consisted of 34 kinematic variables in 9343 trials of the hip flexion test. The sequence of nodes that best represent each frame of the movement can be visualized as a trajectory and represents the evolution of coordination throughout the movement. In a second-level SOM analysis the trajectory coordinates of the original SOM for each trial were projected into weight space and used to train a second SOM to classify trials. On the second SOM, nodes represent movement patterns for the entire trial (Figure 1).

RESULTS AND DISCUSSION

The SOM analysis showed that there was considerable overlap between the two pain groups. However, isolating LBP participants who tested positive on either the *Faber test* or the *Thigh Thrust test* eliminated nearly all movement patterns matching those typical of SI joint pain participants (Figure 1). The mapping shows that (with the exception of one participant) the bottom left corner of the map, which frequently represents movement patterns by SIJ participants, only represents LBP participants who scored positive on either of the above-mentioned tests (to be called the LBP+ subgroup; see Figure 1).

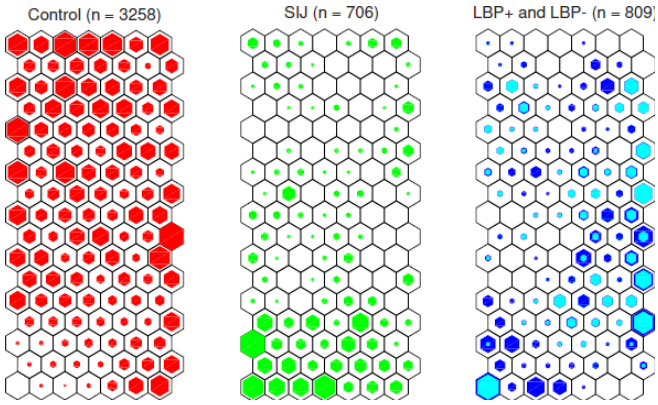

Figure 1: Second-level SOM showing Control (left), SIJ (middle) and LBP trials (right). Marker size indicates the number of trials represented by each node. SIJ trials are more frequently found in the bottom left corner; Control trials are rarely found there. LBP- trials are superimposed on the LBP+ trials, note that the large LBP- trial at the bottom left corner represents all trials of a single outlying participant.

We subsequently conducted a Statistical Parametric Mapping analysis to compare various kinematic variables for the LBP- and LBP+ subgroups. T-tests comparing LBP- and LBP+ showed clear differences between the groups. In particular, LBP+ showed more lateral COM displacement, more lifting hip abduction, slower lifting hip flexion, more pelvis posterior tilt, more lateral pelvic tilt (lifting leg side is higher) and more support knee abduction compared to LBP-. A one-way ANOVA comparing the SIJ, LBP- and LBP+ groups showed similarity between SIJ and LBP+ across several variables including, pelvic tilt, pelvic rotation, hip acceleration, velocity and range of movement.

CONCLUSIONS

Our results show that the Faber and Thigh Thrust tests may be important predictors of clinically relevant movement patterns related to SIJ dysfunction in LBP. While we were able to correctly identify kinematic variables that distinguished the LBP+ and LBP-, we caution clinicians and researchers from trying to reduce a complex movement to its components. Instead the SOM approach provides a characterization of multi-segment movement coordination as a whole, which can be interpreted relative to other data in a large and varying dataset.

INTRODUCTION

It is known that the symptoms of lumbar spinal stenosis (LSS) patients are gotten worsening or relief according to the lumbar alignment, such as anterior or posterior tilt. The purpose of this study was to clarify whether the spinal and pelvic movements during gait influenced leg or low back pain worsening by the gait loading test in the LSS patients.

METHODS

Fourteen LSS patients with neurogenic intermittent claudication participated in this study. For gait analysis, a three-dimensional motion analysis system (VICON MX: Vicon Motion Systems, Oxford, UK) with 16 infrared cameras (100 Hz; Vicon Motion Systems, Oxford, UK) and eight force plates (1000 Hz; AMTI, Watertown, USA) recorded 24 reflective markers attached to the patients' back, pelvis and lower extremities. All patients walked along a 10-m walkway at self-selected speed before (pre-effort) and after (post-effort) 6-minutes gait loading test. Anterior tilt of the trunk, thoracic, lumbar spine, and pelvis was calculated. All anterior tilt data were normalized by subtracting from the reference value during standing. We extracted the peak values during the stance phase from each anterior tilt data.

We assessed a visual analog scale (VAS) of leg pain (LP) and low back pain (LBP) in both pre- and post-effort. The increase in each VAS scores from pre- to post-effort were calculated, and the cohort was then classified into two groups as follows: LP dominant (LP) group, and LBP dominant (LBP) group.

Differences in kinematic data between the groups before and after the gait loading test were examined by using two-way mixed repeated-measures analysis of variance with factors of the group (LP and LBP) and the loading effect (pre- and post-effort). Furthermore, stepwise multiple linear regression analysis was conducted with the increase in the VAS scores of LP or LBP as the dependent variable and kinematic data of spine and pelvis as the independent variables. The level of statistical significance was < 5%.

RESULTS AND DISCUSSION

From the results of the VAS scores, six patients were included in the LP group and the others in the LBP group.

No interaction was observed in each kinematic variable. Anterior tilt of the thoracic showed a significant main effect of the group, and that is, was smaller in the LP group than in the LBP group at both pre- and post-effort (Table 1). Anterior tilt of the lumbar showed a significant main effect of before and after gait loading test (loading effect), and that is, was larger at post-effort compared to pre-effort in both groups, especially in the LP group.

Table 1: The peak values of each kinematic variables during the stance phase.

(°)	LP group		LBP group	
	pre-effort	post-effort	pre-effort	post-effort
Trunk	4.2 ± 4.5	6.9 ± 5.9	6.6 ± 2.8	6.5 ± 4.3
Thoracic	0.3 ± 3.7*	0.7 ± 3.3*	5.0 ± 2.1	5.1 ± 2.4
Lumbar	4.4 ± 2.0	6.7 ± 3.6†	3.2 ± 2.5	3.5 ± 3.2†
Pelvis	4.0 ± 2.4	4.2 ± 3.1	2.9 ± 2.3	3.7 ± 2.3

Values are the mean ± standard deviation.
* and † are significantly different from the LBP group and pre-effort, respectively, at $p < 0.05$.

From the results of stepwise multiple linear regression analysis, the increase in the VAS scores of LP was significantly explained anterior thoracic tilt at pre-effort, whereas that of LBP was significantly explained the change from pre- to post-effort for the anterior pelvic tilt.

In general, the patients who had worsened LP after gait loading test walked with smaller thoracic tilt before the test, and the lumbar anterior tilt increased after the test. A previous study reported that in the LSS patients, the epidural pressure was decreased with lumbar flexion compared to with the normal position during gait [1]. In the LSS patients, smaller thoracic tilt might induce LP, and an increase of the lumbar anterior tilt was caused compensatory. On the other hand, the patients who had worsened LBP after gait loading test got larger in the pelvic tilt after test compared to before test. It might be the cause of LBP that although there were no differences in the anterior tilt of thoracic and lumbar spine between before and after gait loading test, the pelvic tilt only increased in the LBP group.

CONCLUSIONS

In the LSS patients, smaller thoracic tilt before gait loading test caused severe LP after the test, and an increase of the lumbar anterior tilt was caused compensatory after the test. The increase of the anterior pelvic tilt after gait loading test compared to before test caused severe LBP after the test.

EFFECT OF LOWER LIMB EXERCISE THERAPY ON SPATIOTEMPORAL GAIT VARIABLES IN RECREATIONAL RUNNERS WITH CHRONIC LOW BACK PAIN

INTRODUCTION

There is currently no specific exercise therapy for managing runners with chronic low back pain (cLBP). In the general population, the treatment effect of various back exercises on cLBP have shown inconclusive results [1]. One recent study showed that recreational runners with cLBP exhibited diminished knee extensor strength compared with asymptomatic runners [2]. The authors postulated that weakness of the knee muscles may reduce capacity for shock attenuation, transmitting higher forces to the low back during running. This suggests that strengthening lower limb muscles may contribute to reducing loading and pain at the low back; hence it is worth considering lower limb exercise therapy in managing cLBP among runners.

We conducted a single-blind (assessor was blinded) randomized trial to evaluate the effectiveness of lower limb exercises, compared with conventional back exercises, in managing cLBP in recreational runners. We hypothesized that the lower limb exercises would be more effective in improving self-rated running capability and running gait than the conventional back exercise (lumbar extensor and lumbar stabilization) therapies.

METHODS

Ethical approvals were granted from the Nanyang Technological University Institutional Review Board and the National Healthcare Group Domain Specific Review Board. 84 recreational runners with cLBP [male = 42; mean age = 27.3 (SD 5.5) y] were allocated to 1 of the 3 exercise groups for an 8-week intervention: 1. lower limb (LL), 2. lumbar extensor (LE), or 3. lumbar stabilization (LS) exercises. LL group involved resistance exercises targeting the hip and knee muscles (**Figure 1**). LE group performed isometric exercises to strength the lumbar extensor muscles. LS group received a series of transversus abdominis and lumbar multifidus muscle activation and motor control training.

Figure 1: Lower limb exercises during supervised sessions (a. hip abductors, b. hip extensors, c. leg press) and prescribed home exercises (d. single leg squat, e. wall-sit).

Participants were requested to attend supervised exercise sessions with their physiotherapists twice a week for 8 weeks. They were also asked to perform home exercises on other days of the week, guided by an instruction sheet. All participants were asked to stop their home exercises after completing the 8 weeks of exercise intervention.

Participants were assessed at pre-, mid- and end-intervention, as well as followed up at 3 and 6 months. First, self-rated running capability was assessed using the Patient Specific Functional Scale (PSFS) (0 stands for unable to perform running and 10 stands for able to perform running at the same level as before the cLBP condition). Next, running gait was analysed using the OptoGait system when running on a treadmill at a self-selected speed. Four spatiotemporal gait variables were extracted for analysis: self-selected speed, step length, flight time, and contact time. Generalized estimating equation was adopted to examine group-by-time interaction ($\alpha = .05$).

RESULTS AND DISCUSSION

LL group improved 0.949 points per time point in self-rated running capability (PSFS $p < .001$), which was higher than the LE (B = -0.198, $p = .001$) and LS groups (B = -0.263, $p < .001$). Self-selected running speed did not differ across the 3 groups ($p = .444$) or over time ($p = .185$). Running speeds significantly differed between sexes ($p < .001$), with male participants running 2.37 km/h faster than their female counterparts (95% CI: [1.875, 2.856], $p < .001$). Changes in running step length differed across the 3 groups over time ($p = .046$). Participants in the LL group achieved an average increase of 2.46 cm in step length over each time point (95% CI: [0.953, 3.975], $p = .001$), which was similar to the LE group (B = -1.690, 95% CI: [-3.64, 0.26], $p = .089$). Comparing to the LL group, the step length in the LS group increased less at a rate of 2.21 cm per time point (95% CI: [-3.96, -0.468], $p < .001$). Step length differed between sexes ($p < .001$), with longer step length in male participants (B = 26.12, 95% CI: [21.38, 31.84], $p < .001$). Flight time remained stable with no changes over time ($p = .208$) and no difference across the 3 groups ($p = .931$). Similarly, contact time also did not change over time ($p = .371$) or differ among the 3 groups ($p = .931$).

CONCLUSIONS

LL exercise therapy was more effective than conventional back exercises in improving self-rated running capability and increasing running step length among recreational runners with cLBP.

INCREASED COMPENSATORY BUT NOT ANTICIPATORY POSTURAL ADJUSTMENTS FOLLOWING EXERCISE FOR PEOPLE WITH CHRONIC LOW BACK PAIN

[1] Michael F Knox, and [1]**Paul W Marshall**
[1]Western Sydney University
Corresponding author email: p.marshall@westernsydney.edu.au

INTRODUCTION

In the last 20-years exercise rehabilitation for chronic low back pain (CLBP) has been influenced by discussion about trunk muscle motor control [1]. Measurement of trunk motor control often involves examining the anticipatory postural adjustment (APA) associated with a perturbation, typically from the onset time of various trunk muscles. Clinical trials examining APA changes after exercise are confusing and contradictory [2]. While some studies have shown that acute experimental back pain reduces the amplitude of APAs [3], no studies have examined whether the APA amplitude changes following exercise. Also, only two studies have examined change in the compensatory postural adjustment (CPA) following exercise for CLBP. We examined the changes in APAs and CPAs after 8-weeks of either exercise or usual activities in people with CLBP.

METHODS

Twenty-four people with CLBP (mean ± SD; age 33.3 ± 2.0 years, height 1.68 ± 0.02 m, weight 78.2 ± 2.8 kg, symptom duration 12.1 ± 2.0 years) were randomly assigned to either an exercise intervention or usual activities (control), with measurements performed before and after 8-weeks. Exercise was supervised 3-times per week and used a comprehensive whole body and trunk focused regime. APAs and CPAs were measured from bilateral surface EMG recording of; transverse abdominis/internal obliques (TA/IO), rectus abdominis (RA), and erector spinae (ES) in response to rapid shoulder flexion. Onset times and amplitudes of the APA, and both the early (CPA1, 50 to 200ms post prime mover onset) and late CPAs (CPA2, 200 to 350ms post prime mover onset) were processed for analysis. Clinical outcomes were examined with self-rated pain (VAS) and disability (ODI) scales.

Linear mixed model ANOVA procedures were used for data analysis (significance set at $p \leq 0.05$).

RESULTS AND DISCUSSION

ODI scores were reduced from 27.8 ± 12.6 % by 9.5 ± 7.6 % after exercise ($p=0.032$) only. VAS scores were unchanged in both groups.

Muscle onset times became later for ES after exercise ($p=0.009$). No other changes were observed. All average muscle onset times were within the window (+50ms after prime mover onset) for feedforward activity.

APA amplitudes did not change for any of the trunk muscles. Following exercise both CPA1 and CPA2 increased for TA/IO (Figure 1; $p<0.05$), although this was only observed on the same side of the trunk (right) as the shoulder that was moved.

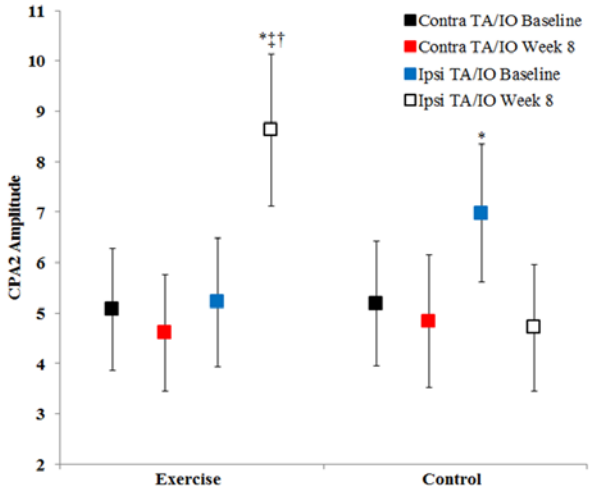

Figure 1: Contra- and ipsi-lateral (with respect to right shoulder movement) TA/IO CPA2 amplitudes at baseline and week 8 for the exercise and control group. * $p < 0.05$ compared to baseline; ‡ $p < 0.05$ between groups; † $p < 0.01$ between sides. Data are mean and 95% confidence interval.

CONCLUSIONS

Recent trends in CLBP exercise literature are moving away from acknowledging any relevance to examining trunk muscle motor control. While specific exercises may not be warranted, trunk muscle motor control appears to be a factor that is impaired in people with CLBP which does change following successful exercise interventions. Clarifying the measurements in this field will improve the confusion. Examining the amplitudes of postural adjustments showed a change in the compensatory periods after exercise. The pattern after exercise for a clear between side difference in the compensatory response mirrors recent findings in healthy individuals [3], and may reflect a positive change following exercise.

ACKNOWLEDGEMENTS

FLUID–STRUCTURE INTERACTION IN MODELLING OF ANEURYSM HAEMODYNAMICS

INTRODUCTION

A description of the blood flow in a circulatory system is one of the challenging and topical problems in fluid dynamics and biomechanics. One of the issues is a difficult mathematical problem of fluid–structure interaction (FSI). There are still a number of open questions both in analytical methods and in problems of numerical scheme construction [1]. In this work, a numerical simulation of haemodynamics in cerebral vessels with a giant aneurysm is performed. Our main goal is to analyse three different approaches that are widely used to simulate the blood flow: rigid-wall assumption, one-way FSI approximation and two-way FSI.

METHODS

One of the most common approach to description of the circulation is a mathematical model in which the blood flow is governed by the Navier–Stokes equations and the vessel walls are considered rigid. In such a case, only the hydrodynamic problem for the blood flow is solved. In relatively large cerebral arteries one can consider blood as a viscous incompressible Newtonian fluid [2].

There are two approaches for determination of the deformations and stresses in the vessel wall: the so-called one-way fluid–structure interaction (FSI) and two-way FSI. In the former formulation the counter-reaction of the vessel wall onto the blood flow is neglected, while in the latter one mutual interaction between the wall and the flow is taken into account.

In the one-way FSI approximation the solutions of the hydrodynamic and elasticity problems are split into two consecutive steps. Having found the blood flow in the rigid-wall assumption, the deformation of the vessel wall is sought as a reaction to the flow. In this work the vessel wall is modelled by an isotropic linearly elastic material [3]. In the full (two-way) statement of the FSI problem one needs to find the fluid flow and the wall's deformations coupled through the boundary conditions on the fluid–solid interface (kinematic and dynamic ones).

We illustrate the importance of the fluid–structure interaction with the modelling of the haemodynamics in the cerebral vessels with a giant aneurysm. The geometry of the cerebral vessels with the giant aneurysm is reconstructed from the magnetic resonance scans of a real patient. The boundary conditions for the blood flow are derived from the clinical data obtained during the intraoperative endovascular measurements of the velocity and pressure that were carried out in this patient during the surgery [4].

RESULTS AND DISCUSSION

The simulation in the rigid-wall assumption shows that the flow in the aneurysmal sac is vortical with a high-speed jet flow along the anterior wall of the aneurysm. In the centre of the aneurysmal sac, the flow is much slower.

The modelling in the FSI formulation reveals significant difference in the flow pattern (Figure 1). A difference between the velocity fields clearly shows that the second high speed jet flow in the aneurysmal sac exists when the fluid–solid interaction is taken into account. The existence of the second jet flow can be also seen in the analysis of the wall shear stress.

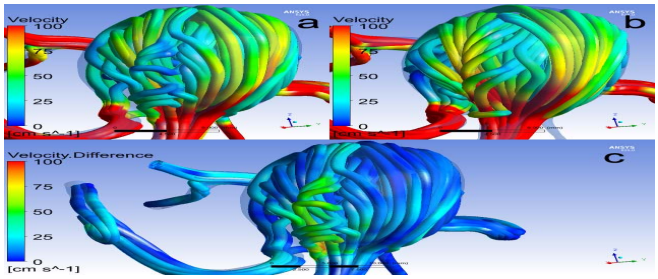

Figure 1: Comparison of the velocity streamlines in the two solutions: a — rigid walls, b — FSI, c — difference.

A comparison of the numerical solutions shows that mutual fluid–solid interaction can result in qualitative changes in the structure of the fluid flow. Other characteristics of the flow (pressure, stress, strain and displacement, except the wall shear stress, which depends of the flow pattern) qualitatively agree with each other in different approaches. However, the quantitative comparison shows that accounting for the flow–vessel interaction, in general, decreases the absolute values of these parameters.

CONCLUSIONS

Three different approaches to the modelling of the haemodynamics give similar results in many cases. In this work we showed that in the FSI formulation, in addition to quantitative changes in haemodynamic parameters, one can obtain a qualitatively different flow pattern, however, at a cost of highly increased computational time.

CEREBRAL AUTOREGULATION IN COMMON CAROTED ARTERY USING FLUID STRUCTURE INTERRACTION AND LUMPED PARAMETER MODEL APPROACH

[1]**Saeed Siri**, [2]Malikeh Nabaei and [3]Nasser Fatouraee
[1,2,3] Amirkabir University of Technology, Biomedical Engineering Department
Corresponding author email: m_nabaei@aut.ac.ir

INTRODUCTION

Shear induced autoregulation is the instinct ability of an organ to maintain the local hemodynamic stresses in a stable condition in spite of altering perfusion rate. Endothelium cells are shear sensitive mechanoreceptors that are responsible for regulating the arterial wall architecture and mechanical properties in order to maintain homeostasis. According to the lack of numerical models for WSS induced blood flow regulation, in this paper we presented a multiscale model of local flow regulation.

METHODS

First, a lumped parameter model (LPM) of the whole cardiovascular system was implemented. Then a 3D numerical model of human common carotid artery (CCA) was constructed considering fluid structure interaction. The CCA inflow waveform obtained from an extended 0D model was applied to the 3D model as the boundary condition (BC). After applying the Head-Up Tilt (HUT) test, the local hemodynamics was disturbed. By considering the wall shear stress as the regulation criterion and altering the arterial mechanical properties and the following vasodilation, shear forces exerted on the inner lining of the vessel was regulated and returned to the normal range.

RESULTS AND DISCUSSION

Autoregulation of WSS was modeled in the human common carotid artery and performed for different regulation rate factors and its effect on the regulation procedure was analyzed. Figure 1 shows the regulation curves for three different RRFs (0.985, 0.98 and 0.99). It can be observed that decreasing the value of RRF leads to a longer time interval for WSS regulation. According to Guyton's medical physiology, the time duration for WSS regulation should be about 5 seconds and as a result, we considered 0.99 as preferred RRF. Increasing flow rate leads to higher velocity gradients and therefore higher WSS. It can be observed in figure (1-c) that the mean WSS increased from 0.59 Pa to 1.1 Pa after the disturbance. This imposes higher shear forces or viscous drag from the blood flow on the inner lining of the vessels which is covered with endothelium cells. Endothelium cells are very sensitive mechanoreceptors and intend to keep the hemodynamic forces in normal and stable condition [1-3]. Higher WSS intensively bends the endothelium cells in the direction of flow and greatly increases release of NO from them. As it mentioned before, NO is an endothelium derived relaxation factor. It affects smooth muscle cells (SMCs) causing them to relax and reduce the modulus of elasticity of the arterial wall. This process was started by activation of the regulation code in our model and caused the Young modulus to decrease from 1 MPa to 0.86 MPa (figure 1-a). This in turn leads to vasodilation or increasing the vascular diameter. Figure 1-b shows 3.81% dilation of the CCA lumen due to WSS regulation.

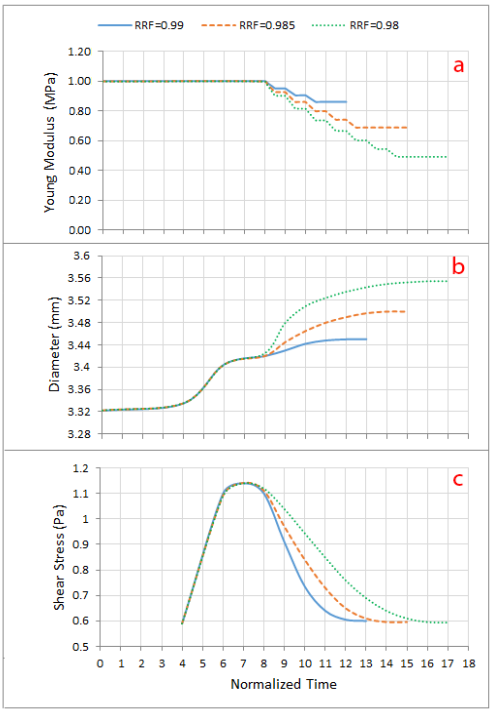

Figure 1: Young's modulus of elasticity of the arterial wall (a), arterial diameter (b) and WSS (c) for different RRFs.

CONCLUSIONS

The present 0D/3D model can be considered as a platform for a comprehensive model of cardiovascular regulation. Image based patient specific geometries can be used in local FSI model to get advantage of a 3D realistic distribution of hemodynamic forces. Different local and systemic regulation mechanisms can be taken into account to achieve a complete model. In addition to physiologic regulation, it can be applied to pathologic conditions. It is also applicable for predicting the genesis and initiation of several vascular diseases, which are originated from hemodynamic forces like aneurysms or atherosclerotic plaques. It may also be useful for recognizing the most effective treatment method for relevant cardiovascular disorders.

INTRODUCTION

The endovascular coiling is popular treatment method to prevent the rupture of the cerebral aneurysm. In this procedure, the coiling to the aneurysm induces blood flow stagnation and thrombus formation in the aneurysm sac, which finally occluded the whole aneurysm sac. Since the incomplete occlusion increases the risk of aneurysm recurrence leading to its regrowth and rupture [1], comprehensive understanding of the mechanism of the aneurysm occlusion is required to improve the clinical outcome. The present study developed a computational model to express the thrombus formation in the cerebral aneurysm after the endovascular coiling. The mechanical interaction between the hemodynamics and the flow resistance due to the existence of the thrombus was treated in the computational fluid dynamics (CFD) simulation.

METHODS

We used a patient-specific aneurysm geometry with the realistic coil configuration (packing density=27%) constructed in the previous study [2]. The blood flow analysis was done by means of a Cartesian-grid CFD simulation [3], in which the coiled aneurysm geometry was represented by using a volume fraction (VOF). The Blood flow was expressed by solving the incompressible N.S. equation and equation of continuity by the finite difference manner and the wall boundary was treated by the boundary data immersion method [4]. The blood was treated as a Newtonian fluid with the viscosity of 3.5×10^{-3} Pa·s and the density of 1.05×10^{3} kg/m^3. On the boundaries, steady flow mass (Re=441) was set at the inlet, constant zero pressure was set at the outlet and No-slip boundary condition was set on the wall.

We developed a phenomenological approach to represent the mechanical interaction between the hemodynamics and the thrombus formation. Based on the experimental observation [5], we modeled the thrombus ratio in the blood domain as a function of the shear rate $\dot{\gamma}$ of the blood flow given by

$$\text{Thrombus ratio} = 1/2\left[1-\tanh\left\{\alpha\left(\dot{\gamma}-\beta\right)\right\}\right] \qquad (1)$$

where the α and β are the coefficients set to 0.2 s and 15 s^{-1}. The flow resistance due to the existence of the thrombus was estimated by the isotropic porous media theory. The CFD simulation with considering the thrombus modeling was calculated iteratively until convergence.

RESULTS AND DISCUSSION

The blood flow was sufficiently stagnated especially in the aneurysm dome even without the thrombus formation (Fig. 1(A), left). After convergence of the thrombus formation, the velocity magnitude was sufficiently decreased in whole domain (Fig. 1(A), right), however the velocity magnitude locally increased in the neck (shown in circles in Fig. 1(A)). Thrombus formation proceeded in the whole aneurysm and finally covered with the whole aneurysm volume except for the aneurysm neck (Fig. 1(B)). Note that the local flow path was generated in the aneurysm neck (shown in the circle in Fig. 1(B)), which is often observed in the clinical practice and experimental observation as the risk factor of the aneurysm recurrence [6].

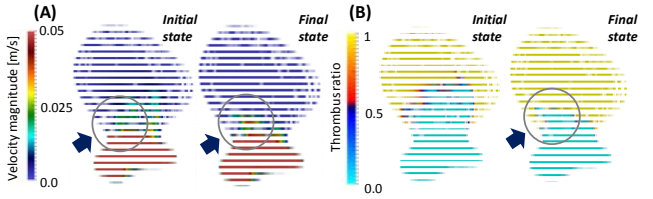

Figure 1: Spatial distribution of the velocity magnitude (A) and thrombus ratio (B) in the cross-sectional area of the coiled cerebral aneurysm at the initial stage without thrombus formation and final stage when the thrombus formation was converged.

CONCLUSIONS

We developed the computational framework to investigate the thrombus formation and progress in the coiled cerebral aneurysm. The result successfully exhibited the mechanical interaction between the blood flow characteristics and the thrombus formation. Since the proposed thrombus model is driven only by the hemodynamic factor, this approach may be generally feasible to evaluate the effect of various endovascular treatments on the aneurysm occlusion.

INTRODUCTION

In 2016, 58.3% of the population with spinal cord injuries (164 400 persons in US) result from cervical compression leading to partial or complete tetraplegia (respectively 45 and 13.3%) generating health care and living expenses (NSCISC, 2016).

Medullar lesions are critical and extension of such lesion could be harmful for the recovery of long term result of myelopathies. The influence of cerebro-spinal fluid (CSF) on such lesions and their consequences is still unknown. Additionally, cervical canal stenosis which could be consecutive to trauma is usually diagnosed by magnetic resonance imaging through two indices: Torg-Pavlov ratio is described as the ratio of spinal canal diameter over the vertebrae diameter and is considered as normal when equaled to 0.95±0.14. The medullary canal ratio is also described as the ration of pia diameter over the dura diameter.

While current recommendation for myelopathy diagnostic [1] did not include quantitative measurement of the CSF, CSF motion is generally visualized and phased contrast measurements is performed in Chiari malformation. Recent study also report the use of 4D-Phased contrast (PC) flow imaging techniques to visualize CSF pattern and potential coherent structure [2]. Pulsatile characteristics of the CSF flow have been reported to be link to patient gender and age [3]. This work aims to quantify the influence of anatomical variability on the fluid structure interaction (FSI) in the cervical SAS at C5-C6 level and to assess the use of the feasibility of CSF flow measurements in the myelopathies diagnostic.

METHODS

FSI simulation was performed using Arbritrary Lagragian Eulerian (ALE) formulation based on the SM2S model previously described in [4]. Briefly, such finite element model of the spinal cord includes vertebrae, joins, intervertebral disks, pia, dura, white and grey matters. CSF was considered as a pulsed Newtonian fluid (ρ= 0.001; K=2089; $\nu 8=8.9e^{-4}m^2.s^{-1}$). Pia and Dura matter properties were respectively: ρ= 0.001; ν=0.45; E=2.3 and E=5. Eulerian grid has cub element sized of 2mm. 9 CSF cycles were simulated.

Age and gender differences on CSF flow profiles are simulated following normal value given in [3] (S1: young male, S2: young female and S3: elderly male). Medullary canal ratio was computed average between maximum and minimum diameters values in the section (C5 and C6) and altered with morphing of the pia matter to reduce the ratio by 10% (S4).

Post processing analysis include vorticity and path-lines analysis on a CSF cycle as well as velocities intensity through the cycle were analyzed

RESULTS AND DISCUSSION

Velocity flow pattern around the pia matter was slightly different depending of gender and aging (max velocity: S1:21.5cm/s , S2: 16.2cm/s, S3: 11.8cm/s).

Reduced medullary canal ratio was tested in S4 and compared to S1 (S1:0.656 and S4:0.787) for a young male patient. Influence of the medullary canal ratio in the velocity pattern was directly depicted on Figure 1 (Velocity max S4:24.1cm/s)

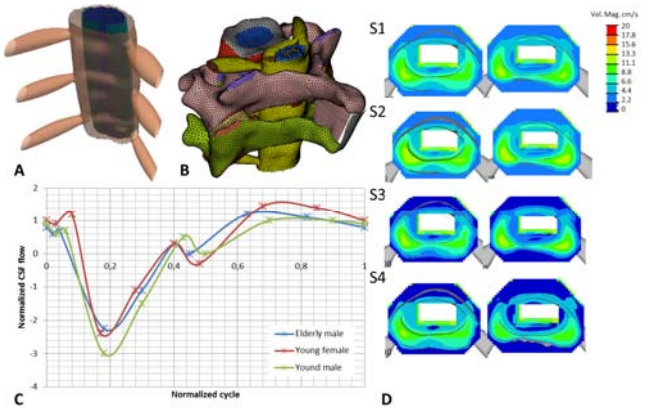

Figure 1: Dura and Pia anatomy in S1 (blue), S4 (green) geometry (A) C5-C6 vertebrae model (B) CSF flow profiles simulated for S1, S2 and S3 (C) and ALE simulation velocity fields (C).

CONCLUSIONS

As previously reported simulation of Chiari malformation [5], ALE simulations of CSF flow show velocity pattern presenting higher velocity in the anterior part of the SAS and is influenced by the CSF flow profile as well as in patients with reduced medullar canal ratio.

ROLES OF SHEAR FORCE IN THE DEVELOPMENT OF ACHILLES TENDINOPATHY

INTRODUCTION

Achilles tendon is commonly affected by tendinopathy and rupture. Mechanical loading is regarded as a major causative factor for tendon microtrauma, degeneration, and eventually failure. However, the mechanism for mechanical loading to induce Achilles tendinopathy is unknown.

Lubricin, a mucinous glycoprotein, has been found on the gliding surface of cartilage, tendon and other musculoskeletal tissues to facilitate tissue sliding [1]. A number of studies revealed that it is shear force that specifically stimulates lubricin expression in tendons [1], cartilage [2] and engineered tissue constructs [3]. Therefore, the presence of lubricin provides the evidence of the sliding motion and shear force in tissues.

This study was to investigate the distribution of lubricin in normal and pathological Achilles tendon, and to understand the roles of shear force in the development of Achilles tendinopathy.

METHODS

Achilles tendons were harvested from cadavers with the approval by Institutional Review Board. The 5-mm segments from the mid-portion of Achilles tendon, which located at 2 to 6 cm proximal to the calcaneal insertion, were collected, fixed in 10% neutral buffered formalin, dehydrated, and embedded in paraffin. Sections of 5 μm in thickness were cut along the long axis of the tendon in both frontal and sagittal planes. The distribution of lubricin was investigated with immunohistochemistry.

RESULTS AND DISCUSSION

Achilles tendon rotates as it descends from its musculotendinous junction to calcaneal insertion. The rotation of Achilles tendon could produce sliding motion of one part of the tendon against another, and lead to shear force and tendon injuries, especially at the mid-portion of the Achilles tendon. However, evidence of sliding motion and shear force inside the tendon to verify the above theory is lacking [4].

Lubricin was identified in all Achilles tendon samples in this study. In normal tendinous tissue (Figure 1A), the bundles of collagen fibers were well aligned. Fibroblasts were arranged between the parallel collagen bundles with the fine spindle shape. Lubricin mainly localized at the splits between collagen bundles, but did not evenly distribute at these splits. The cells at the splits occasionally were stained positive for lubricin. The cells, especially far from the splits, were negative for lubricin staining. The results support the occurrence of sliding motion between collagen bundles as Achilles tendon is used. The sliding motion induces shear force at the interface of collagen bundles. Shear force stimulates lubricin expression. Lubricin facilitates interfascicular movement in Achilles tendon as it does in tendon and other musculoskeletal tissues.

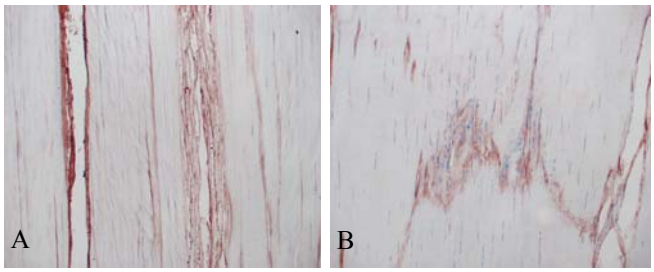

Figure 1: Lubricin in normal (A) and pathological (B) tissues of human Achilles tendon.

In addition to normal tendinous tissue, lubricin was identified abundant in pathological tendinous tissue, in which the structure of tendon bundles was disrupted, and the cells were present in much higher density with rounded nuclei (Figure 1B). It was found that lubricin could inhibit cell attachment, proliferation, and tissue healing [5-7].The presence of lubricin in the area of pathological tissue provided a rationale for the failed healing response in the tendinopathic Achilles tendon.

Overuse is regarded as a major causative factor for tendinopathy [4]. It is able to introduce extra shear force in Achilles tendon. Extra shear stress could result in abrasion of Achilles tendon. Meanwhile, extra shear force stimulates the over-expression of lubricin. Over-expressed lubricin inhibits tenocytes to repair the abrasion. The synergy of the abrasion resulting from shear force and a weak healing ability with the influence of over-expressed lubricin could induce progressive microtrauma, degeneration and rupture of Achilles tendon.

CONCLUSIONS

This study provides the evidence that shear force exists in Achilles tendon, and shear force could play the important roles in the development of Achilles tendinopathy.

INTRODUCTION

The incidence of Achilles tendon rupture (ATR) has increased in recent decades, but an agreement on the appropriate treatment of this injury has yet to be reached [1]. All available treatments, whether surgical or conservative, lead to long-term functional deficits in patients [2-3]. As it remains unclear how these functional deficits develop in ATR patients, their prevention is difficult. It has been suggested that the development of altered sagittal plane mobility may be linked to post-injury lengthening of the Achilles tendon (AT) [2-3], but this remains to be observed in both short-term and long-term assessments. Gait analysis and ultrasonography allow for non-invasive measurements of in vivo ankle mobility and AT length, and therefore offer a strong combination for examination of post-operative status. We hypothesized that the injured AT, when compared to the contralateral side, would increase in length with time after treatment, which would simultaneously yield changes in sagittal plane mobility.

METHODS

Two groups were compared in this work: a prospective patient cohort (n=14) assessed at 8, 12, and 16 weeks after ATR, and a retrospective patient cohort (n=20) assessed 2-6 years after ATR. This study was approved by the local ethics commission and all patients gave informed consent and received percutaneous ATR repair by the same surgeon. Ankle mobility was assessed with gait analysis, in which lower extremity kinematics were collected using 10 infrared cameras (f=120Hz, VICON-MX, Oxford, UK) and 22 reflective markers. Ankle angles were calculated using ISB-recommended conventions [4]. Resting AT length was non-invasively measured using B-mode ultrasonography (f=25Hz, Esoate, Genoa, Italy), while patients were seated with an outstretched knee and 20° of ankle plantarflexion. Data was collected for both the injured and contralateral sides for all assessments. Maximum dorsiflexion and plantarflexion angles, overall sagittal range of motion (ROM), and resting tendon length were compared by time point (8, 12, 16 weeks and 2-6 years post-op). Statistical differences were calculated in SPSS (IBM, Armonk, USA) using one-way ANOVAs and paired t-tests.

RESULTS AND DISCUSSION

At all measurements, patients exhibited significantly lower sagittal ROM, and lower maximal plantarflexion angles during gait (Fig. 1), on the injured (INJ) compared to the contralateral (CON) limb. Higher dorsiflexion was found on INJ starting at 12 weeks post-op when compared to CON. When comparing across time points, maximal plantarflexion on INJ was significantly lower at 8 (p=0.001), 12 (p=0.011), and 16 weeks post-op (p=0.019) compared to 2-6 years post-op (Fig. 1), which were also seen on CON.

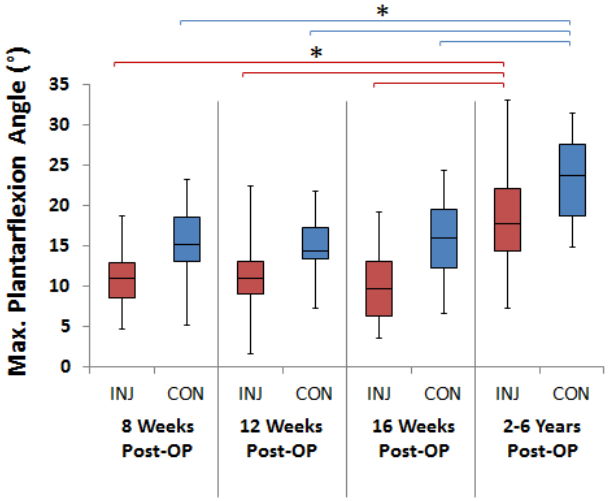

Figure 1: Maximal ankle plantarflexion during gait at all time points. (* denotes p<0.05)

Though rest tendon length was found to be significantly longer on INJ than CON at all time points, no differences were found when comparing the different time points.

CONCLUSIONS

The primary findings of this work indicate that AT lengthening is already present at 8 weeks after surgery and remains unchanged thereafter. Though limited changes were found in rest tendon length at all different time points, maximal plantarflexion increased with time after surgery on both INJ and CON. This increased plantarflexor mobility is unlikely to be due to changes in rest AT length, considering that these changes occur on both limbs, but more plausibly due to increased strength in the triceps surae muscles connected in series. Furthermore, the potential cause for higher dorsiflexion values on the INJ limb may stem from a longer AT rest length in the MTU, which supports previous trends found in smaller cohorts [2]. This indicates that post-ATR deficits in both function and structure are already established as early as 8 weeks after repair, similar to results from radiological studies [5]. Furthermore, these functional and structural deficits remain present in ATR patients long after injury. Future investigations that aim to hinder tendon lengthening after ATR should closely monitor the initial two months after injury.

MUSCLE MODULARITY IN RABBITS WITH ACHILLES TENDINOPATHY

INTRODUCTION

Inappropriate mechanical loading of the Achilles tendon causes tendinopathy leading to locomotor impairment. Muscle synergies represent the underlying neuromuscular strategies of different locomotor tasks in healthy and pathological conditions. Muscle synergy consists of muscle weightings and non-negative factors of lower dimensionality than the number of muscles. The extracted non-negative factors can also be fitted with Gaussian curves to create Gaussian excitation primitives (XPs), which are more fundamental representation of multi-muscle activation patterns. Although rarely studied, task-specific and common-shared synergies exist across tasks in humans and animals [1], the latter characterizing a single set of task-generic synergies. Modulation of these synergy modules can be sufficient to estimate electromyograms (EMGs) of different tasks, including those not used for establishing these synergies [2]. However, it is still unknown whether it is possible to create a single set of generic synergies, which can represent different locomotor tasks of both healthy and pathological conditions, i.e. condition-task-generic synergies. If so, these synergies can be used to construct a larger set of muscle excitations than experimentally available, which then can be used to drive neuromusculoskeletal (NMS) models. To-this-end, using the rabbit as an animal model, we examined for differences in synergies across healthy rabbits and rabbits with induced Achilles tendinopathy (RwAT) for hopping and small box-jumping tasks. Also, we examined if condition-task-generic synergies can reconstruct EMGs of different tasks and health conditions or it is necessary to optimize either or both of synergy weightings and/or Gaussian XPs to improve the EMGs reconstruction quality of different tasks and health conditions.

METHODS

Four rabbits were injected with collagenase in the mid-portion of left Achilles tendon to induce tendinopathy. EMGs were recorded from eight muscles from three healthy rabbits and five muscles from four RwAT. Across both health conditions, four muscles were common. EMG data were band-pass filtered, full-wave rectified, and low-pass filtered to create EMG linear envelopes. Using non-negative matrix factorization algorithm, synergies were extracted from five EMG datasets: 1) healthy hopping, 2) healthy small box-jumping, 3) tendinopathy hopping, 4) tendinopathy small box-jumping, and 5) condition-task-generic. We first reconstructed the EMGs of RwAT using synergies of both conditions to identify differences in synergies. Then, we investigated whether EMG reconstruction quality of condition-task-specific EMGs reconstructed from the condition-task-generic synergies could match those reconstructed from condition-task-specific synergies. We further assessed if reconstruction quality of these EMGs could be improved if: (i) condition-task-generic Gaussian XPs were optimised, and muscle weightings were fixed, (ii) muscle weightings were optimised, and Gaussian XPs were fixed, (iii) both the muscle weightings and Gaussian XPs of condition-task-generic synergies were optimised. Reconstruction quality of the EMGs was assessed using variability accounted for (VAF) and coefficient of determination (R^2).

RESULTS

Four synergy modules were extracted from healthy rabbit's dataset and three synergy modules from RwAT and condition-task-generic dataset (Figure 1).

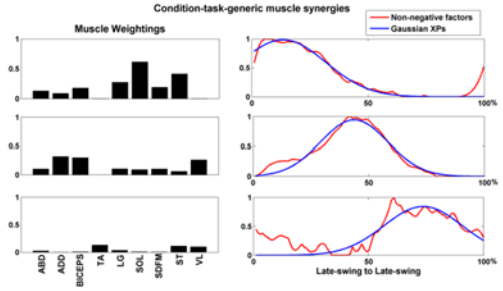

Figure 1: Muscle synergies extracted from condition-task-generic EMG datasets.

Reconstruction of EMGs of RwAT using synergies from both health conditions showed differences in modules across health conditions for both the tasks. Condition-task-generic synergies well reconstructed most of the EMGs of different tasks for both health conditions if the muscle weightings were optimised and the Gaussian XPs were fixed with VAF and R^2 values of each muscle $\geq$ 75% and 0.45.

CONCLUSION

Our results indicate that condition-task-generic Gaussian XPs with optimized weightings can predict EMGs across task and health conditions. Subsequently, a single set of condition-task-generic synergies with optimized weightings will be used to drive NMS models to estimate Achilles tendon forces in healthy rabbits and RwAT to provide insight into the tendon strain in healthy and pathological rabbits.

VARIATION IN TIBIALIS POSTERIOR MUSCLE AND TENDON INTERACTION: IMPLICATIONS FOR TENDON DYSFUNCTION.

Jayishni N Maharaj, Andrew G Cresswell and Glen A Lichtwark
The University of Queensland
Corresponding author email: jayishni.m@uq.edu.au

INTRODUCTION

While all tendinous structures in the human body act to transfer muscular forces to the bone, some also have the potential to operate as springs to recycle energy. Storage and return of elastic energy within tendons can maximize force generation by mimimising the shortening of muscle fascicles. Strains of up to 7% [1] have been measured in the Achilles tendon during running; recycling energy but potentially predisposing itself to injury if too large.

Like the Achilles tendon, the tibialis posterior (TP) tendon is capable of recycling mechanical energy, which helps power subtalar joint (STJ) motion during walking [2]. In early stance, the tendon absorbs energy as the fascicles produce force relatively isometerically to resist STJ pronation. Although injury to the TP tendon has been implicated in populations which demonstrate large degrees of STJ pronation, it remains unclear whether tendon strain is a consequence of larger forces required to resist larger STJ displacement, or altered material properties of the tendinous tissues. Therefore, the aim of this study was to assess the relationship between muscle fascicle and tendon strain and STJ kinematics and kinetics (moments, and work).

METHODS

Twenty-four asymptomatic participants (13 male, 11 female, age 21-28 yrs, body mass 57-83 kg) walked barefoot on a force instrumented treadmill at their preferred velocity. 3D-motion capture, ground reaction forces, electromyography and ultrasound images of the TP muscle were simultaneously recorded. Muscle fascicle lengths were measured from the ultrasound images (80 Hz) using a semi-automated tracking algorithm. Joint kinematics, kinetics and muscle tendon unit (MTU) length changes were determined using a scaled Opensim model and inverse kinematics and inverse dynamics. The length of the tendinous tissue was determined by subtracting the length of TP fascicles in the direction of the tendon from the change in whole TP MTU length. Length changes were calculated relative to toe-off and normalized to their respective length during quiet standing. Calculated STJ moments, the net internal moments produced by the structures at the STJ, were normalised to foot length and body mass and were expressed in non-dimensional units (NDU). Linear regression analysis was performed to associate STJ mechanical measures (peak displacement and moments) with TP muscle dynamics (peak fascicle shortening and tendon strain) during the negative STJ power period (early stance).

RESULTS AND DISCUSSION

Although TP muscle fascicles differed in their pattern of length change to that of the MTU during stance, peak fascicle shortening failed to statistically demonstrate any meaningful relationships to peak STJ moments or displacement. During stance, the tendon functioned in similar manner to that of the MTU, experiencing peak strains during the negative STJ power period. Tendon strain was not associated with peak joint moments (Fig 1E) or the onset and duration of muscle activation. Tendon strain was significantly associated with STJ displacement during pronation (R^2 = 0.52; P = <0.01, see Fig 1F) as well as negative STJ work (R^2 = 0.23; P = 0.02), which characterises mechanical energy absorption.

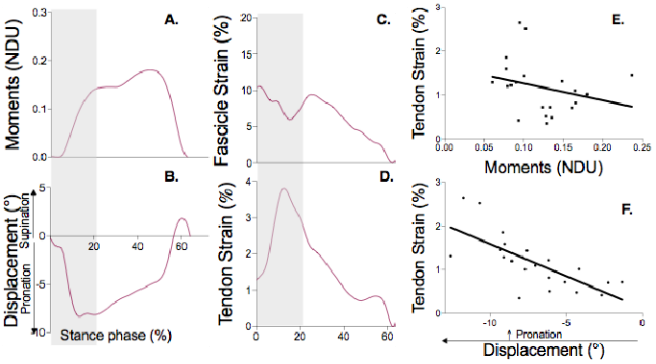

Figure 1: Representative data of subtalar joint (STJ) moments (**A**), STJ displacement (**B**), tibialis posterior (TP) fascicle strain (**C**), and TP tendon strain (**D**). STJ moments are expressed in non-dimensional units (NDU). Shaded area represents the period of negative STJ power. The plots on the right represent the effect of STJ moments (**E**) and displacement (**F**) on TP tendon strain during the negative power period.

CONCLUSIONS

These results illustrate that when walking at a preferred velocity, the TP muscle fascicles experience similar length changes across different individuals despite the differences in MTU length change. The lack of association between fascicle shortening and STJ mechanical measures suggests that the TP muscle generates similar forces despite variations in STJ displacement. Similarly, because there was no relationship between STJ joint moment and tendon strain, this implies that increased tendon strain may not necessarily be a result of greater muscle forces but perhaps due to differences in the mechanical properties of the tendon itself. This is supported by previous studies that have reported broad variations in both stiffness and elastic modulus in individuals during in-vivo measurements of the human Achilles tendon [1]. As such, people with more compliant TP tendons are likely to undergo greater pronation during energy absorption in early stance.

FIBRE TORSION IN THE ACHILLES TENON REDUCES STRESS CONCENTRATION AND IMPROVES TISSUE STRENGTH

[1,2] **Vickie B. Shim**, [1]Geoff Handsfield, [1]Justin Fernandez, [2]David G Lloyd and [1]Thor Besier

INTRODUCTION

Achilles tendon injuries are common, occurring about 250,000 per year in the US alone, yet the mechanisms of tendon injuries and degeneration remain unknown. One interesting feature in the structure of the Achilles tendon is that the fibres of the Achilles tendon do not descend straight down but experience a variable degree of spiral torsion. A number of authours have speculated that fibre torsion is nature's way of increasing tendon strength that allows elongation and elastic recoil in the tendon while others suggested that fibre torsion results in less fibre buckling leading to less deformation of individual fibres under tension[1-3]. However, quantitative analysis of the role of fibre torsion in the Achilles tendon has not been done. The aim of this study is to investigate the role of fibre torsion presents in the Achilles tendon using subject-specific FE model and tissue mechanical experiment.

METHODS

Data from a previous study [4]was used, which we used to generate ten subject-specific finite element models of the Achilles tendon (eight female and two male, average age 68 yrs) [5]. Van Giles et al. [3] reported the existence of fibre torsion in the Achilles tendon and quantified the degree of torsion to be between 10 to 60 degrees with the average around 37 degrees. We used the mutually-orthogonal curvilinear material coordinate system in our FE models and aligned it according to the fibre torsion in the Achilles using a previously validated fibre fitting procedure [6]. Five different torsion angles were implemented – 0,15,30,45,60 degrees. The values of material coefficients for transversely isotropic material properties [7] were estimated with parameter optimization. In order to characterize the influence of fibre torsion, material coefficients for different torsion angles were obtained separately. Therefore, for each tissue, we performed five material parameter optimizations at the five different torsion angles investigated – 0, 15,30,45 & 60 degrees. We then numerically predicted tendon rupture load using the experimentally reported failure stress value of the Achilles tendon (~100N). For each torsion angle (0,15,30,45,60 degrees) case, we applied uniaxial stretch to the tendon using the force ratio of triceps components [8] until failure and recorded the rupture load. This was repeated for the ten subject-specific models at the five different torsion angles (total 50 simulations) to analyse the influence of fibre torsion in tissue strength.

RESULTS AND DISCUSSION

Fibre torsion was successfully implemented as shown in Fig 1. Stress distribution patterns changed after implementation of fibre torsion in the model. When no fibre torsion is present, the stress is concentrated primarily on the medial side of the tendon but fibre torsion redistributed this stress concentration to both medial and lateral sides, essentially relieving stress concentration. As seen in Fig 2, the degree of fibre torsion plays a role in how much stress is redistributed. As for rupture loads, it was found that fibre torsion angles of up to 30 degrees significantly improved tissue strength up to 33% (p=0.008). When considering the predicted rupture loads from all five cases, there appears to be a range of torsion angles that are optimal for tissue strength and when goes outside of this range, the tissue strength actually decreased.

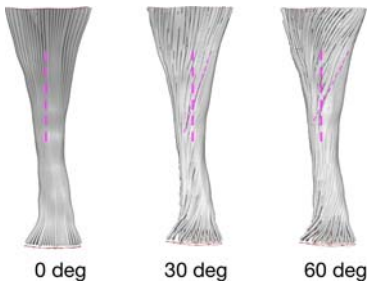

Fig 1. Fibre torsion implemented in FE models. It is a posterior view with medial on the right and lateral on the left

CONCLUSIONS

Our results showed that fibre torsion in the Achilles redistributes stresses on both medial and lateral side. The motion of the foot from dorsiflexion eversion to plantar flexion inversion results in medial side of the tendon to experience higher stress and strains[9] (0°case in Fig. 2). This will be detrimental to the tissue and will weaken the overall strength of the tissue. Fibre torsion, however, redistributes this stress concentration on the medial side to wider areas, subsequently relieving stress concentrations. This will improve the strength of the tissue especially under in-vivo loading cases.

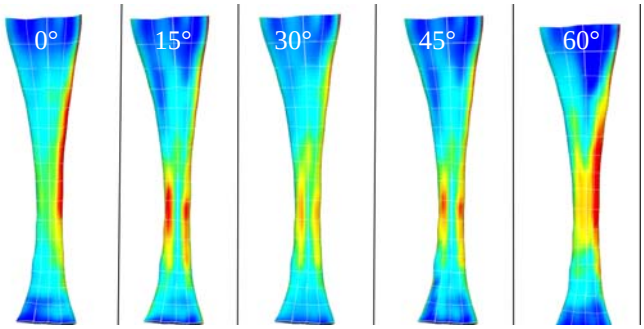

Fig 2: Stress changes with respect to the fibre torsion angle changes. The presence of fibre torsion changes the stress concentration on the medial side to both medial and lateral sides

INTRODUCTION

The uterus is an organ where an embryo/fetus grows inside the mother's body during pregnancy. While there are many severe uterine related diseases, many of the patients in most of cases are subjected to hysterectomy that refers to a removal of uterus from the patients. As the needs of uterine regeneration have been raised, many researchers are attempting to solve this issue through tissue engineering approaches.

Our group firstly attempted a uterine regeneration using decellularized matrix (DM) fabricated by high hydrostatic pressure[1]. Although the DM has been regarded as a powerful tool in regenerative medicine, the scaffold may disturb any biochemical interaction between embryo and native tissues during early implantation of embryo for further development of the embryo inside the uterus. On the other hand, we developed a method to fabricate a scaffold free tissue (SFT) using bovine chondrocytes[2]. Since the SFT does not require any artificial materials that may cause foreign body reaction after transplantation, the use of SFT in uterine regeneration has been highlighted. The aim of this study is to reconstruct the scaffold-free tissue using rat endometrial stromal cells and further to evaluate its function with regard to regeneration *in vitro*.

METHODS

Rat endometrial stromal cells (rESCs) are isolated from 9 weeks old female GFP Sprague Dawley (SD) rat. The rESCs were cultured with DMEM-LG medium containing 10% fetal bovine serum (Funakoshi) and 1% Antibiotic-Antimycotic (GIBCO). In order to form a monolayer of rESCs, the cell suspension at a density of 1.0×10^5 cells/ml was transferred into a glass cloning ring (Asahi glass), which was placed on a gas permeable lummox dish (Sarstedt). After 2 days of incubation at 37°C with 5% CO_2, we transferred another cell suspension at a density of 2.5×10^6 cells/ml on top of the monolayer. The cloning ring was removed gently after 3 hours of incubation, and a single layer of tissues was formed. This step was repeated until stacking three layers together, fabricating SFT using rESCs.

The rESC SFT was then transplanted into 9 weeks old female SD rat. The uterus consists of three different layers; epithelial cell layer (inner), endometrial stromal cell layer (middle), and smooth muscle cell layer (outer). The rat was subjected to anesthesia followed by partial uterine defect including removals of epithelial and stromal cells layer. At the location where the partial uterine defect was made, the SFT was inserted and recovered for 3 days. The SFT transplanted was then collected for histological assay.

RESULTS AND DISCUSSION

The rESC SFT collected was evaluated by histological assay. Hematoxlyin and Eosin (HE) staining results showed

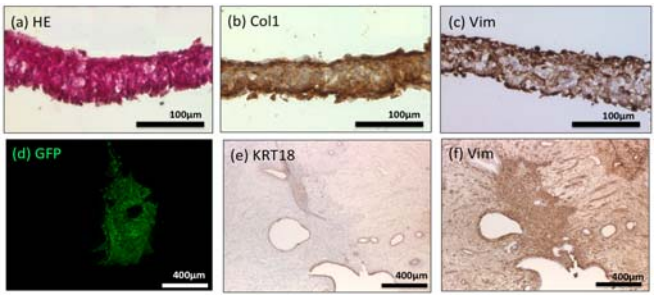

Figure 1: The staining images of rESC SFT *in vitro* (a) – (c) and *in vivo* after 3 days of transplantation (d) – (f); (a) Hematoxylin and Eosin (HE) staining, (b) Type I collagen (Col1) and (c) Vimentin (Vim), (d) GFP image, (e) cytokeratin 18 (KRT18), and Vimentin (Vim).

that the rESC SFT was successfully formed in a disc shape with a thickness of 100 – 125μm. The SFT was tightly packed with cells without any vacant space that may indicate cell death. Moreover, immunostaining results represented that vimentin and type I collagen were entirely detected inside the SFT.

Then, the SFT was transplanted into SD rat for 3 days. In Fig. 1(d), the location of GFP detected in the uterus corresponded to where vimentin were strongly expressed in Fig. 1(f). In Fig . 1(e), the epithelial cell marker, cytokeratin 18 (KRT18) was also detected around the SFT as well as native tissues. The epithelial cells from the native tissue seemed to cover the SFT after 3 days. The results altogether showed that the SFT was integrated into the donor tissues without any foreign body rejection in as little as 3 days.

CONCLUSIONS

In this study, we developed a novel method to fabricate the SFT using rESCs. Unlike general methods in cell-sheet engineering, our novel method did not require thermo-responsive culture dishes, so that it is a cost friendly method. The SFT was successfully formed, expressing vimentin and type I collagen. In as little as 3 days, the SFT was successfully integrated into the donor tissue in SD rat *in vitro*. In further study, we need to transplant with a greater size of SFT for whole uterine regeneration. Moreover, the pregnancy test will be carried out to exert its pregnant ability as normal after transplanting the SFT.

INTRODUCTION

The treatment of cartilage defects and disease has remained a challenge due to the avascular nature of cartilage tissue, which prevents the tissue from self-repairing. Cell-based tissue engineering is emerging as a promising clinical option to address tissue and organ failure by implanting biological substitutes for the compromised tissues, and offers the potential advantage of immediate functionality.

Although traditional methods of tissue engineering typically use scaffolds, scaffold-free tissues are of increasing interest as there is immediate biocompatibility and less material required to produce the tissues. On the other hand, mechanical stimulation can be used to alter the signaling of cells; for instance, low-intensity pulsed ultrasound (LIPUS) can modulate the metabolism of cells and induce cartilage matrix formation. Our purpose was to clarify the modulatory effects of the TGF-β3 treatment through LIPUS on scaffold-free dedifferentiated bovine articular chondrocyte tissues.

METHODS

Full-thickness articular cartilage was isolated from 4-6 week old bovine calves within 24 hours of slaughter. Bovine articular chondrocytes at passage 2 were subcultured and washed twice with Dulbecco's Modified Eagle Medium high glucose and resuspended with chondrogenic medium consisting of DMEM-high glucose supplemented with dexamethasone, sodium pyruvate, ascorbic acid 2-phosophate, L-proline, ITS-plus, penicillin, streptomycin and fungizone, at a density of 4.3×10^7 cells/mL. The cell suspension was transferred into glass cloning rings of 0.7 cm inner diameter at 250μL/ring, and then placed on a semi-permeable hydrophilic membrane dish. After 24 hours of incubation, the rings were removed and the tissues were further incubated for 24hours and then transferred to a 6-well plate containing 5 mL of chondrogenic medium in each well. The medium was exchanged every two days.

The ultrasound emission apparatus was provided by Sigmax, Japan and consisted of a power supply, function generator and three transducers connected to a timer that automatically applied the LIPUS each day. A LIPUS signal in a square wave with 200μs tone bursts at a frequency of 1MHz was delivered to the tissues from the LIPUS transducers through a silicone gel coated with ultrasound gel.

LIPUS treatment was applied for 20min per day over a 10day period. Tissues were divided into four groups: control (no LIPUS or TGF-β3 applied), LIPUS alone, TGF-β3 alone, and LIPUS+TGF-β3. All tissues were cultured in 5mL of chondrogenic medium per tissue per well.

RESULTS AND DISCUSSION

In this study, we presented how LIPUS inhibited TGF-β3-induced hypertrophic gene expression and signaling, and further enhanced the re redifferentiation of dedifferentiated chondrocytes. TGF-β3 up-regulated cartilage-specific gene expression and increased GAG and collagen protein production; however, there was also the up-regulation of hypertrophic markers of collagen type X and MMP13, and the phosphorylation of p38, indicating that TGF-β3 could not suppress terminal differentiation. However, the addition of LIPUS to TGF-β3-treated tissues significantly down-regulated some hypertrophic gene expression (Fig. 1) and cellular signaling, and enhanced collagen type 2 protein production, suggesting that LIPUS can modulate the effects of TGF-β3 towards a chondrogenic lineage in dedifferentiated articular bovine chondrocytes. By inhibiting hypertrophy in the tissue prior to implantation, the tissue could potentially better develop into articular cartilage instead of fibrocartilage, as commonly seen in damaged cartilage. Therefore, the LIPUS system in combination with TGF-β3 treatment can be an effective tool in clinical studies for cartilage tissue engineering.

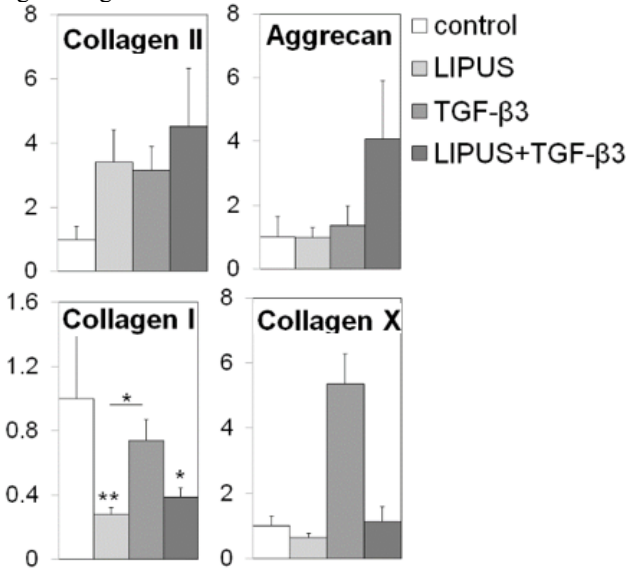

Figure 1 Gene expression relative to the control case of tissues subjected to 55 mW/cm^2 LIPUS for 20 min/day over 10 days with or without TGF-β3. All values at n=3 mean±STD, significance relative to control unless indicated by bar, * $p<0.05$, ** $p<0.01$

CONCLUSIONS

We demonstrated that LIPUS treatment can effectively down-regulate the mRNA expression of cartilage degrading enzymes and prevent the phosphorylation of p38, a hypertrophic marker, initiated by TGF-β3 treatment in a scaffold-free model with customizable shape. Through these results, we propose that LIPUS can be used to modulate the effect of TGF-β3 on the chondrogenic differentiation of dedifferentiated bovine articular chondrocytes and may be an effective tool for the engineering of cartilage tissues for the treatment of cartilage diseases.

ESTIMATION OF GLYCOCALYX LAYER DEFORMATION IN VASCULAR ENDOTHELIAL CELLS IN RESPONSE TO FLUID SHEAR STRESS

INTRODUCTION

It has long been reported that vascular endothelial cells (ECs) respond to fluid shear stress and change their morphology and functions, such as permeability and production of various chemical substances. Recently, it became clear that several-100-nm-thick glycocalyx layer (GL) that covers the surface of ECs plays pivotal roles in their biomechanical responses [1]. When their glycocalyx layer is removed enzymatically, ECs fail to show elongation and alignment in response to shear stress. Removal of glycocalyx layer also decreases nitric oxide production in response to shear stress severely. Since GL is made of sugar chains coming up from the endothelial surface, it may be sheared by fluid flow and this may amplify the torque applied to mechanoreceptors on the cell membrane [2]. However, to our knowledge, there is no quantitative data on the deformation of GL in response to fluid shear stress. In this study, we estimated shear deformation of GL in response to fluid shear stress by measuring 1) thickness change in the GL, 2) change in fluorescent intensity distribution across the boundary of photobleached area on the GL, and 3) displacement of quantum dots bound to the top of the GL and the surface of cell membrane.

METHODS

A murine vascular endothelial cell line F-2 (Riken BioResource Center, Tsukuba, Japan) was used as the test model. The cell membrane and the glycocalyx layer of the F-2 cells were stained with CellMask Plasma Membrane Stains (Invitrogen, Carlsbad, CA, USA) and DyLight 488 Tomato Lectin (Vector Laboratories, Burlingame, CA, USA), respectively. We plated the cells in a laboratory-made laminar flow chamber to apply fluid shear stress under a confocal laser scanning microscope (FV-1200+IX-81, Olympus, Tokyo, Japan). If the GL is sheared, its thickness may decrease. We measured the thickness with a 100x oil-immersion objective (N.A.=1.4). When the GL with photobleached area is sheared, its borderline may become blurred more (Figure 1).

We then applied quantum dots (Qdots) to the top of heparan sulfate and PECAM-1 on the cell membrane. Qdot525 streptavidin conjugate (Invitrogen) was bound to the top of heparan sulfate via Anti-Heparan sulfate glycosaminoglycan biotin conjugated (US Biological, Salem, MA, USA). Qdot655 anti-IgG conjugate (Invitrogen) was bound to PECAM-1 via Anti-PECAM-1 antibody (Santa Cruz Biotechnology, Dallas, TX, USA). We then measured the displacements of Qdots in response to fluid shear stress.

RESULTS AND DISCUSSION

The GL thickness decreased from 840 nm to 750 nm in response to shear stress of 6 Pa, which corresponds to 4.5°/Pa. By measuring fluorescent intensity distribution across the borderline before and after application of fluid shear stress (6 Pa) and analyzing it with a simple physical model, we obtained shear deformation of 5.1°/Pa. We then measured the displacements of Qdots in response to fluid shear stress (2 Pa), and found that displacement was larger by 200 nm for Qdots bound to the heparan sulfate than that bound to PECAM-1. This value corresponds to 7.1°/Pa if the GL thickness is assumed to be 800 nm.

CONCLUSIONS

All of these methods gave similar results. The shear deformation of the GL might be 5-10°/Pa.

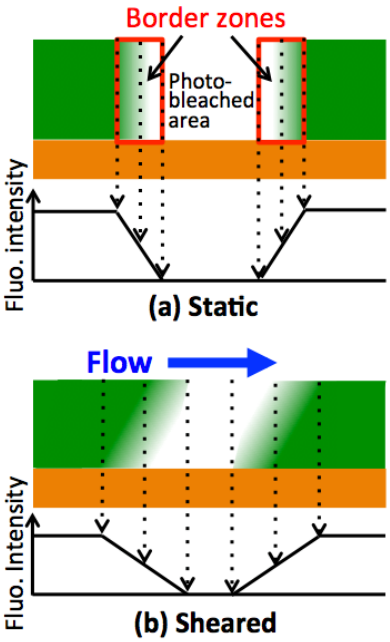

Figure 1: Schema of deformation of photobleached area of the glycocalyx layer. Slopes of fluorescent intensity in the border zones may decrease in response to fluid shear stress.

A MOLECULAR DYNAMICS STUDY ON THE ELASTICITY AND UNFOLDING PATHWAY OF SINGLE TROPOCOLLAGEN MOLECULES

INTRODUCTION

Collagen is the main structural protein found in vertebrates, providing the mechanical integrity for connective tissues including bone and cartilage. In recent years, molecular dynamics (MD) simulations have been extensively used to characterize the mechanical properties of collagen-like molecules. However, there is a significant gap between the loading strain rates in computational studies and those employed in experimental characterizations which tend to be more close to the physiologically relevant deformation rates. Gautieri et al. investigated the effect of deformation rate on the deformation behaviour and mechanical properties of an 8-nm-long collagen-like molecule [1]. This study found that the unfolding pathway and the Young's modulus of the molecule converge when the pulling rate is under a certain value. However, this study has two limitations: 1) the length of the studied molecule is 8 nm which is much shorter than the full length (300 nm) of the collagen molecule; 2) and the molecule does not possess the diversity of the triplets in the wild-type collagen molecules. This study aims to fill this gap by investigating the deformation rate effects on the collagen segments located in the second overlap region and the intact second D-period of the microfibril.

METHODS

We generated the collagen segments located in the second overlap region and the intact second D-period of the 3HR2 microfibril based on the low-resolution fiber diffraction type I collagen structure (pdb code: 3HR2).

In this study, all MD simulations are carried out using GROMACS 5.0.4 with GROMOS96 54a7 force field. Each collagen molecule segment is fully solvated using a triclinic SPC water box, making sure that there is a 1.0 nm water boundary on all sides. For the charged protein models, appropriate number of counter-ions (Cl- and Na+ ions) are added to neutralize the whole system. Periodic boundary conditions are applied to all the directions. Covalent bond lengths involving hydrogen bonds (H-bonds) are constrained using the SETTLE and LINCS algorithms, allowing a time step of 2 fs. Non-bonded interactions are calculated using a cutoff distance for neighbour lists at 1.2 nm, with a switching function between 1.0 nm and 1.2 nm. The fourth order Particle-Mesh Ewald sums (PME) method is employed to calculate electrostatic interactions, with a columbic cutoff distance of 1.2 nm. The steepest descent algorithm is applied to minimize the energy of the system. To achieve a good starting point for MD simulations, each model is further equilibrated in the following three steps: firstly, a 30 ns NVT MD simulation is carried out at a temperature of 310 K (37 ℃); secondly, a 30 ns NPT MD simulation is performed at a pressure of 1 bar and a temperature of 310 K, in which the whole protein is held fixed to relax water molecules; finally, another 20 ns NPT MD simulation is used to equilibrate the system where only the first and last Cα-atoms of each polypeptide chain are restrained.

RESULTS AND DISCUSSION

The unfolding pathway and the Young's modulus of the collagen molecule converge when the deformation rate is smaller than a certain value. However, this critical value is intimately related to the length of the collagen molecule and its amino acid sequence.

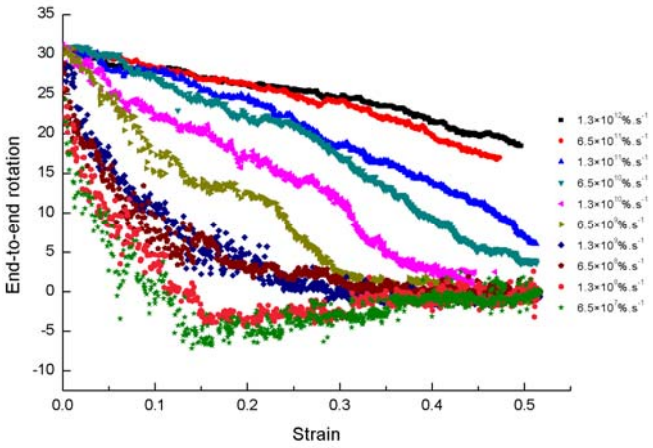

Figure 1: End to end rotation of the collagen segment located in the second overlap region of the microfibril under different pulling rates.

Figure 1 displays three different types of unfolding pathway of the collagen molecule segment under different pulling rates, which indicates that the deformation behavior of the collagen molecule is dependent of its deformation rates.

CONCLUSIONS

This study suggests that it is possible to capture the mechanical properties of a single collagen molecule at physiologically relevant deformation rates using atomistic MD simulations, when the strain rate employed is under a critical value.

IMPROVING CELL SEEDING EFFIECIENCY THROUGH OPTIMUM STRUCTURAL DESIGN OF TISSUE SCAFFOLDS

INTRODUCTION

Despite significant developments in the field of bone tissue engineering, numerous challenges still remain on the way of bone scaffolds to become practical replacements for conventional bone substitutes such as allografts and autografts in clinic. One major issue is poor cell distribution and insufficient nutrient supply [1]. Cell survival in bone scaffolds relies on efficient and sustained oxygen transport, which is especially important in static culturing conditions. Inappropriate and non-uniform increase in cell population can result in formation of diffusion barriers and reduce nutrient transport efficiency which may develop into hypoxia and cause deterioration of cell vitality in the core region of scaffold constructs [2]. The solution to sustaining nutrient supply considerably lies in the structural design of porous tissue scaffolds, which aims to minimise the adverse effect of cell proliferation and deposition.

In the current study, the method of topology optimisation has been proposed to improve the cell seeding condition by creating scaffolds with functionally graded porosity. The key idea is to determine an optimal porosity profile of the scaffold in order to minimize the creation of diffusion barriers resulted from cell deposition, and thereby enhance cell growth and viability in the scaffold.

METHODS

The importance of scaffold porosity in nutrient transport and cell survival is well known in the field of tissue engineering. In the current topology optimisation method, the porosity of the scaffold is considered as a design variable. The topology optimisation seeks improvement in better accommodating total cell number, viability and cell infiltration length by altering regional scaffold porosity. One-dimensional steady-state cell growth simulation is conducted and the response surface method has been employed to relate the tissue scaffold parameters to the cell living conditions. To simulate the changing oxygen concentration over time as a result of oxygen intake by cells, an oxygen diffusion-advection model has been created in a fixed design domain. This domain represents the scaffold environment, containing the tissue scaffold structure, cells and fluid. Cell number and oxygen concentration in the tissue scaffolds can be numerically solved and be used to predict the final cell seeding results. The optimal solutions for cell growth have been obtained and are defined by their step-like porosity profiles.

Moreover, the experimental tests were conducted in order to investigate the effectiveness of the optimized scaffolds structures in terms of improving cell seeding efficiency. For this purpose, gradient porosity polymeric scaffolds were manufactured based on the optimized models. Osteoblast-like cells were seeded onto the fabricated scaffolds to investigate cell seeding outcome in the optimized scaffolds compared with the homogenous pore size scaffolds having similar overall porosity.

RESULTS AND DISCUSSION

The results demonstrated that the proposed topology optimization method can enhance both overall oxygen level and cell viability by manipulating the porosity profile through the scaffolds. The numerical results were validated by the in-vitro experiments which indicated the optimized gradient porosity scaffolds could effectively improve cell seeding efficiency compared with the homogenous pore size scaffolds having similar overall porosity.

CONCLUSIONS

In this study, the optimised structural profiles of tissue scaffolds for cell survival were characterised. The results showed that multi-porosity structures are required to maximise the cell seeding outcome. Moreover, the effectiveness of the proposed optimization method was verified by relevant in-house experimental data.

BRAIN INJURY TOLERANCE LIMITS PER AGE-CLASS BASED ON AXONAL ELONGATION COMPUTATION

Caroline Deck, Debasis Sahoo and Rémy Willinger
University of Strasbourg, UMR 7357-CNRS
Corresponding author email: deck@unistra.fr

INTRODUCTION

Traumatic brain injury (TBI) is the leading cause of death and permanent impairment over the last decades. In both the severe and mild TBI, diffuse axonal injury (DAI) is the most common pathology and leads to axonal degeneration. Computation of axon elongation by using finite element head model in numerical simulation can enlighten the DAI mechanism and help to establish advanced head injury criteria which could permit to evaluate and to optimize head protective systems. The main objective of this study is to propose a brain injury criterion per age-class based on multiscale computation of axonal elongation of a huge head trauma accident reconstruction.

METHODS

A state-of-the art finite element head model (figure 1) with enhanced brain and skull material laws was used for numerical computation of real-world head trauma.

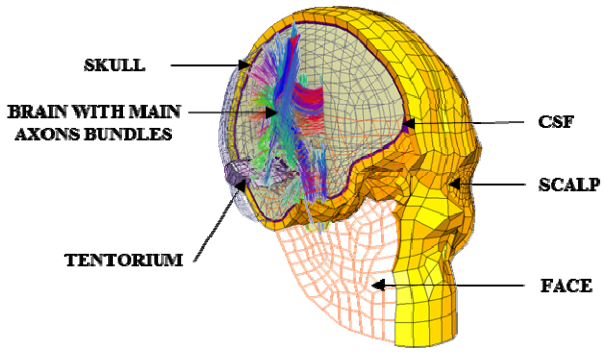

Figure 1: Strasbourg University Finite Element Head Model (SUFEHM)

The implementation of new medical imaging data such as, fractional anisotropy and axonal fiber orientation from Diffusion Tensor Imaging into the FE brain model was performed to improve the brain constitutive material law with more efficient heterogeneous anisotropic visco-hyper-elastic material law [1] and enables it to compute axon elongation at the time of impact [2].

Further, 109 well-documented head trauma cases [2] were simulated by using this state of the art finite element head model. The head trauma database was divided into three different groups depending on victims' age:

- Lower than 30 years old (45 cases),
- Between 30 to 50 years old (34 cases),
- Upper than 50 years old (27 senior cases).

For each head trauma reconstruction, axon elongation as well as Von-Mises stress/strain and first principal stress/strain were computed to derive brain injury tolerance curve per age-class. Statistical analyses of these intra-cerebral parameters were conducted to obtain the most suitable parameter to predict moderate DAI and to derive brain injury tolerance limits per age-class.

RESULTS AND DISCUSSION

A total of 109 head trauma reconstructions were conducted with a state of the art finite element head model. The finite element head model was utilized to perform head impact simulations in accordance with the victim's kinematic analysis outcome. Nine different potential intracerebral parameters to predict DAI were computed during the simulations. Binary logistic regression method was then used for statistical analysis of the correlation between computed intracerebral parameters and the occurrence of brain injury especially moderate DAI corresponding to a victim's loss of consciousness. Based on the statistical analysis of different intra-cerebral parameters, it was shown that axonal strain was the most relevant candidate parameter to predict moderate DAI for each age-class studied. The robustness of the different parameters was also calculated and compared in terms of Nagelkerke's R^2 value.

The proposed brain tolerance limit in terms of axon elongation for a 50% risk of moderate DAI has been established per age-class at:

- 15.2% for age-class lower than 30 years old associated with a Nagelkerke's parameter of 0.94
- 14.5% for age-class 30 to 50 years old associated with a Nagelkerke's parameter of 0.76,
- 14.1% for senior people associated with a Nagelkerke's parameter of 1

This is the first attempt to propose brain injury tolerance limit for senior and more cases involving senior people are needed to confirm this trend.

CONCLUSIONS

An extensive real-world head trauma simulation exercise including age-class analysis was performed on an advanced head FE model including the computation of axonal elongation. Based on the statistical analysis, axonal strain was the most relevant candidate parameter to predict moderate DAI. It was showed that the threshold value in terms of axonal strain for a 50% risk of moderate DAI decrease with the increase of victim's age. Senior people seem to be more sensitive to moderate DAI than the other age-classes.

INTRODUCTION

Concussion is an inherent risk associated with participation in many full contact and collision sports. Rugby has the third highest incidence of concussions in sport [1], however little is known regarding the mechanics of concussive rugby tackling events, their differing impacting systems, and the ensuing cerebral response during rugby game play [2].

The incidence of concussion in the National Rugby League (NRL) corresponds to approximately 14.8-28.3 concussions per 1,000 playing hours, with tackling identified as the most common cause of injury. Shoulder-to-head collisions account for the highest incidence (35%) of rugby league concussive impacts, with both tacklers and ball carriers at greatest risk for injury [1]. There are two common methods of shoulder tackles in rugby league: the ball carrier "fend" and the defensive tackle [3].

While some studies report that the ball carrier is at a greater risk of sustaining a concussion [4], others have demonstrated a greater incidence of tacklers being removed from play for sideline concussion evaluation [1]. Given this discrepancy, the purpose of this study was to compare dynamic response and brain tissue deformation for concussive impacts to determine if an association existed between tackling technique, player position, and reported rates of concussion.

METHODS

Video analysis was used to establish the parameters to reconstruct the real-world concussive events in laboratory. Professional-level rugby league footage provided high-quality game videos, differing camera angles, and instant replays of concussive impacts to allow for an appropriate estimation of the impact location, velocity, and compliance for each reconstruction.

Ten cases of the tackler being injured and ten cases of the ball carrier being injured were reconstructed using a pneumatic linear impactor striking an instrumented 50th percentile Hybrid III headform. The headform was positioned according to the reconstruction data collected during the video analysis, with the position of the impacting arm corresponding to the referenced locations, and the neckform angled based on the real-world event.

RESULTS AND DISCUSSION

There was no significant difference between the two impact conditions for peak resultant linear (a) and rotational accelerations (α), maximum principal strain (MPS), striking velocity (v) and duration (t) (Table 1).

Table 1. Dynamic response and MPS results for defensive tackler and ball carrier shoulder-to-head reconstructions

	Ball carrier	Defensive tackler
a (g)	34.16 (18.00)	27.67 (13.23)
α (krads/s^2)	4.42 (1.84)	3.81 (1.00)
MPS	0.41 (0.12)	0.41 (0.10)
v (m/s)	4.79 (0.91)	5.20 (0.95)
t (ms)	30.72 (4.97)	30.75 (4.73)

There was no significant difference in inbound velocity during shoulder-to-headform reconstructions, when the tackler was injured in comparison to the ball carrier. Shoulder impacts in rugby league result in a longer duration, lower magnitude event, as opposed to the short duration, higher magnitude relationship reported in previous rugby union research [2].

CONCLUSIONS

The main objective of this study was to compare dynamic response and brain tissue deformation in ball carriers and tacklers during rugby league shoulder-to-head concussive impacts. The results yielded no significant differences in dynamic response or MPS metrics between impacting offensive and defensive players during these concussive events. Shoulder impacts in rugby league result in a longer duration, lower magnitude event, as opposed to the short duration, higher magnitude relationship reported in previous rugby union concussion research. This study reflects the importance of accounting for impact compliance when describing the risk associated with collisions.

EVALUATING THE INFLUENCE OF THE AMERICAN FOOTBALL HELMET ON DIRECTIONAL COMPONENTS OF DYNAMIC RESPONSE AND THE MAGNITUDE OF MAXIMUM PRINCIPAL STRAIN

[1] **Karen L. Taylor**, [1]T. Blaine Hoshizaki
[1]University of Ottawa

INTRODUCTION

Advancements in American football helmet designs have led to dramatic reductions in the incidence of traumatic brain injury (TBI) [1]. However, despite helmet use, concussion rates remain high in football [1]. The discrepancy between mechanism of injury and current helmet design objectives have led to non-optimal protection for concussive injury risk. Researchers have shown concussion is primarily the result of tissue strain [2]. Due to the low shear modulus, inhomogeneity, and anisotropic nature of brain tissue, the extent to which tissue is strained is strongly influenced by directionality and degree of three-dimensional (3D) brain motion [3,4]. Consequently, motion of the brain in certain axes may be more detrimental than others as resilience of the head/brain system varies and is influenced by changes in the direction of the impact vector. Therefore, to provide information for helmet innovation aimed to reduce the risk of concussive injury, an understanding of how brain motion influences tissue strain magnitudes under various impact conditions (location and direction) is required. Determining the correlation between the three directional components of 3D brain motion, the dominant directional component, the resultant, and tissue strain will allow helmet designers to target reductions to the impact response variable most strongly associated with higher strain values. The purpose of this study is to determine correlations between directional components of 3D brain motion, the dominant component, the resultant component, and brain tissue strain.

METHODS

Dynamic response is collected by impacting a bare and helmeted 50th percentile Hybrid III head-form with a linear impactor. A standard American football helmet with 3D engineered liner structures was used (m=2016g). Impacts at 20 conditions (5 locations, 4 directions) were replicated three times for repeatability.

Nine single-axis Endevco accelerometers (Endevco, San Juan Capistrano, CA) were used and signals were passed through a TDAS Pro Lab system (DTS, Calabasas, CA) before being processed by TDAS software. The output from the DTS software is the (X,Y,Z) and resultant (R) linear and rotational acceleration (dynamic response) loading curves. Dominant coordinate axis is defined as the coordinate component with the greatest peak magnitude.

Brain deformation, measured as maximum principal strain (MPS), is established using the University of College Dublin Brain Trauma Model (UCDBTM). Correlations between peak resultant, peak coordinate components, peak dominant component and MPS were determined collapsing across 20 impact conditions and two impact velocities (2.0 and 4.0 m/s) for the bare and helmeted impacts individually.

RESULTS AND DISCUSSION

For bare headform impacts, strong correlations exist between peak resultant linear acceleration, peak dominant linear acceleration, peak resultant rotational acceleration, peak dominant rotational acceleration and MPS. Moderate correlations exist between the peak coordinate components X,Y,Z of dynamic response and MPS. The same level of correlation exists for the helmeted impacts, indicating the helmet does not significantly change the overall directional motion of the head.

Dynamic Response	Component	r Value	
		Bare	Helmeted
Linear	Resultant	0.897	0.841
	Dominant	0.869	0.806
	X	0.482	0.559
	Y	0.659	0.580
	Z	0.558	0.707
Rotational	Resultant	0.907	0.926
	Dominant	0.888	0.907
	X	0.656	0.729
	Y	0.459	0.700
	Z	0.707	0.671

Table 1: R values for peak resultant, dominant and coordinate components of linear and rotational acceleration and MPS for bare and helmeted conditions

The results show a high correlation between peak resultant dynamic response and MPS. This supports the use for helmet performance evaluation in terms of injury risk protection when using MPS as the measure of injury risk.

However, in order to improve helmet technology, dominant coordinate axis, which is also strongly correlated to MPS should be used. The resultant of dynamic response represents the combined motion of the brain. However, the dominant coordinate dynamic response is able to provide a better representation of the direction of the brain motion. Technology to manage specific brain motion should be developed in order to reduce MPS. Future helmet innovations and helmet designs should target dominant coordinate response metrics to improve head protection.

CONCLUSIONS

Current football helmets are not designed to specifically manage the direction of impact accelerations. When developing helmet technology for American football, it is important to consider targeting reductions in the dominant coordinate component of brain motion in order to reduce magnitudes of maximum principal strain.

BRAIN TISSUE STRAIN RESULTING FROM HELMET-TO-HELMET HEAD IMPACTS IN AMERICAN FOOTBALL (STRUCK VS STRIKING PLAYER)

[1] **Clara Karton**, [1]T Blaine Hoshizaki and [2]Michael D Gilchrist
[1]University of Ottawa

INTRODUCTION

It has been well established that American football participation carries with it one of the highest risks/rates associated with head and brain injury. Much of the biomechanical research to date has primarily examined risk in terms of concussion. Typically the player being struck by another is at greatest risk of sustaining a concussion, resulting in the offensive team being more vulnerable to injury [1]. However, American football like many contact sports has a high risk of sustaining repetitive brain trauma associated with neurological disorders [2]. Contact using the head is integral to how this game is played, resulting in a high frequency of head contact experienced during a game and over a season. Impacts not manifesting through signs and symptoms that we are accustom to recognizing as injury may still be causing metabolic and/or physiological changes within the brain [3]. The difference in brain response between a striking and a stuck player during the same collision has not yet been documented. Therefore the purpose of this study is to examine the difference between both players involved in the collision in the context of strain magnitude on brain tissue.

METHODS

Game video of ten helmet-to-helmet impacts in professional American football was reconstructed in laboratory. Inbound velocity was calculated by establishing the distance between the heads of both players three to five frames prior to the impact using a perspective grid of known field dimensions (Kinovea 0.8.20). The ten impacts varied in terms of impact location (front, front boss, side, rear boss, rear, crown) and inbound velocity ranged from 2.5-7.9m/s. All event reconstructions were performed using two 50th percentile adult male Hybrid III headforms (4.54 ± 0.01 kg) instrumented with nine single-axis Endevco accelerometers sampled at 20 kHz. The headform representing the struck player was attached to a neutral unbiased neckform (1.54 kg) with similar mass and dimensions of the Hybrid III headform; a stiff Hybrid III neckform was used for the striking player to represent minimal neck bending characteristic of the striking player [4]. A linear impacting system with a free-moving tubular arm (1.28 m; diameter 0.05 m; 16.1 kg) and supported stationary frame was used to reconstruct all events. The neck of the striking player was attached to the end of the impact arm using an L-frame via an angled wedge of either 15°, 30° or 45° in order to obtain the desired neck angle. The arm was pneumatically accelerated using a piston and compressed air, which was fully released prior to impacting the struck player's head. Both players were outfitted with a large football helmet of identical brand and model and three impact trials were performed for each event. Dynamic response time histories of the three-dimensional head motion were used as input into the University College Dublin Brain Trauma Model to determine peak tissue maximum principal strain (MPS) within the cerebrum corresponding to each impact.

RESULTS AND DISCUSSION

Results from ten helmet-to-helmet impact events are presented in Figure 1.

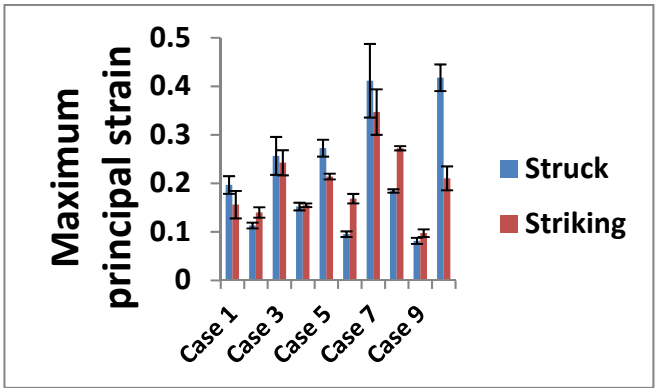

Figure 1: Maximum principal strain experienced by striking and struck players during helmet-to-helmet collisions.

MPS experienced by the struck player ranged from 0.08- 0.41 and striking player MPS ranged from 0.09-0.34 for the 10 case events. An independent samples t-test revealed no significant differences between the struck ((M=0.218, SD=0.119) and striking (M=0.200, SD=0.072) players t(58)=0.699, p=0.487. Interestingly, as the energy of the impact increased (higher velocity events) the struck player trended towards higher brain tissue strains. Also noteworthy is that both players experienced brain strain levels that have been associated with functional impairment of signal transmission in the absence of structural damage [5,6].

CONCLUSIONS

The tendency for struck players to experience higher strains at higher energy helmet-to-helmet collisions compared to their striking opposition may help explain why these players are typically more vulnerable to concussions. On the other hand, collisions are causing strain levels high enough to elicit a tissue response in both players. The conception that it is less dangerous to be on the striking end of a head collision may be providing a false sense of security when considering the long-term consequences of brain trauma.

A BIOMECHANICAL ANALYSIS OF EVENT SPECIFIC CONCUSSIVE IMPACTS IN AMERICAN FOOTBALL

[1] **Lauren E Dawson**, [1]Andrew Post, [2] Michael Gilchrist, [1]Michio Clark, [1]Janie Cournoyer, [1]Clara Karton, [1]Anna Oeur, [1]Karen Taylor and [1]T. Blaine Hoshizaki

INTRODUCTION

Research in head injuries in American football has increased as a result of their potential long-term effects and influences on player's mental well-being. Despite the continued effort to design safer equipment and implement rule changes, the rate of concussions in football remains high. At this moment, there is no one metric that is able to predict the risk of an impact. It is important to understand how players are injured in order to find ways to better protect them.

Currently, brain injury research and helmet standard testing use metrics and thresholds that are more reflective of TBI injury. Metrics that identify risk of concussive injury across multiple events within a sporting environment may be more useful in improving standards for head injury and helmet design. Different events in football have distinctive impact parameters, which create unique loading conditions for the brain during an impact. Evaluating these impacts using multiple variables can aid in determining if multiple variables are needed to capture a greater portion of risk within the game. The purpose of this study is to evaluate the predictive ability of common head injury metrics to distinguish between injury and non-injury events in American football.

METHODS

Five elite American football seasons were analyzed from 2009/2010 to 2013/2014 for concussive and non-concussive events. All concussive events were identified using publicly available official team reports of brain injury from team physicians. All non-concussive cases were impacts that resulted in the player remaining in the game as well as the following game with no injuries reported. The impacts that led to the concussion and non-concussion outcomes were then analyzed in video software to obtain variables required for laboratory reconstruction (inbound velocity, impact location, injury event).

A pneumatic linear impactor impacted a helmeted hybrid III headform equipped with 9 single axis accelerometers with a shoulder or helmet striker at the location and velocity identified during video analysis. The shoulder impactor was a 0.142m ± 0.001 thick VN 602 foam with an American football shoulder pad and the helmet striker consisted of a 0.0357 ± 0.001 m thick VN 602 striker with a nylon cap.
Three trials were completed per impact event reconstruction and peak resultant linear and rotational acceleration and rotational velocities were calculated. The time histories from resultant linear and rotational acceleration were used as inputs into the University of College Dublin Brain Trauma finite element model to determine MPS. All reconstruction data was analyzed using a univariate logistic regression to determine the predictive capacity of each variable.

RESULTS AND DISCUSSION

The results of the video analysis found 82 helmet-to-helmet impacts (22 non-injury; 60 injury) and 38 shoulder-to-head impacts (13 non-injury; 25 injury). The concussive helmet-to-helmet kinematic and MPS results were comparable to what is reported in current literature [1]. However, the shoulder impacts produced kinematic results below reported thresholds yet still yielded injurious stain variables [1,2]

The logistic regression for the helmet to helmet indicated all metrics to be significant in predicting concussive injury with

Table 1. Results from binary logistic regression for head to head and shoulder to head impacts

Injury Event	Variables	% correct classification	Concussion likelihood		p value
Helmet to Helmet	Linear Acceleration (resultant)	74.4	15g 42g 78g	for 25% for 50% for 80%	**<0.001**
	Rotational Accelertaion (resultant)	75.6	1.0 krad/s² 3.2 krad/s² 6.0 krad/s²	for 25% for 50% for 80%	**<0.002**
	Rotational Velocity (resultant)	70.7	--- 17 rad/s 41 rad/s	for 25% for 50% for 80%	**<0.05**
	Maximum Principle Strain	74.4	--- 0.22 0.41	for 25% for 50% for 80%	**<0.002**
Shoulder to Helmet	Linear Acceleration (resultant)	65.8	16g 25g 32g	for 25% for 50% for 80%	**<0.02**
	Rotational Accelertaion (resultant)	68.4	--- 1.6 krad/s² 2.8 krad/s²	for 25% for 50% for 80%	**<0.05**
	Rotational Velocity (resultant)	63.2	--- 14.5 rad/s 27.5 rad/s	for 25% for 50% for 80%	p=0.091
	Maximum Principle Strain	68.4	--- 0.14 0.27	for 25% for 50% for 80%	p=0.075

MPS having the largest % correct classification. For shoulder impacts, peak linear and rotational acceleration were the only significant metric in predicting injury. This result may suggest that MPS may not be sensitive enough to unique loading conditions from high compliance events such as shoulders to capture the differences between injury and non-injury. A new metric that is more sensitive to human tissue tolerance of injury may be needed for events of higher compliances.

CONCLUSIONS

The results of this study show the limitations of using a single biomechanical metric to predict risk, as not all variables were sensitive enough to predict injury across events. These findings should be considered for improvements to current helmet standards and innovative design to decrease risk of head injury in American football.

SUBJECT-SPECIFIC FOOT PROGRESSION ANGLE MODICIFIATION TO REDUCE THE KNEE ADDUCTION MOMENT

INTRODUCTION

The knee adduction moment (KAM) is a surrogate measure for medial compartment knee loading and is related to osteoarthritis progression. The KAM has two peaks during the stance phase of walking. In general, toe-in and toe-out gait modifications reduce the first and second KAM peaks, respectively [1]; however, not all subjects reduce their peak KAM when assigned the same intervention [2]. We hypothesized that subjects would reduce their larger KAM peak by more when walking with a subject-specific foot progression angle (FPA) than when all subjects were assigned the same toe-in or toe-out modification.

Knee loading is also affected by the knee flexion moment (KFM) and quadriceps-hamstring co-contraction [3,4]; increased knee loading could be transient from learning a new movement pattern or a result of the gait modification itself. We also hypothesized that the KFM and quadriceps-hamstring co-contraction would increase when subjects initially learned their subject-specific FPA, but would reduce to baseline levels following 20 minutes of training.

METHODS

Twenty healthy adults walked on an instrumented treadmill while marker positions, ground reaction forces, and electromyograms from the vastus lateralis and biceps femoris were synchronously recorded. Subjects walked normally, then were given real-time vibrotactile feedback teaching them to toe-in and toe-out by 5° and 10° relative to their natural FPA. Each subject's subject-specific FPA was determined as the angle at which they maximally reduced their larger KAM peak. Subjects then trained with feedback for 20 minutes to walk with this FPA.

Medial contact force was estimated with a linear regression using the KAM and KFM peaks [3,5]. Electromyograms normalized to maximal activation during normal walking were used to compute quadriceps-hamstring co-contraction [6] during the loading response, midstance, terminal stance, and terminal swing phases of the gait cycle. Paired t-tests were used to compare peak knee moments, medial contact force, and co-contraction between different trials with a significance level of $p<0.05$. Reported values are mean±SD.

RESULTS AND DISCUSSION

Eighteen of 20 subjects significantly reduced their larger KAM peak with a change in FPA, 8 by toeing-in and 10 by toeing-out. Five subjects had a larger first KAM peak, and reduced this peak the most by toeing-out, potentially due to the significant increase in step width observed when all subjects toed-out compared to baseline. When all subjects walked with their subject-specific FPA, they reduced their larger KAM peak by 18.6±16.2% which was significantly greater than the 7.7-11.0% reductions achieved when all subjects adopted the same FPA modification (Figure 1). The peak KFM increased by 12.4±23.1% ($p=0.027$) when subjects first walked with their subject-specific FPA compared to baseline. As a result, only 13 subjects significantly reduced their medial contact force, with an average reduction among all subjects of 6.7±6.2%. Following 20 minutes of training, the peak KFM remained significantly greater than baseline.

Co-contraction increased significantly compared to baseline when subjects first walked with their subject-specific FPA during all 4 analyzed phases of gait, but returned to baseline levels following 20 minutes of training for all phases of gait.

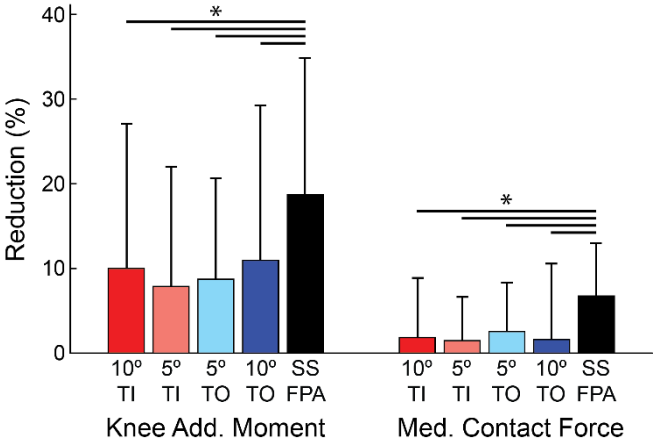

Figure 1: When walking with their subject-specific foot progression angle (SS FPA), subjects reduced their peak KAM and medial contact force by more than when they all toed-in (TI) or toed-out (TO) by 5° or 10° (*$p<0.05$).

CONCLUSIONS

Subject-specific gait modification can reduce the KAM by more than assigning the same modification to all subjects, making it a potentially promising intervention to slow the progression of medial compartment knee osteoarthritis. Additionally, for gait modifications that reduce the KAM but increase the KFM, considering the effect of the KFM on medial contact force gives a more comprehensive view of medial compartment loading than analyzing the KAM alone.

IDENTIFICATION OF GAIT SPEED DEFICIT CAUSES AFTER TOTAL HIP REPLACEMENT SURGERY

Vassilios G. Vardaxis
Department of Physical Therapy, College of Health Sciences; Human Performance Laboratory;
Des Moines University, Des Moines, IA, USA
Corresponding author email: vassilios.vardaxis@dmu.edu

INTRODUCTION

Individuals with end-stage hip Osteoarthritis (OA) have been shown to walk at slower speeds and take smaller steps, with pain been the limiting factor. Total Hip Arthroplasty (THA) is an effective surgical intervention for these individuals providing relief of pain and functional mobility. Despite these significant improvements, literature findings show persisting post-THA shortcomings, such as: walking speed, hip range of motion (ROM) and strength, with ambulatory ability implications [1]. The ambulatory ability of the patients post-THA is one of the most common and useful outcome measures, it is considered a pre-requisite for discharge purposes and has been reported to predict independence in mobility, hospitalizations, and fall-risk [7], however, such benefits claimed by different versions of the minimally invasive surgery (MIS) surgery have not been substantiated by the literature [2,3,8]. In individuals with hip OA walking speed is reduced pre-surgery and continues to be limited up to one year post-THA [4]. A strong relationship has been shown between walking speed and peak anterior ground reaction force (aGRF) [5]. The primary contributors to peak aGRF are the trailing limb angle (TLA) and ankle plantarflexion moment (Ma) [6]. The purpose of this study was to determine the effectiveness of two MIS surgeries on the restoration of the walking ability of THA patients following surgery as reflected by the percent contribution of the TLA and Ma mechanisms to augment walking speed.

METHODS

Forty (N=40) terminal stage hip OA patients were recruited to participate in the study. Twenty received PL and twenty DA minimally invasive THA and were given standard post-operative care. All patients had gait analysis done on them using the Helen Hays model and were tested over 4 visits to the lab: at Pre, 3, 6, and 12 months post-surgery. During each visit the patients were asked to walk at a self-selected walking speed across a 10m walkway. Kinetic and kinematic data were collected using Cortex 1.1.4 (Motion Analysis Corporation). Spatio-temporal gait parameters along with trailing limb angle (TLA), peak anterior ground reaction force (aGRF), external ankle moment (Ma), and ankle moment arm data were produced in Visual3D (Figure 1A). The contributions of TLA, external Ma, their interaction, and moment arm to changes in aGRF during the early (Pre to 3 months) and late (3 to 12 months post-surgery) rehabilitation period were assessed [6]. Statistical analyses on these results were done in SPSS 22 (IBM).

RESULTS AND DISCUSSION

The patient walking speed increased significantly from 0.85 to 1.08 m/s over the year, however, it remained significantly lower than age matched controls. The peak aGRF was highly correlated to walking speed, as expected (Figure 1B). Regardless of the surgery type, the overall contribution of TLA and Ma to aGRF was heavily weighted towards the TLA (57.8% and 27.9%, respectively). The pooled across surgery contribution of the Ma decreased significantly over time (31.3% to 23.5%), while the TLA contribution increased from 52.5% to 67.3%, indicative of the relative importance of the ankle moment in the early rehabilitation stages. There were no differences in TLA and Ma contribution to the propulsive force between groups in the late rehabilitation stage, however, in the early rehabilitation stage the PL group was found to rely more on the Ma as compared to the DA group ($p<0.05$). Over time the PL group significantly increased the TLA and decreased the use of the Ma mechanism to generate propulsive force ($p<0.05$).

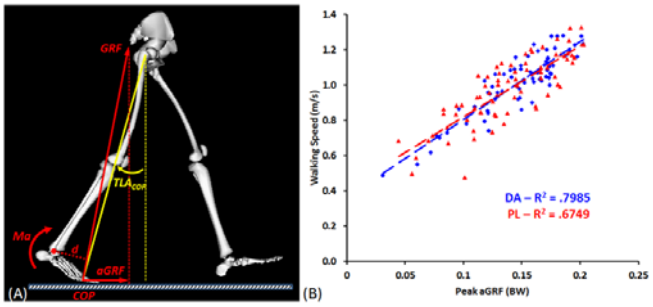

Figure 1: (A) TLA and Ma contribution to aGRF, (B) Correlation between aGRF and walking speed by group.

The pooled TLA plus Ma contributions, accounted for 83.9% and 90.1% of the change in the peak aGRF propulsive force of the surgery limb at the early and late post-THA rehabilitation period, respectively. Contributions by the contralateral limb and other body parts to propulsive force during gait were not considered in this analysis.

CONCLUSIONS

TLA is the predominant mechanism used to increase walking speed in the THA patients. The PL surgery group seems to use the ankle moment (Ma) mechanism more during the early rehabilitation period. The breakdown protocol of the surgical limb contributions to aGRF can be used to identify surgery specific discrepancies and possible patient specific weaknesses post-THA surgery.

BIOMECHANICAL DIFFERENCES OF DISSATISFIED TOTAL KNEE REPLACEMENT PATIENTS DURING STAIR DESCENT

[1] **Kevin A. Valenzuela**, [1]Lauren E. Schroeder, [1]Joshua T. Weinhandl, [2]Harold E. Cates, and [1]Songning Zhang

INTRODUCTION

Stair negotiation is one of the more difficult daily activities reported by total knee replacement (TKR) patients. Patient dissatisfaction with TKR outcomes ranges from 6-19%, with patients often citing an inability to perform certain activities. Dissatisfied TKR patients have reported increased difficulty with stair negotiation, however it is unknown what the underlying mechanical issues are for this population. Therefore, the purpose of this research was to examine the knee joint biomechanics of dissatisfied TKR patients during stair descent.

METHODS

A total of nine dissatisfied TKR patients (34.6±14.3 months from surgery), 15 satisfied TKR patients (29.3±12.8 months from surgery), and 15 healthy participants performed stair descent trials on a five-step instrumented staircase at a preferred gait speed. Patient satisfaction was assessed using a five point Likert scale (very dissatisfied, dissatisfied, neutral, satisfied, very satisfied), with neutral responses being excluded. Kinematics and kinetics were measured using a 12-camera Vicon motion analysis system (240Hz) and two AMTI force platforms (1200Hz) to which the staircase was secured. Internal knee joint moments and ground reaction forces were calculated using Visual3D. A 2x3 (limb x group) mixed model ANOVA was used for statistical analysis ($p<0.05$).

RESULTS AND DISCUSSION

There were significant interactions for 1st and 2nd peak knee extension and abduction moments (Table 1). The dissatisfied group showed lower knee extension and abduction moments in their replaced limb. The 2nd peak vertical ground reaction force (VGRF) and 1st and 2nd peak knee internal rotation moments showed lower moments for replaced limbs compared to non-replaced limbs. First peak VGRF was reduced for dissatisfied group compared to satisfied and healthy groups. The dissatisfied TKR group had significantly increased pain levels on their replaced limb compared to all other groups and limbs. The dissatisfied group had reduced gait speed compared to the satisfied and healthy groups.

Reductions in knee extension moments have previously been shown to occur with reductions in gait speed for TKR patients [1]. The reduction for the dissatisfied group in their replaced limb may be related to the joint pain, which in turn causes them to walk slower. Increased pain and slower speed may lead to an extension moment avoidance gait pattern which alters the gait, creating some additional joint moment reductions in the frontal plane. This renders the given task more difficult to complete.

CONCLUSIONS

Increased pain levels lead to reduced descent speed and peak loading-response and pushoff sagittal plane knee joint moments in dissatisfied total knee replacement patients during stair descent. This creates an asymmetry in the extension loading response moment for the dissatisfied group, with the non-replaced limb showing increased joint moments whereas the satisfied and healthy groups do not have that imbalance. This contributes to reduced gait speed due to an inability to load the replaced knee compared to the non-replaced knee.

BIOMECHANICAL CLASSIFICATION OF GAIT FOLLOWING TOTAL KNEE REPLACEMENT SURGERY

INTRODUCTION

Incidence of osteoarthritis (OA) is steadily increasing amongst the developed world, with the knee being the most commonly affected joint. Total Knee Replacement surgery is a common procedure to treat moderate to late stage OA of the knee. The outcome of surgery is typically measured using patient reported outcome measures, however there is a growing wealth of evidence that self-reported measures of function have limited use in detecting changes in performance-based function [1] [2].

A Dempster-Shafter theory (DST) classification technique has been previously shown to accurately discern biomechanical data between healthy and osteoarthritic (OA) knee function arriving at a degree of belief of OA, non-pathological function and uncertainty [3]. Alongside discriminating OA biomechanical function, this also facilitates the objective quantification of post-operative recovery. This study proposed to compare techniques to assess changes in gait biomechanics following TKR surgery, and compare these to commonly used PROMs.

METHODS

1. Training the classifier on OA gait biomechanics

Human motion analysis (HMA) was initially performed on 31 non-pathological (NP) and 41 subjects with late stage knee OA whom had been recommended for TKR surgery. Subjects walked barefoot over-ground at a self-selected pace.

Hip, knee and ankle kinematics and kinetics were calculated within Visual 3D (C-Motion, USA). Principle component analysis was performed on the data to identify distinct biomechanical features, and the original data was then reconstructed using these components to interpret the clinical relevance of each biomechanical feature.

The first three principle components were initially selected for each variable, resulting in 70 discrete variables per subject. The data set was randomly split into two groups (15 NP, 21 OA) and (16 OA 20 NP), and the DST classifier was used to rank the input variables for both data sets. 18 biomechanical variables identified as being highly ranked in each group were retained for further analysis. Subjects were then classified using DST, using these 18 biomechanical features, to arrive at degrees of belief of OA and NP biomechanical function, and uncertainty, U.

2. Quantifying changes following TKR surgery

Of the 41 subjects, 22 have returned 12 months post-operatively, and the same methodology was utilized to objectively summarise biomechanical improvement following surgery. Function improvement in gait biomechanics was quantified as a reduction in the belief of OA, B(OA). This objectively defined biomechanical recovery was compared to the Oxford Knee Score and Knee Outcome Survey PROMs.

RESULTS AND DISCUSSION

The trained DST classifier could accurately discriminate OA function, resulting in a leave-one-out cross-validated classification accuracy of 98.6%.

Within the 22 TKR subjects, pre-operatively, B(OA) was significantly moderately correlated with KOS (r=-.545, p=0.004) and OKS (0.507, p=0.008), however there was no relationship to PACS pain.

Postoperatively, B(OA) was significantly moderately correlated to all three scores (KOS – r=-0.6, p=0.002, OKS, r=-0.652, p=0.01, PACs, r=-0.509, p=0.015).

Figure 1 displays the pre-and post-operative B(OA) for each subject. Reduction in B(OA) following surgery was variable, with no clear groups of improvement, with only 12 subjects achieving a B(OA) of less than 50%. The biomechanical features which improved most considerably following surgery were those representing a biphasic nature of the hip adduction moment ($p<0.001$) and the vertical ground reaction force ($p<0.001$). Also, highly rated was a complex feature which reconstructed both a reduced ROM throughout stance phase, and a delayed peak knee flexion angle (p=0.0012).

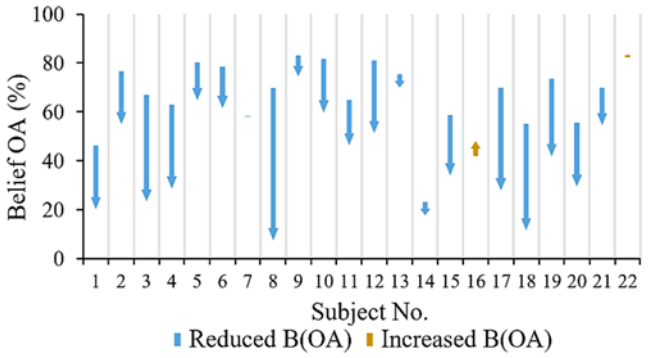

Figure 1: Arrow chart of individual changes in B(OA) for all 22 subjects from pre to post-surgery of the operative leg

CONCLUSIONS

Biomechanical improvement following TKR surgery was variable, with some subjects achieving little benefit or performing worse following surgery. These changes are only moderately correlated with OKS and KOS outcome measures. Further work is needed to explore why some patients received little or no improvement in objectively measured gait function following surgery.

DYNAMIC ROM IN THA PATIENTS WITH LARGER FEMORAL HEAD DIAMETERS

[1] **Emma Turner**, [1] Claudio Belvedere, [2] Andrea Ensini, [2] Matteo Cadossi, [1] Silvia Tamarri, [1] Alberto Leardini

INTRODUCTION

In the human hip, pain and reduced function are the major symptoms of coxarthrosis, and, in severe cases, Total Hip Arthroplasty (THA) is the only solution. The main THA goals are pain relief and restoration of normal mobility. Following THA, several factors, e.g. femur and acetabular cup implant design and the femoral head diameter relating to the femoral neck ratio, can alter normal hip ROM and may result in cup-to-neck contact [1]. Past literature has investigated the issues associated to this ROM by using experimental methods, mathematical modeling and computer simulations, but no direct in-vivo analyses have been reported. Clinical measurements are not accurate enough in this context, and careful joint motion from instrumental gait analysis is necessary. It is hypothesized that larger femoral head diameters lead to larger ROM, which also reduces the risk of cup-to-neck contact at extreme arcs of motion.

Therefore, the purpose of this study is to uniquely combine gait analysis, and radiograph examination to assess in vivo ROM limitations and likely cup-to-neck contact risk, in THA patients implanted with differing femoral head diameters.

METHODS

11 patients undergone a cement-less THA procedure, and were randomly allocated into three differing head diameter groups, respectively a 28mm (Corail Pinnacle Acetabular System), and 36 and 40mm (Corail Delta Motion). At 12 month follow up gait analysis (8-camera Vicon 612 system synchronized with 2 force Kistler platforms and an 8-channel EMG Cometa system) was conducted using an established protocol [2,3]. ROM was measured in extreme exercises such as: full squat, lunge backward, lunge forward, hip step, tailor sitting and squat. Flexion/extension (Fle/Ext), abduction/adduction (Abd/Add) and internal/external rotation (Int/Ext) were calculated accordingly. 3D fluoroscopy was also conducted on the same patients [3,4] to derive cup-to-neck distance information.
ROM was calculated from gait analysis data using 3 methods, with the goal also to select the best representation. Method 1 identifies the patient's maximum or minimum value separately in each of the three anatomical planes. Method 2 identifies the patient's maximum or minimum in the Fle/Ext, and then selects the corresponding values in Abd/Add and Int/Ext. Method 3 identifies maximum or minimum values in each motion direction, during the interval of 45-55% of the gait cycle. Additionally, certain motor tasks were combined to investigate absolute ROM when transferring between the two tasks, e.g. lunge backward and forward for large Flex/Ext ROM. A paired t-test was used to establish any significant differences between methods. Regression analysis was conducted to identify correlations between ROM and distance. P value < 0.05 was considered as significant.

RESULTS AND DISCUSSION

Good maximum hip joint ROM in Fle/Ext was found as 102.5°, 30.7°, 99°, 109.2°, 91.8° and 107.5° respectively in the six exercises. In Abd/Add and Int/Ext maximum ROM were 39.3° and 55.8° found in lounge forward hip step.
Method 1 was found the most variable and methods 2 and 3 more consistent inter-patients. Significant correlations between cup-to-neck distance and the three joint rotation ROM were found in method 3.
Linear regression analysis revealed a general consensus between the 3 methods and ROM, with significant positive correlations in Int/Ext when increasing head diameter, except in stepping from 36 to 40 mm (Figure 1). Positive correlations in Fle/Ext between 28 and 36mm were also found. A few significant negative correlations were found in the 36-to-40 mm step, likely due to small sample size. A significant positive correlation between the cup-to-neck distance and head diameter was found only in squat.

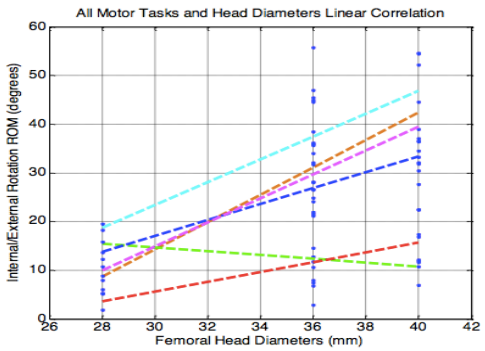

Figure 1: Int/ext Linear Regression Correlation of Head Diameters 28-36-40 mm.

CONCLUSIONS

The results confirm the hypothesis, increasing head diameter size in turn increases the ROM, reliably represented when using data from 45-55% of the gait cycle (Method 3). No risk of cup-to-neck contact was observed in patients during extreme motor tasks; therefore successful ROM assessment was conducted in vivo combining gait analysis with X-ray examinations. This study can contribute to future THA biomechanical analyses in identifying ROM and risk of cup-to-neck contact.

A METHOD FOR AUTOMATIC 3D CLASSIFICAITON OF GLENOID BONE DEFECTS

[1,2]**Katrien Plessers**, [3]Filip Verhaegen, [2]Roel Wirix-Speetjens, [3]Philippe Debeer, [4]Ilse Jonkers, [1]Jos Vander Sloten

INTRODUCTION

The use of three-dimensional (3D) imaging and planning is becoming more frequent in shoulder arthroplasty. Visualizing the bone defect in three dimensions helps to quantify a glenoid bone defect and so improves the decision-making process [1, 2]. To describe the glenoid morphology several classification systems are available in literature [3, 4, 5]. However, most of these classification systems are only based on two dimensional views and do not incorporate information in the third dimension when available.

In this study we combined two commonly used classification systems for glenoid bone defects: the Wallace classification method [4] in the axial view and the Antuna classification method [5] in the frontal view. This resulted in a three dimensional classification method that is easily applicable by surgeons. Moreover, a workflow is presented to semi-automatically and objectively classify a glenoid bone defect according to the presented classification system.

METHODS

A statistical shape model (SSM) containing 64 healthy scapulae was set up to reconstruct glenoid bone defects, as described in Vanden Berghe 2016 [6]. Ten scapula CT scans with varying glenoid bone defects were selected and converted to 3D meshes. The defect glenoid was manually cut out and the SSM was fitted to reconstruct the original glenoid shape.

The reconstructed glenoid surfaces were then used to assess the glenoid bone loss. Bone loss was defined as the distance between the reconstructed glenoid surface and the defect surface, and was assessed at all points on the reconstructed glenoid surface. The color plot in Figure 1 shows the bone loss at each point of the reconstructed glenoid surface.

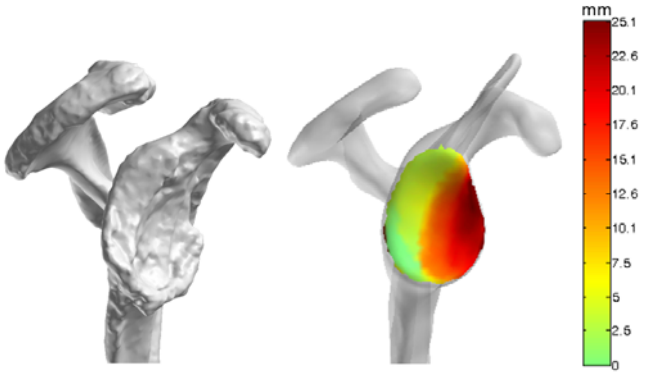

Figure 1: A scapula with a glenoid bone defect (left) and the corresponding color plot of this bone defect (right). The color plot illustrates the amount of local bone loss.

Next, the reconstructed glenoid surface was divided in 4 regions: superior, inferior, anterior and posterior. The percentage of bone loss in each region was computed. If the difference in bone loss between opposite regions exceeded a certain threshold, then the respective region was assigned to the bone defect. If the bone loss was spread equally over the 4 zones, the defect was classified as a central bone defect. This descriptive classification method is based on Antuna 2001. [5]

Using the point correspondence of the SSM, the lateral coracoid base and the medial spinoglenoid notch could be automatically indicated on the reconstructed scapula. These landmarks were used to define the Wallace zones [4] and the relevant Wallace type of the bone defect: The points on the reconstructed glenoid surface were projected towards the defect surface and the location of those projected points was compared with the location of the two landmarks. If the percentage of points in zone two or three reached a certain threshold, then a Wallace type 2 or 3 was assigned.

RESULTS AND DISCUSSION

This study combines two commonly used classification systems and presents a semi-automated workflow to classify a glenoid bone defect accordingly. Using this automatic 3D classification method, all 10 glenoid bone defects could be classified with a Wallace type and an Antuna region. One of the bone defects is illustrated in Figure 1 and was classified as a Wallace type 2 anterior bone defect.

CONCLUSIONS

In this study, we were able to combine two existing 2D classification systems and achieve a clinically relevant 3D classification method. The automatic workflow enables integration in preoperative planning software and allows for objective classification of glenoid bone defects. Moreover, the generated color plot enables visualization of the defect in a way that is easily interpretable. Hence, the proposed method can provide a high added value in quantifying bone defects and making decisions in preoperative shoulder planning.

DETECTING MUSCLE ACTIVITY IN KNEE OSTEOARTHRITIS PATIENTS DURING GAIT: THE ROLE OF QUIET STANDING IN THE TEAGER-KAISER ENERGY OPERATOR METHOD

[1]Philippa Jones, **[1]Paul Biggs**, [1]Joanne Williams, [1]Aseel Ghazwan, [1]Gemma Whatling, [1]Catherine Holt
[1]Cardiff School of Engineering, Cardiff University, UK
Corresponding author email: jonesp29@cardiff.ac.uk

INTRODUCTION

Knee osteoarthritic patients are known to present with altered muscle co-contractions [1]. However, the potential presentation of more global muscular dysfunction is yet to be established and requires the ability to detect muscle activation patterns which is often challenging. Li et al. [2] propose a Teager-Kaiser Energy Operator (TKEO) method which detects muscle activity by calculating the energy of a surface electromyography (sEMG) signal, thus taking into consideration both amplitude and frequency components. Whilst this method improves the signal to noise ratio and the detection of muscle action potentials [2], a baseline muscle activity is required to calculate a threshold above which a muscle is deemed active. Such baseline muscle activity has historically been determined using a quiet standing task [3]. Given the known muscle dysfunction presented by knee OA patients [1], investigations into the appropriateness of the quiet standing task in this cohort warranted exploration. This was undertaken as a preliminary study with a small subgroup of patients.

METHODS

This research was performed on patient data previously collected as part of a longitudinal investigation into the progression of knee OA in High Tibial Osteotomy (HTO) patients. Ethical approval was obtained from the Research Ethics Committee for Wales and Cardiff and Vale University Health Board. 3 knee OA patients awaiting HTO surgery (Age 45.7 ±2.5yrs; BMI 34.6 ±4.2; Male; Kellgren and Lawrence Scores 2-3) performed 5 level gait trials along an instrumented walkway (1,080 Hz, Bertec, USA) whilst wearing 7 lower limb sEMG electrodes (1080 Hz, Delsys, USA) and a full body marker based motion capture system (60 Hz, Qualisys, Sweden). sEMG electrodes were positioned on the rectus femoris, vastus medialis, vastus lateralis, semitendinosus, biceps femoris, medial gastrocnemius and lateral gastrocnemius after performing skin preparation and applying conductive gel. A quiet standing trial was also performed and utilized to determine baseline sEMG activity.

Data processing was performed within Visual3D (C-Motion, USA) and Matlab®. Gait events were defined using a combination of ground reaction force data and automatic kinematic gait event detection. Movement files were normalised to a full gait cycle for the operative leg. Raw sEMG signals were band-passed filtered (20 Hz – 400 Hz) before applying the TKEO function, removing the DC offset, performing wave rectification and applying a further low pass filter (50 Hz). Muscles were deemed active when the TKEO signal remained above the baseline detection threshold (defined as TKEO signal mean + 6* TKEO signal SD during the quiet standing trial) for more than 25 ms. Muscle activity derived from the TKEO method was compared to those identified through visual inspection to determine the suitability of the TKEO and threshold detection method for a HTO cohort. This was performed on 15 signals per muscle and a total of 105 signals.

RESULTS AND DISCUSSION

When visually compared to processed sEMG waveforms, the TKEO muscle activation method resulted in clear muscle activity going undetected during gait (exemplified in Figure 1). This was particularly problematic within the quadriceps muscle group, with the threshold proving too high for 42/45 signals. This was also evident in the hamstring and gastrocnemii muscles but to a lesser extent (14/30 and 3/30 signals). Subsequently, it appears that HTO patients may find the task of standing still challenging and activate their muscles more than healthy controls in order to complete the task. This is in agreement with [4] who recognised a need to perform a supine task when detecting baseline muscle activity to reduce muscular response in children with cerebral palsy.

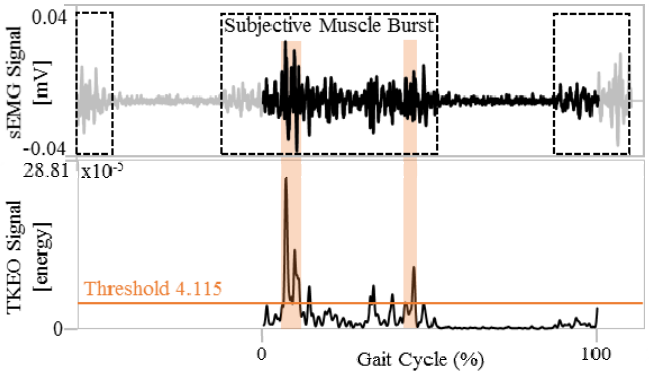

Figure 1: Example of vastus lateralis muscle activity detected through TKEO method (shaded orange) with the detection threshold set too high resulting in muscle activity going undetected.

CONCLUSIONS

HTO patients appear to over-activate their leg muscles during a quiet standing task which makes it inappropriate for the detection of baseline muscle activity. Exploration into the use of an alternative task which elicits lower muscular responses is recommended prior to the application of the TKEO method in HTO cohorts.

TIME-FREQUENCY COHERENCE OF CATEGORIZED sEMG DATA DURING DYNAMIC CONTRACTIONS OF BICEPS, TRICEPTS AND BRACHIORADIALIS AS AN APPROACH FOR SPASTICITY DETECTION

[1] **S. Becker**, [1]S. C. F. A. von Werder, [1]A.-K. Lassek and [1]C. Disselhorst-Klug

INTRODUCTION

The functionality of upper extremities is a mandatory requirement for the performance of daily activities. Especially, extension and flexion movements of the elbow are involved which are mainly initiated by biceps, triceps and brachioradialis. However, in some cases the muscular activation of these muscles can be altered in diverse pathologies with a lesion of the central nervous system, for instance triggered by stroke. One reason for this effect can be spasticity which is in general described as a velocity-dependent response of the muscles to passive stretching [1].

A widely used method for the assessment of muscular activation is surface electromyography (sEMG). Further on a categorization of the recorded sEMG data allows us to show dependencies of muscular activation on different impact factors, for instance angular velocity during the movement. Adding time-frequency analysis to the assessment of sEMG data opens up more extensive possibilities for the validation of muscular co-activation in synergistic or normally non-synergistic muscles. One approach for comparing muscular activation of two muscles could be the calculation of coherence which correlates the sEMG of both muscles in the frequency domain [2].

Based on the aforementioned approach we expect higher and velocity-dependent coherences in patients during extension movements corresponding to Lance definition of spasticity.

METHODS

Dynamic physiological and pathological elbow flexion and extension movements were performed by 6 patients with spasticity and 10 healthy subjects at different angular velocities (30-120°/s), joint angles (25-125°), external loads (1kg, 5kg) and contraction types (eccentric, concentric). Thereby the muscular activity of biceps, triceps and brachioradialis was measured by bipolar surface electromyography (sEMG) and the kinematic data for the calculation of joint angles and angular velocities by an optical motion tracking system.

After preprocessing (band-passed filtered, rectified, smoothed and normalized) the discrete-time analytic signal of the sEMG was determined by Hilbert transform, the time-frequency distribution of the analytic signals was calculated and coherences between biceps, triceps and brachioradialis were estimated. Finally, the coherences were categorized according to the aforementioned categories.

Comparability between pathological and physiological coherences is enabled by calculating the relative deviation between the coherence of the 6 patients and the averaged coherence of the 10 healthy subjects.

RESULTS AND DISCUSSION

Generally, higher coherences in pathological than in physiological data could be detected corresponding to the coherence course over measurement time. These findings indicate that in spastic patients the muscles are co-activated more strongly than in healthy subjects. However, there were no significant patterns and differences apparent regarding pair of muscle, movement and external load. Further on the extent disparities in the coherences between several patients underline the exceptional individuality of the diseases.

In consideration of angular velocity and joint angle could be identified that angular velocity has the greatest influence on muscular activation, especially in comparison of pathological and physiological coherences. As an example figure 1 shows the alteration of coherence between triceps and brachioradialis during extension movements and 1 kg external load. Represented is the relative deviation of coherence between physiological and pathological data including six investigated patients. The relative deviation of coherence increases in higher velocity ranges. Further on different velocity ranges could not be reached by the patients because of their restricted range of motion.

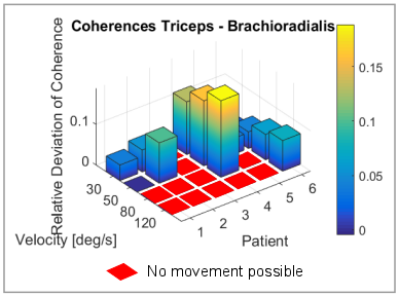

Figure 1: Relative deviation of coherence between pathological and physiological data during extension.

CONCLUSIONS

The combination of categorization and frequency analysis opens up new possibilities to show muscular co-activation between synergistic or normally non-synergistic muscles in dependence on several impact factors. The effect of velocity-dependent coherence is most pronounced during extension between the eccentric contracted brachioradialis and biceps with the concentric contracted triceps. Further on the approach can enable to differentiate between physiological and pathological data, more precisely the extent disparities between both allows us to recognize spastic patients on the basis of sEMG signals.

SPATIALLY CORRELATED NOISE AMONG ELECTRODES IN HDsEMG

Alessandro Russo, **Roberto Merletti**
Lab. for Engineering of the Neuromuscular System (LISiN), Politecnico di Torino, Italy
Corresponding author e-mail: roberto.merletti@polito.it

INTRODUCTION

The many applications of High Density surface EMG (HDsEMG) are often limited by the noise generated at the electrode-skin interface [1]. When measured on a fully relaxed muscle, after removal of power line interference, the monopolar noises of the individual channels show spatially correlated non-propagating transients that resemble motor unit action potentials and might be interpreted as generated by remote motor units. Since very similar transients are observed when the gelled electrode grid is applied on a piece of pig skin these signals cannot be due only to muscle activity. It is the purpose of this work to investigate the nature of this noise.

METHODS

An 8x8 flexible electrode grid (IED = 5 mm, Ø = 3 mm) was applied on a piece of shaved and scraped pig skin by means of a double adhesive foam layer (1 mm thick) with holes filled with conductive gel matching the 64 electrodes. Monopolar signals were collected from the 64 electrodes with respect to a reference ECG adhesive electrode placed on the pig skin 20 mm away from the edge of the grid. The signals were amplified (G=10k) and bandpass filtered (10 –750 Hz analog filter) with a 64 ch EMG amplifier, sampled at 2048 samples/s converted in digital form (12 bit A/D converter, LSB RTI = 122nV) and filtered with a zero phase (bidirectional) 4th order digital filter (20-400 Hz). Power line interference was reduced using the spectral interpolation technique [2].

Fig 1 depicts the signals collected from three of the eight columns of the grid. Two dimensional maps (over sequential 50 ms epochs) were made with colors showing the average correlation coefficient (ACC) between each signal and its eight neighbors. The grid and the reference electrode were also placed on a clean stainless-steel plate (no gel) to measure the RTI voltage noise of the amplifiers.

RESULTS AND DISCUSSION

Fig. 1 shows the presence of occasional, strongly correlated, signals across rows and columns. Minor local correlations are also evident .The sequence of maps of the ACC shows spatial regions of high correlation (ACC ranging from 0.2 to 0.9) moving in space and in time. Differential signals had RMS values of 0.5-1.0 µV and inter-channel correlation < 0.2. The RTI RMS monopolar noise with short circuited inputs was < 1 µV (INA 121 front-end amplifier) and small correlated fluctuations were present.

Both on human and pig skin, correlated fluctuations seem to be generated, under one or a few electrodes, as local transients diffusing to nearby electrodes because of the surface conductivity of the skin. Smaller but correlated output transients, observed with short circuited inputs, might be due to the amplifier's DC power supply fluctuations (PSRR =80dB) creating correlation across channels. Well filtered DC supply is a requirement.

CONCLUSIONS

The presence of spatially correlated monopolar noises detected by an electrode grid applied on a piece of shaved and scraped pig skin has been demonstrated. On humans these correlated fluctuations might be misinterpreted as crosstalk or end-of-fiber effects. They seem to be due to local transients diffusing to nearby electrodes because of the skin conductivity. They might also be due to poor filtering of transients on the DC power supply of the front-end amplifier. It is important that this is well stabilized.

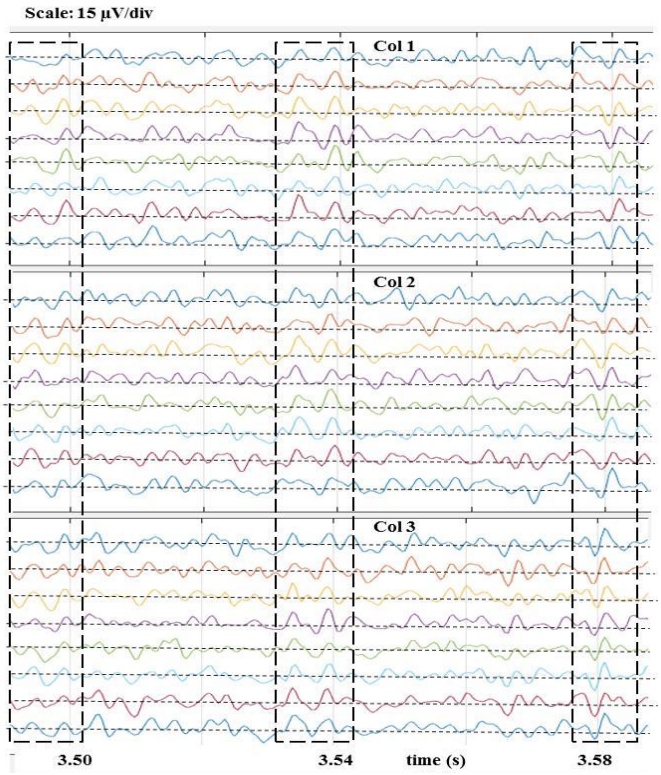

Figure 1. Monopolar signals detected from three columns of an 8x8 electrode grid applied on a piece of shaved pig skin. Spatially correlated signals are outlined within the dashed boxes. Other correlated fluctuations are evident.

INTRODUCTION

Tendon and whole muscle transfers are done to restore lost motor function. Orthopedic surgeons transfer the gracilis muscle from the lower limb to the upper limb to regain elbow flexion. However, the transferred muscle often loses one grade of muscle strength [1]. It is believed that this strength loss may be due to improper tensioning of the muscle during surgery resulting in sarcomere lengths that are too short or too long. Accordingly, this study was performed to determine gracilis in-vivo sarcomere lengths and compare the results to a computational model of this muscle in order to enable future modelling of muscle transfer surgery.

METHODS

Biopsy: Muscle biopsy samples (n=7) were taken from six patients (39±17 years; 1 female) to evaluate sarcomere length at three different joint angles. While the patient was under anesthesia, the surgeon exposed the gracilis at mid-belly to allow for dissection. Each patient's limb was positioned in one of the joint configurations described in Table 1. A bundle of muscle fibers was dissected with biopsy clamps used to take a sample [2]. The tissue was fixed in 10% buffered formalin for subsequent laser diffraction measurements of sarcomere length [3].

Table 1: Joint configurations used to vary the muscle length. Muscle biopsies were taken at each configuration.

Joint Con-figuration	Hip Rot. (◦)	Hip Abduction (◦)	Hip Flexion (◦)	Knee Flexion (◦)
1(n=1)	-40	-45	45	120
2(n=3)	-40	-30	45	90
3(n=3)	-40	-30	45	0

Model: OpenSim was used to estimate the sarcomere length, L_s, at each joint configuration. The Rajagopol's et al. musculoskeletal model [4] was used to estimate musculotendon lengths and L_s was estimated from muscle fiber length, L_f using the musculotendon model from Millard et al. [5], and the relationship $L_f = nL_s$. The number of sarcomeres per fiber, n, was determined using the optimal length, L_o = 22.78 cm, found by Ward et al [2].

RESULTS AND DISCUSSION

The measured range of sarcomere lengths was 3.27 to 3.40µm, which is comparable to upper extremity data from Lieber et al. [6]. The model predicted sarcomere lengths are within the 95% confidence intervals of the experimentally measured values (Figure 1). OpenSim predicted the general sarcomere length across different muscle lengths, but did not predict the lack of change of sarcomere length seen in the experimental data. The data and model suggests the gracilis operates, at least in part, on the descending limb of the force length curve assuming an optimal sarcomere length of 2.7µm.

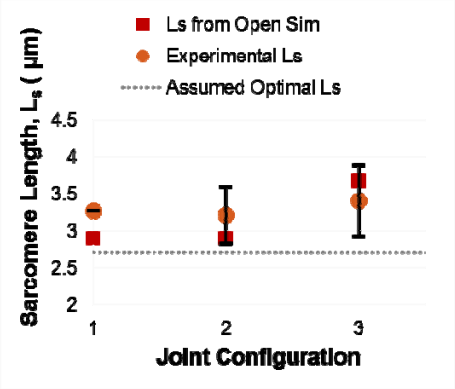

Figure 1: Sarcomere length estimated in OpenSim (squares) compared to those from muscle biopsies (circles). Error bars represent 95% confidence intervals.

CONCLUSIONS

These novel data provide a direct comparison of a commonly used computational model to in-vivo experimental data. The results can be used to guide future patient-specific models. Collection of more data is needed, especially at muscle lengths less than the length seen in joint configuration 1, before definitive conclusions can be made regarding the performance of the computational model to predict muscle properties and data to improve orthopedic surgeries.

MECHANOSENSING IN MYOFILAMENTS STABILIZES THE DESCENDING LIMB OF FORCE LENGTH RELATIONSHIP

[1] **Gudrun Schappacher-Tilp**, [2] Walter Herzog
[1]University of Graz, Austria
[2]University of Calgary, Canada

INTRODUCTION

Lengths of half sarcomeres arranged in series forming a myofibril are non-uniform. Due to the negative slope of the descending limb of the force-length relationship of myofibrils, it has been assumed that the descending limb of the force-length relationship is inherently unstable – while strong sarcomeres shorten, weak sarcomeres yield and are stretched beyond actin-myosin filament overlap. This so-called sarcomere popping should be most prominent during active stretches on the descending limb. However, popping of half sarcomeres has either not been observed at all (e.g. [1,2]) or is not more prominent than under isometric conditions at optimal overlap (e.g. [3]). Therefore, the descending limb of the force-length relationship seems to have some sort of regulation stabilizing the system.

One possible regulation could be an only recently revealed mechanosensing in myofilaments [4], which regulates the number of myosin motors available for interaction with the actin filaments. More specifically, another study [5] has shown that the elastic extension of titin filaments regulates the availability of myosin heads. The aim of this study is to test the hypothesis that a regulation based on a titin dependent activation of myosin heads stabilizes the descending limb of the force-length relationship of myofibrils.

METHODS

We build a structural model of a myofibril consisting of non-uniform half sarcomeres arranged in series and introduce stress-based activation of myosin heads. Specifically, we use the average extension of titin strands in a half sarcomere as a controller. Non-uniformities are implemented as Gaussian distributed variabilities in force generating capacities of half sarcomeres.

The state of the system at each time step of the simulation, i.e. lengths and shortening / stretching velocities of individual half sarcomeres, is determined by non-linear optimization. Active and passive forces are estimated by Monte Carlo simulations. Passive forces are based on a structural titin model allowing force-dependent unfolding of substructures of the titin filament [6]. Active forces are based on an enhanced three state model [7, 8] allowing for the regulation of active force production due to mechanosensing in myofilaments.

We simulate passive stretches of short myofibrils consisting of 2 and 16 half sarcomeres to the descending limb of the force-length relationship, followed by activation and further stretching on the descending limb. We compare the predictions to simulations based on the non-regulated model. Furthermore, we compare the results qualitatively to published data [1,2,3].

RESULTS AND DISCUSSION

The simple mechanosensing mechanism of recruitment of myosin heads based on the average extension of titin strands in a half sarcomere can stabilize the descending limb. Differences in half sarcomere lengths are less prominent and forces in regulated myofibrils are significantly higher than forces predicted by the conventional muscle model.

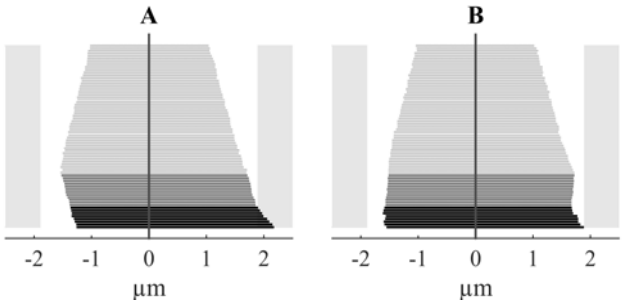

Figure 1: Half sarcomere lengths of a non-uniform sarcomere predicted by the classical model **A** and the regulated model **B**. From top to bottom: The sarcomere is passively stretched to 3.2µm (light grey), activated and held at 3.2µm (dark grey). After 3 seconds, the sarcomere is actively stretched to 3.4µm (black grey). The stretching velocity is 0.1µm/s per sarcomere. The weaker half sarcomere pops in the classical model **A**.

However, due to the detailed nature of the model simulations of longer stretches of long myofibrils is very time consuming. Hence, a less detailed model depending on average titin forces [6] and mean field approaches for cross-bridge dynamics might be favorable for future studies.

CONCLUSIONS

Although half sarcomeres are non-uniform they seem to be as stable on the descending limb of the force-length relationship as on the plateau region. We conclude that a conventional sarcomere model including a simple mechanosensing mechanism can stabilize the system without further adaption of the model.

LOCALLY DEACTIVATED SARCOMERES DO NOT OVER-LENGTHEN IN MYOFIBRILS

Tim Leonard, Azim Jinha and Walter Herzog
University of Calgary
Corresponding author email: leonard@ucalgary.ca

INTRODUCTION

Muscle (the smallest functional unit being the sarcomere) generates active force through cyclic interactions between myosin and actin and the amount of active isometric force generated is proportional to the length of the sarcomere [1]. Passive forces in the sarcomere are also length dependent and are supported by the molecular spring-like protein titin [2]. Instability of sarcomeres has been proposed as a mechanism for injury in muscle since sarcomeres arranged in-series must sustain the same force along a myofibril and sarcomeres that are weaker than adjacent ones are expected to over-lengthen since there is a disparity in active force producing potential. This instability results in a sarcomere that is rapidly lengthened (termed "popping") until only passive structures (titin) sustain the in-series force, with damage occurring to that sarcomere [3]. The purpose of this study was to measure the length of each sarcomere in a single myofibril during activation and then follow these sarcomeres with time as portions of the sample are deactivated to see whether weaker sarcomeres behave as predicted, and do in fact, over-lengthen.

METHODS

Skeletal muscle myofibrils were generated using rabbit psoas muscle as previously described [4] and were placed in an experimental chamber atop an inverted microscope. Single myofibrils (n=6) were attached at one end to a glass needle/motor assembly for specimen length control and at the other end to a micro-fabricated silicon nitride cantilever pair (68 nN/µm stiffness) for measuring force.

High-resolution (88 nm per pixel) video data (30 fps) were collected continuously during the experiment and analyzed using custom MATLAB analysis code. The myofibril was initially in a relaxed state and the myofibril length adjusted to an average sarcomere length (SL) of approximately 2.4µm. Then the Ca^{+2} rich activating solution was delivered and once the myofibril was fully activated, a second stream of relaxing solution was targeted to the left side of the myofibril. This resulted in a wave of deactivation that started at the left and propagated rightward until it encompassed the entire myofibril, and the myofibril returned to the relaxed state.

RESULTS AND DISCUSSION

In Figure 1, for one typical experiment, the mean SL upon activation was 2.1µm and the stress measured (not shown) was 209nN/µm^2. The infusion of the localized stream of relaxing solution at time-point 12s resulted in the first sarcomere (sarcomere #1) rapidly lengthening from a SL of 2.47µm to 2.65µm. At 13s, the next sarcomere (#2) lengthened from 2.21µm to 2.47µm and at 14s, #3 lengthens from 2.29µm to 2.74µm. At time point 15s, more than half of the sarcomeres have relaxed, the total stress is 110nN/µm^2 and the mean relaxed SL (green horizontal line; Figure 1) is 2.65µm and the remaining active sarcomeres have a mean SL of 2.15µm (red horizontal line). At time 15s, 7 sarcomeres out of 10 have lengthened from their initial active length and are positioned on the descending limb of the force-length relationship. Instability theory would predict these sarcomeres to over-lengthen. In fact, these deactivated sarcomeres would need to lengthen considerably if they were to passively support the 110nN/µm^2 of stress still detected; previous work reports a SL of near 4.0µm would be required [5] and passive force does not appear in this preparation until SL of about 2.8µm. These passive sarcomeres are presumably sustaining this tension by titin alone, and in this example, with the titin stiffness being modulated so that a relaxed sarcomere at 2.6µm can sustain the load.

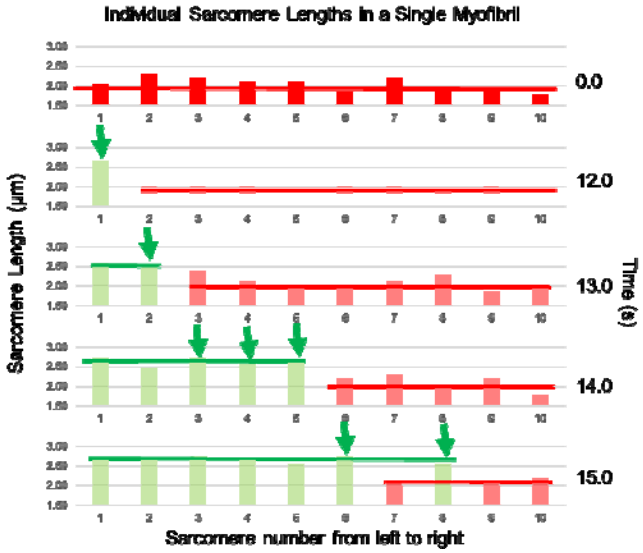

Figure 1: Sarcomere length in an activated myofibril as a wave of deactivation solution moves from left to right. Green arrows highlight activated sarcomeres (red) that transition rapidly to passive (green). Red and green horizontal bars indicate the mean SL for sarcomeres belonging to groups classified as active or passive.

CONCLUSIONS

Weak (deactivated) sarcomeres do not "pop". We speculate that popping is prevented by a "stiffening" of the molecular spring titin. The mechanisms underlying this stiffening of titin need further elucidation.

IN VIVO FASCICLE BEHAVIOUR AFFECTS FORCE DEPRESSION DURING ISOMETRIC CONTRACTIONS

INTRODUCTION

Residual force depression (RFD) describes the reduction in force following active shortening relative to the steady-state isometric force at the same final muscle length [1]. Because muscles in the lower limb typically have long aponeuroses that permit substantial fascicle shortening during isometric contractions [2], *in vivo* RFD may result in underestimations of individual muscle force capacities determined during maximal voluntary isometric contractions (MVICs). Because RFD is related to the amount of mechanical work performed during active shortening [3], we hypothesised that different fascicle behaviour before reaching the same steady-state isometric torque would influence the steady-state muscle activations. To test this hypothesis, (1) a given relative torque was matched after producing low and high isometric preloads. (2) The effective series elasticity of the tibialis anterior (TA) muscle-tendon unit (MTU) was reduced during ramp contractions to investigate how small reductions in fascicle shortening magnitudes affect subsequent muscle activations at the same relative torque.

METHODS

Participants were seated in a reclined position (hip at 140°, right knee at 110°, right ankle at 95°) with their right foot attached via two Velcro straps to the footplate of a dynamometer (IsoMed2000, Ferstl GmbH, Germany). After at least two MVICs of dorsiflexion, participants completed at least six submaximal dorsiflexion ramp and hold contractions in a randomised order. The ramp and holds were performed over a fixed duration (13.2-s) with a constant ramp speed (12.5% MVIC/s). Participants were required to match low-high ramp and holds (5-s hold at 20% then 5-s at 40% MVIC), reference ramp and holds (10-s at 40% MVIC), and high-low ramp and holds (3.4-s at 60% then 3.4-s at 40% MVIC) by dorsiflexing their ankle so that their ankle torque remained within 3% of the target torque. The high-low ramp and holds were also completed with the ankle starting in a slightly more dorsiflexed position (~3-5°) and then the ankle was rotated to 95° during the initial phase of the ramp contraction. This reduced the effective TA MTU series elasticity and ensured that muscle activations and fascicle lengths could be compared at the same final MTU length as the preceding ramp and hold contractions.

Muscle fascicles of TA were visualised with B-mode ultrasound using a 60 mm veterinary transducer operating at 60 Hz with an image depth of 50 mm (LS128; Telemed, Vilnius, Lithuania). Fascicle lengths (FLs) were determined in Matlab post-processing by implementing a semi-automated tracking algorithm [4]. TA muscle activity was measured using surface electromyography (sEMG) and band-pass analogue filtered between 10 and 500 Hz, prior to being sampled at 2000 Hz. Ankle torque was recorded at 200 Hz and synchronized with ultrasound videos and sEMG measurements using a 16-bit A/D card within a Power 1401 data acquisition interface (Spike2, CED, UK).

RESULTS AND DISCUSSION

Preliminary results (n=4) show that the normalised mean TA root-mean-square (RMS) amplitudes were similar for ramp and holds without a rotation, but ~3% lower for the contractions with a rotation (Table 1). This was despite similar mean TA FLs (56.9-57.1 mm) at the same relative torque. However, we found that TA fascicles shortened ~1.5 mm less during the ramp and holds with rotation compared to those with no prior rotation. This probably led to reduced RFD and therefore less activation was required to achieve the same relative torque. In contrast, the greater fascicle shortening magnitudes during the high-low condition did not result in increased activations during hold 2 as we expected. This might be due to a force enhancing mechanism caused by the active fascicle lengthening during ramp 2 (Table 1).

CONCLUSIONS

Preliminary findings suggest that smaller fascicle shortening magnitudes are associated with reduced muscle activations to achieve the same steady-state isometric torque *in vivo*. However, muscle activity can also be reduced when fascicle lengthening from muscle deactivation precedes the isometric hold at the same relative torque. Therefore, variable fascicle behavior during isometric contractions may influence RFD.

SPINAL REFLEX EXCITABILITY, MECHANISMS AND ITS RELATIONSHIP TO ANKLE INSTABILITY

Cassandra Thompson, Peter Clothier, Siobhan Schabrun and Paul Marshall
School of Science and Health, Western Sydney University, NSW, Australia
Corresponding author: c.thompson2@westernsydney.edu.au

INTRODUCTION

Chronic anke instability (CAI) is characterised by feelings of giving way and/or instability surrounding the ankle joint. Altered afferent feedback during dynamic tasks is thought to contribute to instability in CAI. Excitability of the Ia-afferent (or, spinal-relex) pathway has been probed during isometric tasks in this population [1, 2]. However, the functional significance of altered spinal-reflex excitability during a dynamic task and its mechanisms have yet to be comprehensively examined. The primary aim of this study was to examine spinal-reflex excitability during landing and it's relationship to overall stability in persons with CAI. A second experiment was performed to determine the mechanisms of altered spinal-reflex excitability in CAI.

METHODS

Experiment 1. Spinal-reflex excitability was probed during a single-leg, horizontal jump-landing task. Ten bilateral healthy ankles (age, 23 ± 3.7yrs; Ht., 177 ± 5.2cm; Wt., 73.4 ± 6.9kg) and ten bilateral CAI ankles (age, 24 ± 3.7yrs; Ht., 183 ± 5.1cm; Wt., 86.4 ± 11.6kg) were included in the study. Jump height and distance were controlled at 50% of maximal hop height and 25% of maximal hop distance, respectively. Electrically induced spinal-reflex responses (H-reflexes) were elicited in the soleus (SOL) at the short- (SLR) and long-latency (LLR) responses of ground contact. Ten landings with stimulation timed to coincide with the SLR, ten with stimulation at the LLR, and ten landings without stimulation were performed on each limb.

Experiment 2. Paired-pulse h-reflex techniques were applied during double-legged stance. Ten paired-pulse stimuli (of the same intensity) with a 100ms inter-stimulus interval were given to examine intrinsic pre-synaptic inhibition (PSI). Ten paired-pulse stimuli (H-reflex conditioned by M-max) with a 10ms inter-stimulus interval were given to examine post-synaptic, recurrent inhibition (RI). Inhibitory protocols were repeated in both limbs.

Electromyographic (EMG) data from SOL was sampled at 4000Hz, and treated using a 50-1000 band-pass filter. Spinal-reflex excitability was defined as the amplitude of the H-reflex response, expressed relative to ongoing background EMG (20ms around peak of SLR and LLR of trials without stimulation, RMS) and the maximal motor response (peak-to-peak amplitude, mA). Force data was collected using Kistler (model 9286B) and Bioware™ (v5.3.0.7) operating systems. Force was sampled at 1000Hz, rectified and fit with an unbound, third-order polynomial (UTOP) in accordance with previous methodologies [4]. The UTOP method [4] was used to calculate anterior-posterior (AP) and medio-lateral (ML) time to stabilisation (TTS). Ground contact was defined as the first increase in vertical ground reaction force above 10N. Between-group differences in Ia-excitability were determined using two-tailed, paired t-tests. A non-parametric independent sample, Mann-Whitney U test was used to identify differences in AP and ML TTS between groups. Correlations between Ia-excitability and AP/ML TTS scores were determined using *Spearman's Rho* for non-parametric data. Data is presented as mean ± SD.

RESULTS AND DISCUSSION

Preliminary findings indicate the CAI group had significantly greater spinal reflex responses at the LLR (Table 1). Despite a greater input from the spinal reflex pathway in CAI, no difference in overall SOL background EMG activity was observed between groups (CAI, 0.15 ± 0.07; Healthy, 0.19 ± 0.06; p = 0.10). In healthy individuals, the LLR is primarily a cortical response and spinal-reflex excitability is low [3]. Facilitated SOL reflex responses at the LLR with no difference in relative background EMG may indicate a greater contribution of Ia-afferents, and reduced cortical drive in CAI. Findings from experiment two supports the presence of a facilitated spinal reflex response and an inability suppress Ia-afferent responses due to reduced pre-synaptic inhibition. As cortical drive modulates Ia-afferent excitability at the pre-synaptic site [4], reduced pre-synaptic inhibition is thus a potential functional mechanism of facilitated H-reflexes at the LLR. No correlation was observed between spinal-reflex excitability at the LLR and TTS in either AP (*Rho*; -0.02) or ML (*Rho*; -0.1) directions. We used the UTOP method to calculate TTS; it is possible that a different method to calculate TTS (e.g. sequential averaging) which considers the individuals ability to reach and stay within a given threshold of stability (mean of stable force trace ± 3SD's) may be more sensitive at determining the relationship between spinal-reflex excitability and TTS.

Table 1: Differences in spinal-reflex excitability and TTS

	Healthy	CAI	*p-value*
SLR H-reflex	[illegible]	[illegible]	[illegible]
LLR H-reflex	[illegible]	[illegible]	[illegible]
AP TTS	[illegible]	[illegible]	[illegible]
ML TTS	[illegible]	[illegible]	[illegible]
PSI	[illegible]	[illegible]	[illegible]
RI	[illegible]	[illegible]	[illegible]

CONCLUSIONS

Modulation of spinal reflex excitability is different between healthy and CAI populations during a landing task. The inability to suppress an undesirable spinal-reflex response at the LLR is a potential injury mechanism. Future analyses will determine the best method to relate TTS to spinal-reflex control. Differential modulation of spinal-reflexes throughout the entire lower-limb between CAI and healthy populations will also be explored.

INTRODUCTION

Shoulder arthroplasty has been shown to reduce pain and improve shoulder function in osteoarthritic patients; however, complications including prosthetic loosening, dislocation, joint instability and muscle dysfunction occur in an average of 14% of cases [1]. It is well established that rotator cuff muscle integrity is a significant predictor of clinical outcome of shoulder arthroplasty [2]. One of the most common complications of shoulder arthroplasty is anterocranial migration and subachromial impingement due to rotator cuff failure and subsequent loss of the depressor strength [3]. Clinical evidence suggests that the Lima shoulder modular replacement (SMR) anatomical shoulder joint replacement may be associated with rotator cuff degeneration, and higher than normal revision rates in Australia. One hypothesis for this is that the anatomical joint replacement impinges on the supraspinatus, which may ultimately attribute to its rupture, leading to joint instability. To assess this hypothesis, the aim of this study was to develop a cadaveric model to simulate rotator cuff muscle loading and evaluate the contact pressure between the rotator cuff tendons and the prosthetic joint replacement component after implantation of the Lima SMR, and compare the results to those in the natural shoulder state.

METHODS

Eight fresh-frozen, male entire upper extremity specimens were harvested from human cadavers (mean age: 68 years). The skin and subcutaneous soft tissues proximal to the glenohumeral joint were removed and all rotator cuff muscles detached from their respective fossa. Loops of 5-Ethibond Suture were attached to the insertion of the individual tendon of each muscle sub-region and secured. The acromioclavicular, elbow and wrist joints were fused.

Shoulder specimens were mounted onto a testing rig by potting the scapula in a hollow block with dental cement. Nylon lines attached to each rotator cuff tendon were passed through a backing plate. Physiological muscle force associated with each specimen's upper limb were determined for abduction using specimen-specific three-dimensional musculoskeletal models of the upper limbs [4]. Physiological muscle forces were calculated using the model for three shoulder joint positions: 10º, 45º and 90º of humeral abduction in the coronal plane, as well as the positions of full internal and external rotation at 45º of abduction.

For each of the aforementioned shoulder joint positions, muscle forces calculated using the model were applied to the cadaver by means of simulated force application using a dead-weight system, while the humerus and glenohumeral joint was restrained with a clamp. Pressure sensitive Fuji film (2.5MPa capacity) was placed underneath each rotator cuff tendon at the point where the tendon passed over and contacted the glenohumeral joint. The film was scanned and assessed to evaluate peak contact pressure. Experiments were performed for the natural shoulder, and were repeated after total joint replacement surgery using the Lima SMR System. A one-way ANOVA was used to assess the influence of joint angle and surgery on contact pressures.

RESULTS AND DISCUSSION

Overall, both joint angle and shoulder joint replacement surgery had significant effects on the maximum contact pressure measured between the humeral head and all rotator cuff muscle tendons except teres minor ($p<0.05$), with maximum pressure increasing after surgery for all muscles (Table 1). The supraspinatus, one of the initiators of abduction, was found to decrease its contact pressure with the humeral head as abduction increased ($p = 0.008$), and demonstrated a significant increase in contact pressure at 45º of abduction with the humerus externally rotated relative to the natural shoulder (mean difference: 0.36 MPa, 95% CI [0.19, 0.54], $p = 0.001$). The subscapularis and infraspinatus demonstrated significant increases in contact pressure after surgery, with subscapularis contact pressure magnitude significantly influenced by joint position ($p<0.05$).

Table 1: Measurements of maximum tendon contact pressure between the natural shoulder and shoulder after anatomical total joint replacement surgery at 10º, 45º and 90º of abduction. All data are mean pressure values (MPa). Significant differences in contact pressure with joint angles are indicated by 'a', significant differences in contact pressure with joint replacement surgery indicated by 'b',

	Natural			Anatomical			
	10º	45º	90º	10º	45º	90º	
Supraspinatus	1.1	0.8	0.4	1.6	1.0	0.4	a,b
Subscapularis	0.7	1.4	0.7	1.1	1.8	1.5	a,b
Infraspinatus	0.9	0.7	0.8	1.1	1.2	1.3	b
Teres Minor	0.4	0.4	0.5	0.3	0.4	0.4	

CONCLUSIONS

Greater contact pressure between the rotator cuff tendons and the humeral head of the Lima SMR anatomical joint replacement may present increased risk of tendon debridement post-operatively, particularly in that of the supraspinatus which is the major initiator of humeral elevation and develops comparatively large muscle force. The results suggest that decreasing the size of the humeral head component could reduce the magnitude of the tendon-implant contact pressure

EVALUATION OF HANDEDNESS OF SHOULDER BONES USING STATISTICAL SHAPE MODELING: IMPLICATIONS TO IMPLANT DESIGN AND SURGICAL INTERVENTION

INTRODUCTION

Anthropometric variables are useful tools that provide information on differences that exist within human body structures. These variations could be observed in bilateral bones or may be sex-related. Statistical shape models (SSMs) are popular models to embed shape variability [1]. Handedness is an essential feature of human nature; it refers to the natural usage of either the right or left hand more than the other [2]. Shoulder arthroplasty often employs contralateral structure as a guide for correction for restoring function and comfort to pathological shoulder joints [3]. The bone structures involved in this process, humerus and scapula, have variable morphology and hence their anatomy is very important to orthopaedic surgeons and prosthetic component designers. This study investigates the relationship and variation that exist between the left and right humeri and scapulae and its implication for shoulder surgical intervention and arthroplasty implant designs.

METHODS

The method involved three steps: 1) 3D reconstruction of the humeri and scapulae from a CT image database, 2) building SSMs from 3D mesh models of the bones, and 3) morphometric analysis. Thirty-six CT-scan bilateral South African cadaveric humeri and scapulae were used in this study. Segmentation and 3D mesh post-processing were carried out in Mimics (Materialise, Leuven, Belgium, V 19.0) To build the SSMs, two observers landmarked the humeri and scapulae meshes using 13 and 19 anatomical landmarks respectively. The average landmarks were then projected on the surface of each mesh by taking the closest vertex coordinate to each point. The triangular meshes were rigidly aligned after which a non-rigid ICP registration was done to establish dense correspondence [4,5] and the SSMs were created in Scalismo (https://github.com/unibas-gravis/scalismo) using Gaussian processes [6]. The morphology of the average models for both sides of the humeri and scapulae were compared in Amira (FEI, Hillsboro, V 6.20) and the surface distances were recorded.

RESULTS AND DISCUSSION

Since we compared average shapes from each side for each bone, we could only come up with a metric of maximum distance and its location. The Hausdorff error for the humeri was observed around the medio-proximal part of the greater tubercle while for the scapulae it was seen around the distal tip of the medial border. The location of this Hausdorff distance could indicate the significance in anthropometric measures. Since none of these locations were observed around gleno-humeral region, we may say that for surgery or prosthesis design, using contralateral healthy shoulder could serve as an informed decision making tool. These results corroborated previous studies [3].

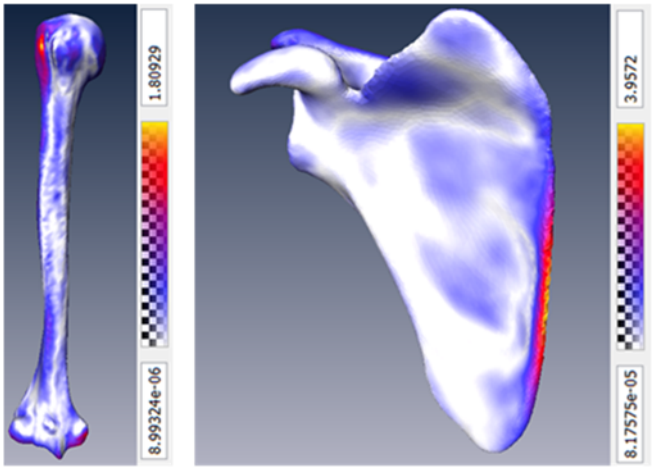

Figure 1: The average shapes from SSMs for the (a)Right humerus (b) Right scapula. The errors are in mm. The left side was mirrored to allow for comparison in same orientation. The temperature maps indicate that the white coloured areas represent minimum error while the maximum error are in yellow.

CONCLUSIONS

The findings of this pilot study can serve as a basis for decision making by comparing the operated shoulder with the healthy contralateral native shoulder. In addition, with a larger sample size, relevant automatic and quantitative anatomical measurements could be obtained from the humeri and scapulae average shapes. These parameters may be useful in designing specific anthropometric shoulder prosthesis.

IMPROVED SHORT-TERM WEIGHT BEARING AFTER DISTAL TIBIAL FRACTURE WITH AN ANGLE STABLE LOCKING SYSTEM

INTRODUCTION

Conventional unreamed intramedullary (IM) nailing of distal tibial fractures often results in high inter-fragmentary movements associated with pain, disuse, and delayed bone healing. An optimized, amount of axial fixation stability with minimum shear at the fracture gap allows the best bone healing outcomes [1], but it remains unclear if this also allows a swifter return to full weight bearing (WB) in patients. An angle-stable locking-nail system (ASLS) has pre-clinically demonstrated increased axial and torsional stability and reduced inter-fragmentary movements in a sheep model [2]. Previous clinical work indicates that ASLS does not subjectively improve WB outcomes [3]; however, objective measures may offer more insight into early patient function. We hypothesize that ASLS-treated patients will exhibit higher WB and function on the operated limb at an earlier time point compared to conventional IM nailing.

METHODS

Data from a previous multicenter prospective, randomized study were used [3], in which distal tibial fracture patients were randomized to conventional IM nailing (n=29) or ASLS (n=36) treatment. This study focuses on four out of eight centers with high compliance regarding gait measurement documentation. Static and dynamic vertical ground reaction forces were collected at 100 Hz using a pressure plate (FDM-SX system; zebris Medical, Isny, Germany) at baseline, 6 weeks, 12 weeks, 6 months, and 12 months post-surgery. Both center of pressure (COP) displacement and forefoot-hindfoot force distribution parameters were measured during static trials. In dynamic trials, patients walked over the platform, landing with a single foot on the platform at their preferred speed. From this data, force-time integrals were calculated and normalized to bodyweight. To determine overall asymmetries in dynamic weight bearing, the force time integral of the ipsilateral limb was subtracted from that of the contralateral limb. A one-way ANOVA compared group differences at each time point in SPSS (IBM, Armonk, NY).

RESULTS AND DISCUSSION

At baseline, static measurements showed that conventional IM patients favored WB on the injured forefoot (65.5±25.4%, p=0.017) compared to ASLS patients (50.0±26.1%). Starting at 6 weeks post-op, both patient groups were similar in injured forefoot-hindfoot force distribution, as well as overall force distribution on the injured limb.

In the initial baseline measurement, both mediolateral (ASLS: 17.1±12 vs. 14.9±27 mm, p=0.048) and anterior-posterior (ASLS: 24.3±13 vs. 23.2±31 mm, p=0.021) COP displacements were slightly higher in ASLS patients compared to conventional IM patients. This trend continued at 6 and 12 weeks post-op.

When comparing the relative asymmetry of the total mean force impulse during walking, conventional IM patients had significantly higher asymmetries (Figure 1), preferring to bear more weight on the contralateral limb at baseline (p=0.010) and 6 weeks post-op (p=0.020).

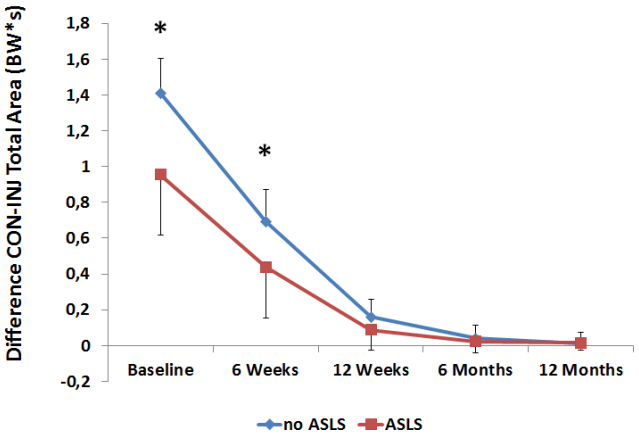

Figure 1: Comparison of the force impulse on the ipsilateral limb in the two treatment groups, calculated as the area below the vertical ground reaction force curve.

CONCLUSIONS

The primary results from this work show that during dynamic trials, ASLS patients show more symmetry in overall vertical loading and are able to apply higher loads to the operated limb compared to conventionally treated patients within the first 6 weeks after surgery. The results from the static tests show that ASLS patients are more likely to apply vertical force to the limb when standing, as there is a comparatively higher percent of force borne by the hindfoot at baseline. Furthermore, patients appear to engage both the ankle and hip muscles earlier, as shown by higher bi-planar COP displacements within the first 12 weeks post-surgery. To the best of our knowledge, this is one of the first reports in human subjects to demonstrate that mechano-biologically optimized implants that are designed to reduce inter-fragmentary shear (by means of the ASLS system) lead to preferentially higher load bearing on the operated limb compared to conventional IM nailing.

RECURRENCE-BASED PHASE SYNCHRONIZATION ANALYSIS OF DIGIT KINETIC SIGNALS DURING PRECISION GRIP

[1]**Ke Li**, [2]Na Wei, [3]Shouwei Yue
[1]Department of Biomedical Engineering, School of Control Science and Engineering, Shandong University, Jinan, China

INTRODUCTION

Precision grip plays a key role in a variety of manual functions. Development of digit coordination quantification provides a novel avenue for diagnosis of peripheral neuropathies, which are usually associated with sensorimotor deficits on the hand [1].

Phase synchronization (PS) is a critical feature of coupled signals. An advanced PS estimation has been proposed based on the cross recurrent quantification analysis (CRQA), This recurrence-based PS is a nonlinear approach that shows reliability in quantifying the phase synchronization of coupled non-stationary signals.

The objective of the current study was to quantify the phase synchronization of digit kinetic signals when the thumb coordinates with the index finger for precision grip. We hypothesized that the compromised tactile sensitivity will lead to a change of phase synchrony across digits.

METHODS

A device was designed to record the three-dimensional force and torque signals by two miniature 6-component sensors. Transparent polyethylene films were tightly wrapped up the distal pads of the thumb and index finger to mimic tactile perturbation. There were totally 4 conditions: (1) none of the digits was blocked; (2) only the thumb and (3) only the index finger was blocked; and (4) the two digits were equally blocked. Subjects gripped and held the device with the tips of their thumb and index finger as stably as they possible for 60 s.

In the cross-recurrence plot (CRP), a line of synchronization (LOS) could demonstrate the synchronization of the coupled dynamical systems. A synchronization index (SI) could be developed from the CRQA. A twin-surrogate hypothesis test would be an important examination of PS to avoid potential randomness of the time series or the noise of system.

RESULTS AND DISCUSSION

The LOS has some segments parallel to the main diagonal of CRP but it also has some segments deviated from the main diagonal, implying desynchronization of the two digits at those exact moments (Figure 1).

The Fz showed higher SI values and higher probability fulfilling the PS norms by surrogate tests than the other kinetic signals. The Py and Tz showed relatively lower PS probabilities than the other kinetic signals. With and without tactile deficits, the PS of Fz showed higher SI values and higher PS probability. The Py and Tz showed relatively lower PS probabilities than the other kinetic signals. When both the thumb and index finger had impaired tactile sensation, the inter-digit PS (SI) of Fz increased compared to the other conditions that at least one digit has normal tactile sensation. This increased PS of Fz would be attributed to a compensative mechanism [1], which may also suggest that the grip force control with tactile deficits was shifting from a feedback strategy towards a feedforward strategy.

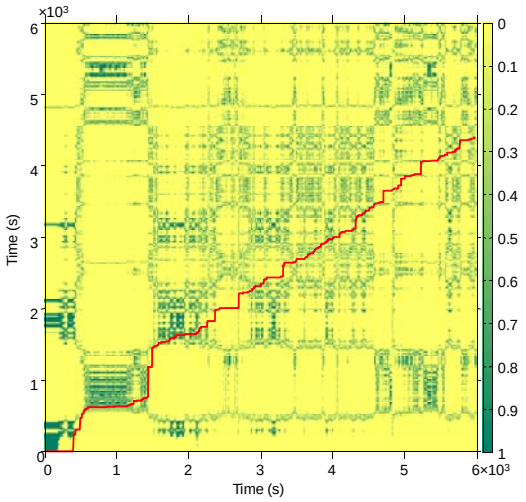

Figure 1: a recurrence plot based on the digit force Fz of the two digits with the LOS.

CONCLUSIONS

The PS between the Fz of the thumb and that of the index finger is a critical dynamical strategy underlying precision grip. When the thumb and index finger suffered from tactile deficits, the PS of Fz increased compared to the conditions without tactile deficits, suggesting a compensatory mechanism relying more on the feedforward control with reduced tactile sensory information.

A BIOMECHANICAL INVESTIAGTION INTO THE FUNCTION OF PALMARIS LONGUS MUSCLE

[1] **Erik Cattrysse**, [1]Julie Vercruyssen and [1,2]Aldo Scafoglieri

INTRODUCTION

The Palmaris longus muscle (PLM) is described as probably the most variable muscle in the human body. Not only in terms of absence but also in variability of origin , insertion and morphology. Literature suggests that when the PLM is present, it may function as a weak wrist and elbow flexor. Other functions of the PLM are assistance in carpo-metacarpal flexion and cupping of the palm, abduction of the thumb, stabilization of the superficial structures in the palm, and tensioning of the aponeurosis palmaris [1]. However, in case of agenesis of PLM, these functions remain. Therefore, it can be assumed that the presence of the PLM is of little overall value to hand function. Because of the lack of agreement about the clinical and functional importance of the PLM it is difficult to determine whether the PLM provides an advantage to handgrip in sport [2]. In the present study research has been conducted to determine whether presence of the PLM provides an advantage to handgrip in a sport such as tennis between elite tennis players and recreational athletes, by investigating differences in maximal grip-strength, fatigue resistance and sensory-motor function in relation to hand-dominance and gender.

METHODS

30 elite tennis players (M23-F7; ranking A to B-15/2) were compared to 30 age and gender matched controls. The presence of palmaris longus was checked by Schaeffer's, Thompson's, Mishra's, Pushpakumar's and Gangata's tests.
Hand-grip strength and fatigue were measured using an electronic Camry hand-held dynamometer. Sensory-motor function was estimated using a Flock-of Birds electromagnetic tracking device to register Joint Position Sense (JPS), Kinesthesia (KIN) and Joint Motion Sense (JMS). Data were processed using a custom made Mathcad routine and were statistically analyzed by descriptive statistics, Chi-squared tests and ANCOVA.

RESULTS AND DISCUSSION

Within the study group 50 subjects were right-handed (5 without, 4 unilateral and 41 bilateral PLM) and 10 were left-handed (1 without, 1 unilat, 8 bilat PLM). The relationship between hand dominance and the presence of the PLM was not significant ($p = 0.423$). And no significant relationships between the presence of the PLM and gender were found ($p = 0.501$). Neither was there a significant relation between elite and non-elite athletes and the presence of the PLM ($p = 0.576$). For maximal grip strength on the dominant side, significant differences were found for age ($p = 0.043$) and gender ($p = 0.000$). On the non-dominant side there was only a significant difference for gender ($p = 0.000$). Fatigue resistance on the dominant side presented no significant differences, but on the non-dominant side it was significant for the elite group compared to the non-elite group ($p = 0.009$). Proprioception as measured by JPS, KIN and JMS did not indicate significant differences between elite and recreational athletes or the presences of Palmaris longus muscle.

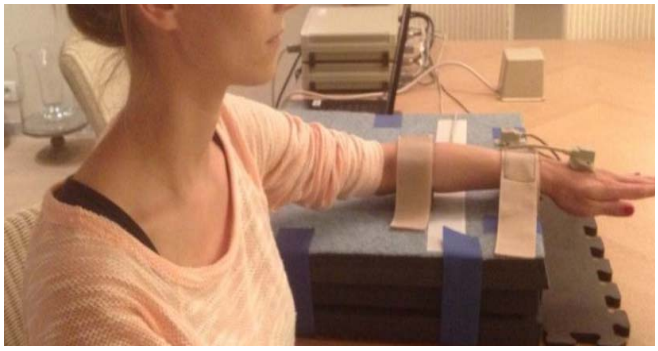

Figure 1: experimental set-up for sensory-motor testing using a Flock-of Birds electromagnetic tracking system

This is the first study reported in literature that measured the wrist proprioception in relation with the presence of the PLM and in relation with an elite sports population. Previously Fowlie et al. suggested that the presence of the PLM could provide a favorable contribution to sustained grip sports and cylindrical grip sports that require a higher level of skill [2] without investigating the effect on wrist functions. The authors suggest that in athletes who participate in a sustained or cylindrical grip sport, the PLM may provide a larger pool of muscle fibers that can be recruited for strength and endurance, or a greater pool of proprioceptors that can contribute to superior grip precision.
A major advantage of registering active movement with an electromagnetic tracking system is that subjects have free, unrestricted movement, unlike in the proprioception testing device, where they are generally limited to one degree of freedom. This is important for the wrist, because natural movement patterns involve multiplanar motions [3].

CONCLUSIONS

In this study, the results indicate that the bilateral presence of the PLM is the most common variation, compared to absence of PLM. More elite tennis players have a bilateral PLM compared to the non-elite athletes, but this difference was not significant. Most importantly, based on the present findings, absence of the PLM does not seem to be correlated with decreased grip strength, fatigue resistance, or proprioceptive measurements and is not different between elite and recreational tennis players.

DETERMINING THE MEDIAL-LATERAL AXIS OF THE FEMUR USING EOS BIPLANE RADIOGRAPHS IN CHILDREN AND ADOLESCENTS WITH TORSIONAL DEFORMITIES

INTRODUCTION

Hip rotation from 3D gait analysis informs clinical decisions regarding correction of femoral torsional deformities. However, it is the least repeatable kinematic measure due to discrepancies in determining the medial-lateral axis of the femur [1].

Conventional methods rely upon manual palpation or visual alignment to identify the axis. Another approach is functional calibration methods which rely upon joint range of motion movements to determine the axis.

Two medical imaging methods have shown promising results in typically developing adults. Freehand 3D ultrasound (3DUS), the coupling of ultrasound with 3D motion capture [2] and EOS, a new imaging modality. EOS acquires low-dose bi-plane x-rays of the subject in standing [3]. The entire lower limb is scanned and the 3D shape of the bones, as well as the 3D position of external markers, may be obtained. Both methods define the medial-lateral axis based on a femoral condylar axis. Neither of these methods have been evaluated in children with torsional deformities.

In this study EOS imaging has been used to determine the condylar axis of the femur and the accuracy of 3DUS, conventional and functional calibration methods to locate the axis in children and adolescents with torsional deformities was evaluated.

METHODS

Twenty-two children and adolescents with lower limb torsional deformities participated in the study. Ten had a diagnosis of spastic diplegic cerebral palsy (CP) (7♂, 3♀) and twelve were typically developing (TD) (2♂, 10♀). Written informed consent was obtained from their parent\guardian and approval granted by the local ethics committee.

Reflective markers were attached to the subject according to the Plug-in-Gait marker set ([4], Vicon Motion Systems). Subjects walked up and down a walkway at their self-selected speed. A 10-camera motion-capture system (Vicon Motion Systems) and 5 force platforms (ATMI, Advanced Mechanical Technology, Inc) were used to measure kinematics and kinetics.

The medial-lateral axis of the femur was determined using 3DUS [2], a knee alignment device (KAD) placed over the medial and lateral epicondyles and two functional methods; the axis transformation technique (ATT) which models the knee as a hinge [5], and a method closely related to the dynamic KAD method which models the knee as a 2dof joint (2dofKnee) [6]. The functional calibration methods were applied to 2 calibration movements; three knee flexion-extensions and three walking strides.

The reference method was the axis obtained from EOS imaging. The accuracy of the other methods was expressed as the angular difference of the various axes in the transverse plane to the reference.

RESULTS AND DISCUSSION

For both the flexion-extension and walking calibration movement significant difference was found in the range of knee flexion angle between groups, mean difference (95% confidence interval) 28° (21°, 35°) and 10° (3°, 17°) respectively. Ultrasound was the closest to the EOS reference, mean difference CP 2° and TD 1°. The KAD and functional calibration methods were predominantly external compared to the reference. Significant differences were found between the CP and TD groups for all functional calibration method x movement except the 2dofKnee using walking (Figure 1).

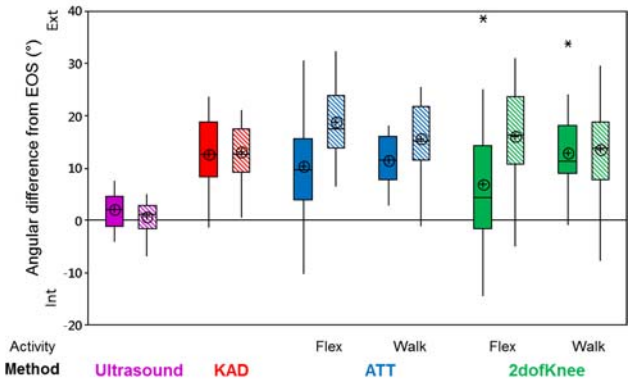

Figure 1: Boxplot of angular difference to EOS condylar axis. Solid fill CP, diagonal shading TD. * denotes outliers.

CONCLUSIONS

We determined the condylar axis of the femur using EOS imaging for the first time in a group of children and adolescents with torsional deformities. Ultrasound results were close to the EOS reference and can be easily obtained during a 3DGA session. The KAD and functional calibration methods performed less well in this population than in healthy adults [2,3].

DEVELOPMENT OF A MOTION ANALYSIS PROTOCOL FOR USE IN ROUTINE CLINICAL CARE

[1] **Lindsay J Millar**, [2]Andrew J Murphy and [3]Philip J Rowe
[1,3]University of Strathclyde, Glasgow, UK
[2]DIH Technology, Chengdu, China

INTRODUCTION

There is widespread agreement that motion analysis is currently the gold standard for measuring human movement in a non-invasive manner [1]. Current commercially available systems, such as Vicon Plug in Gait (PiG, Vicon Motion Systems, Oxford, UK) have been developed over a number of years and are capable of providing a biomechanical analysis which is robust enough to dictate complex treatment plans, such as multi-level surgery [1]. However, due to the vast capabilities of PiG, it is a time consuming and technically complex protocol to deliver. Additionally, there are currently limited options for delivering motion capture using other protocols which vastly limits the use of motion analysis in other aspects of clinical care, such as outpatient rehabilitation. Cluster based marker sets may provide a faster and less technically complex alternative to models such as PiG; however these are currently not commercially available and have thus far been restricted to research environments. Therefore, the aim of this study was to develop a bespoke cluster based motion analysis protocol (Strathclyde Cluster Model; SCM) capable of calculating lower limb kinematics which could be implemented in routine clinical care in order to expand the use of motion analysis beyond research and complex clinical cases. Further aims included an assessment of the kinematic output and reliability of SCM in comparison to PiG.

METHODS

The bespoke marker set comprised seven 3D printed, rigid plastic plates, each with 4 markers attached, for each segment of the lower body. Participant calibration was completed using a digitiser which negated the use of skin surface markers and thus allowed participants to wear their own clothing, providing anatomical landmarks could still be palpated. Anatomical reference frames were calculated in accordance with the International Society of Biomechanics recommendations [2] and the Grood and Suntay [3] method was used to calculate kinematics. To compare the kinematic output of SCM to PiG, five participants completed 10 overground walking trials each whilst wearing both marker sets and flexion/extension (flex/ext), ab/adduction (ab/ad) and internal/external rotation (int/ext) were compared for the hip and knee. Ankle plantar/dorsi flexion was also compared. To assess the reliability of SCM in comparison to PiG, the mean kinematic output, variability and coefficient of multiple correlation (CMC) were compared between and within assessors for six assessors using both models and one subject for all assessments.

RESULTS AND DISCUSSION

Results of the kinematic comparison revealed some significant differences between the two models (figure 1). Differences in flex/ext and ab/ad outputs are likely due to differences in anatomical reference frame definition and kinematic calculation. Differences in int/ext were more evident; however previous studies suggest that there are few similarities in this output when compared between models [4] and therefore this is not a surprising result.

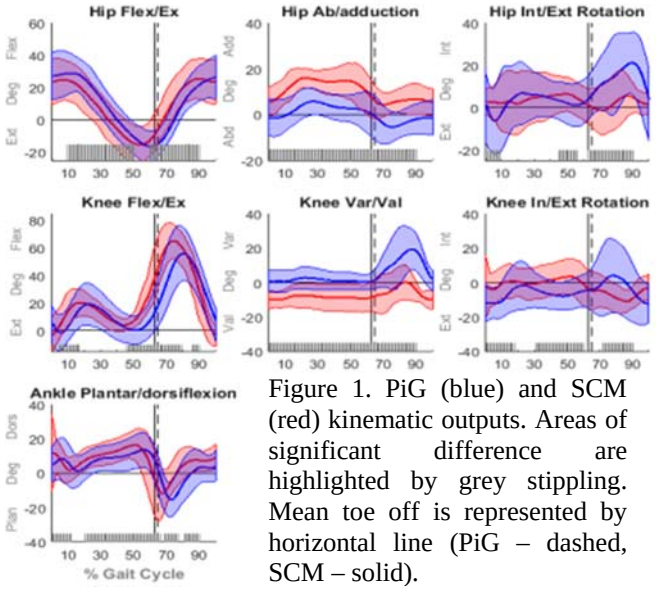

Figure 1. PiG (blue) and SCM (red) kinematic outputs. Areas of significant difference are highlighted by grey stippling. Mean toe off is represented by horizontal line (PiG – dashed, SCM – solid).

For inter-assessor reliability, both models demonstrated high or moderate reliability for all joint rotations. SCM compared favourably to PiG for all rotations except hip int/ext where SCM demonstrated a CMC value of 0.53 compared to 0.94 for PiG. Previous studies are in agreement with these results [5] although this result could also be a reflection of the different calibration methods in that assessors were more confident using pelvic markers in PiG than the digitiser in SCM to calibrate the pelvis and thus calculate the hip joint centre, which would have an effect on kinematic calculation. For intra-assessor analysis, both models demonstrated high CMC values for all joint rotations except hip int/ext in SCM, which exhibited similar values to those seen in inter-assessor results (0.59). However, examination of the kinematic curves revealed limited variability so it is likely that one or two SCM hip int/ext curves were not correlated, but didn't deviate far from the mean, thus resulting in a low CMC but a tight confidence band.

CONCLUSIONS

SCM is a motion analysis protocol which has been developed for routine clinical use, such as outpatient rehabilitation and therefore application of markers and participant calibration is quicker and easier than current commercial alternatives. Further, kinematic output and reliability are comparable between SCM and the current clinical gold standard. Therefore, SCM is a suitable alternative for providing an objective assessment of function and outcome in routine clinical practice.

INTRODUCTION

Three dimensional gait analysis (3DGA) is used in pediatric orthopedics providing useful indications for clinical decision-making in children with cerebral palsy (CP). Nonetheless, approximately one quarter of patients still experience negative outcomes when the recommendations from 3DGA are followed [1].

Most clinical gait laboratories use the conventional gait model (CGM) [2]. This model employs a computational method called Direct Kinematics (DK) to calculate joint kinematics. In recent years user friendly musculoskeletal (MSK) modelling software [3] has emerged which employs a computational method called Inverse Kinematics (IK) and has the advantage of enabling additional analyses on surgically adjustable parameters (e.g. musculotendon lengths) which might improve the clinical decision-making in children with CP.

Before these MSK approaches can be used with confidence in a clinical setting it is necessary to (i) examine if and why differences exist between the joint kinematics derived from the CGM and MSK models, and (ii) assess the reliability of 3DGA results using both approaches, which were the aims of this study.

METHODS

Magnetic resonance images (MRIs) and 3DGA data were collected from eleven children with CP and seven typically developing participants who returned for a second 3DGA session one week later.

To address the first aim of this study, eight personalized skeletal DK and IK models were created from the MRIs (Figure 1) to evaluate the difference in joint kinematics that can be solely attributed to the different computational methods (DK versus IK), anatomical models and marker sets. Additionally, joint kinematics obtained from the Plug-in-Gait (PiG) model, which is the most common CGM, were compared to joint kinematics obtained from the 'gait2392' OpenSim model, which is a commonly used MSK model.

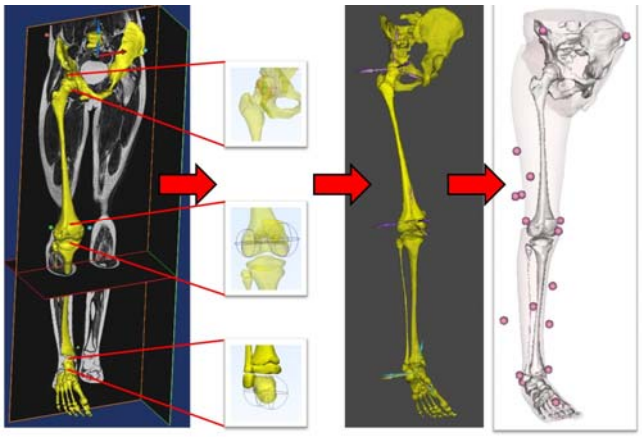

Figure 1: Mimics, 3-matics, NMSbuilder and OpenSim were used for creating personalized models.

To address the second aim of this study, intra- and inter-tester standard deviations (SDs) of kinematic and kinetic waveforms were used to compare the reliability of the (a) Plug-in-Gait (PiG) model, (b) a six degrees-of-freedom DK model which was similar to the CGM but used more accurate methods to estimate joint centres and did not impose joint constraints between segments, (c) the 'gait2392' OpenSim model, and (d) a modified OpenSim model which allowed three rotational degrees-of-freedom at the knee joint.

RESULTS AND DISCUSSION

Kinematic differences of up to 13 degrees were found between the PiG and the 'gait2392' OpenSim model, with 94.4% of these differences attributed to differences in the anatomical models, which included different anatomical segment frames and joint constraints. Different computational methods (DK versus IK) and marker sets were responsible for only 2.7% and 2.9% of the differences, respectively.

All analyzed models showed good reliability with mean SDs of 2.7 degrees. The reliability of sagittal and coronal plane joint kinematics was similar between models with mean intra- and inter-tester SDs below 4 degrees. Intra-tester SDs in the 'gait2392' and modified OpenSim models and inter-tester SDs in the 'gait2392' model for hip internal/external rotations were significant smaller ($p<0.05$) than in the PiG model. Mean intra- and inter-tester SDs for joint kinetics were below 0.08 Nm/kg for all models.

CONCLUSIONS

We quantified the differences and causes of the differences between the CGM and MSK models, and evaluated the reliability of kinematic and kinetic 3DGA output from the CGM, a six degrees-of-freedom DK model and two MSK models.

Different anatomical reference frames and joint constraints were the main reason for differences in joint kinematics between models and, therefore, the same anatomical model should be used for kinematic and MSK analyses to ensure consistency between the obtained joint angles and musculoskeletal estimates.

The modified MSK OpenSim model included all joint rotations currently reported in clinical 3DGA, showed high reliable joint kinematic and kinetic estimates, and, therefore, it is a suitable model for clinical gait analysis. Compared to the CGM, the modified OpenSim model furthermore allows additional MSK analyses on surgically adjustable parameters which might increase the number of positive intervention outcomes in children with CP.

COORDINATION PATTERNS IN REACHING TASKS IN CHILDREN WITH OBSTETRIC BRACHIAL PLEXUS PALSY

[1] **Daiane Lazzeri de Medeiros**, [2]Luis Mochizuki, [3]Richard Van Emmerik, [1]Tenysson Will de Lemos, [1]Natália Borges Agostinho, [1]Isabela Forcin Favaro, [1]Anamaria Siriani de Oliveira

INTRODUCTION

The obstetric brachial plexus palsy (OBPP) is a hypotonic paresis of the upper limb due to a unilateral traction of the brachial plexus during birth. OBPP could lead to weakness of the biceps, deltoid and shoulder external rotators, with possible development of contractures in the internal rotation of the shoulder and flexion of the elbow [1]. These conditions constrain shoulder and elbow ranges of movement, and push children to use compensatory patterns to perform reaching activity needed to perform functional tasks.

The aim this study was to determine the coordination patterns in reaching tasks in children with OBPP and typical children. Coordination patterns were obtained with the coordination mode analysis [2]. Coordination mode analysis decodes the coupling angle time series into a sequence of four coordination modes (inphase, antiphase, proximal phase and distal phase).

METHODS

This study was approved by the local ethics committee (protocol number 50239115.6.0000.5440). Eight children with OBPP (9±2 y, 44.4±14.3kg, 1.45±0.15m), and eight with typical development (9±2 y, 35.9±9.7kg e 1.39±0.10m) matched by sex were compared. Five OBPP children presented Upper Erb's and three Extended Erb's. A motion capture electromagnetic system (Polhemus, Colchester, VT) was used to reconstruct the 3D coordinates of the scapula and upper limb, according to the recommendations of the International Society of Biomechanics [3]. Kinematics of the injured limb of OBPP children and the dominant limb of typical children were recorded during a high-reach task (HRT) (touch a ball), a hand-to-back-pocket task (HBPT), and a hand-to-head task (HHT) in two conditions, preferred speed and as fast as possible speed each with to repetitions.

Three-dimensional data were processed using The MotionMonitor™ software. Coordination Modes Analysis (CMA) was used to evaluate segmental coupling. These were for HRT: UR-SF: scapular upward rotation and shoulder flexion; DT-SF: scapular downward tilt and shoulder flexion; UT-SF: scapular upward tilt and shoulder flexion; SF-EE: Shoulder Flexion and Elbow Extension; for HBPT: UR-SE: scapular upward rotation and shoulder extension; UT-SE: scapular upward tilt and shoulder extension; SE-EF: shoulder extension and elbow flexion; SE-FP: shoulder extension and forearm pronation; and for HHT: UR-SA: scapular upward rotation and shoulder abduction; SD-SA: scapular downward tilt and shoulder abduction; SA-FF: shoulder abduction and flexion forearm; SA-HI: shoulder abduction and head inclination; SA-HF: shoulder abduction and head flexion [3]. The number of different coordination modes was quantified during the whole coordination mode sequence. This quantity was calculated for the beginning (first third), middle (second third) and ending (last third) phases of the tasks. MANOVA was applied to verify the effect of groups and execution speed on the coordination patterns. The Levene test verified the homogeneity of variances ($p > 0.05$).

RESULTS AND DISCUSSION

In relation to the main codons that represent more than 50% of each task in the different coordination patterns (oscillatory, semi-oscillatory and varied), it was possible to observe that there was no similarity between the OBPP children and typical children in the majority of the coupling angle of the HRT, HBPT and HHT tasks. The most common coordination mode sequence for each task, couple angle and velocity was compared between groups. This comparison was proceeded for the early (1–33%), mid (34–66%) and late (67–99%) phases. Children of both groups performed the tasks (HRT, HBPT, and HHT) with similar coordination patterns at the early and in the mid of the task. However, in the late phase, there was statistical evidence of difference between groups ($p = 0.03$). Children with OBPP use compensatory patterns to perform functional tasks, with variability in function performance [4]. These differences may suggest that OBPP children may perform poorly due to the restriction of range of motion that is required at the end of the tasks and the use of compensatory patterns to mask this limitation.

CONCLUSIONS

The OBPP children and typical children presented few matching coordination patterns, however, when the task was divided, similarities were observed in coordination patterns, regardless of speed, at the early and mid of the task; But at the end, there was a difference between the groups. Such differences might suggest that children with OBPP can have worse performance if the goal of hand-oriented upper limb task must be achieved at the end of the movement.

INTRODUCTION

As pointed out by Karol, the use of nonoperative treatment for idiopathic clubfoot is more and more frequent [1]. Two methods are commonly followed for these conservative treatments: the Ponseti cast technique and the French functional [physical therapy] technique [2, 3]. Gottschalk studied the effects of these two techniques on gait patterns focusing on ankle kinematics and kinetics [4]. Mindler documented tibia, hindfoot and forefoot angular relationships in children treated by the Ponseti method [5]. But the effect of tenotomy was not clearly documented.

The aims were to assess the impact of Achilles' tenotomy on kinematics, kinetics and pressure variables including a multi-segment foot model approach and to compare the effect of treatment: Ponseti vs French functional techniques.

METHODS

Thirty two clubfeet (mean age of patients: 7.8 (SD: 2.6) yrs) and seventeen healthy feet (mean age of subjects: 9.6 (SD: 2.6) yrs) were included in this study. Clubfeet were rated according to the Dimeglio scoring system. Tenotomies were performed on 23 clubfeet. Ponseti cast technique was applied on 14 clubfeet and French functional technique on 18 clubfeet.

Children were equipped with a marker set which divided the foot into three segments: hindfoot, midfoot and forefoot. Additional processing included computation of a lateral and medial forefoot and planar angles. Foot segment kinematics was recorded using an optoelectronic system (VICON T40s, 8 cameras) and two force plates (AMTI). Two Footscan pressure plates (0.5m RSscan) were positioned on the force plates and synchronized. All kinematics and kinetics variables were computed using Nexus and Matlab.

Joint angles, planar angles, ankle kinetics parameters were analyzed during stance phase and a subphase between 20 to 45% of the cycle [6] to allow comparison between static and in-motion stances. Lateral and medial pressures were also included in statistical group comparison.

RESULTS AND DISCUSSION

Significant differences were observed between clubfeet and controls with an increased pelvis RoM , an increased knee flexion initial contact, increased knee flexion 20-45 range, an increased in-toing foot progression, a decreased dorsiflexion during swing, a decreased medial pressure and a decreased of ankle power (Fig.1).

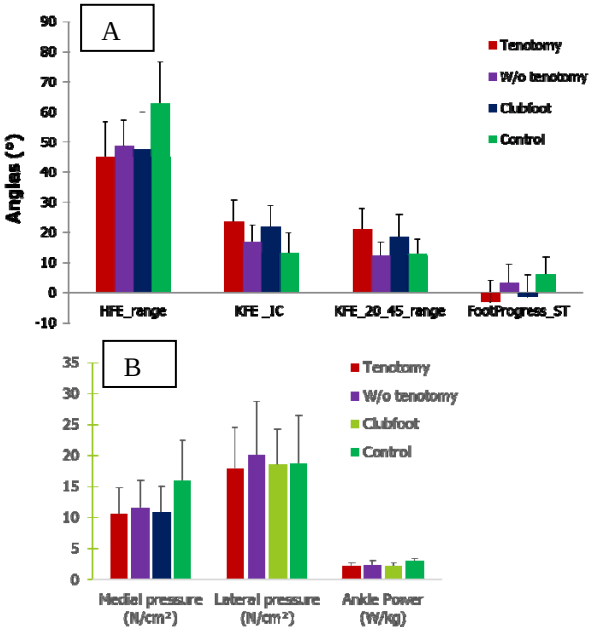

Figure 1: Comparison of A: knee flexion at initial contact and knee extension during 20 to 45% of cycle. B: Lateral and medial pressure and maximal ankle power during stance

CONCLUSIONS

Combining multi-segment foot kinematics, kinetics and pressure data opens new opportunities that may contribute to improve our understanding of clubfoot patterns. For kinematics, significant differences were observed between clubfeet and controls with a significant effect of tenotomy. However, no differences were retrieved between Ponseti vs French techniques. For kinetics, ankle moment and power were also significantly different. Plantar pressure highlighted a significant difference between groups on the medial part of foot. Further development is needed to relate joint/planar foot angle analysis with pressure data to better cover the complexity of clubfoot torsional deformity.

BIOMECHANICAL STUDY OF DIFFERENT FIXATION TECHNIQUES FOR THE TREATMENT OF SACROILIAC JOINT INJURIES USING NUMERICAL AND EXPERIMENTAL APPROACHES

INTRODUCTION

The pelvis is one of the most stressed areas of the human musculoskeletal system due to the transfer of truncal loads to the lower extremities [1]. Sacroiliac joint injury may lead to abnormal joint mechanics and unstable pelvis [2]. Various fixation techniques have been evaluated and discussed in the past. However, it may be difficult to investigate each technique due to variations of bone quality, bone anatomy, fracture pattern, and fixation location [3]. Additionally, the finite element (FE) method is one useful technology for avoiding these variations [4]. Unfortunately, most previous studies neglected the effects of lumbar spine and femurs when they investigated the biomechanics of pelvises [5].

Thus, the aim of this study was to investigate the biomechanical performance of the intact, injured, and treated pelvises using numerical and experimental approaches.

METHODS

Three-dimensional FE models of the spine-pelvis-femur complex with and without muscles and ligaments were developed. The intact pelvis, the pelvis with sacroiliac joint injury, and three types of pelvic fixation techniques, which included the posterior iliosacral screw (PIS) fixation, sacral bar (SB) fixation, and locking compression plate (LCP) fixation, were analyzed (Fig. 1A). The maximum displacement of the sacrum, the maximum von Mises stress of the fixation devices, and the maximum von Mises stress of the pelvises were calculated to evaluate different pelvic fixation techniques.

Concurrently, Single loading tests were conducted to validate the feasibility and applicability of the spine-pelvis-femur complex. The testing specimens were composed of the pelvic fixation devices and the artificial pelvis. The intact specimens, the injured specimens, and three types of the treated specimens were fixed on the experimental jigs, and a specially designed loading jig was developed to mimic the effects of human spine. All test specimens were compressed on the top surface of the sacrum at a loading rate of 1 mm/min. The single loading tests were conducted using a servo-hydraulic material testing system (Instron 8872, Instron Corp., Canton, MA, USA) (Fig. 1B). The load-displacement curves were recorded, and the stiffness of each specimen was calculated to study the stability or fixation stability of different pelvic fixation devices. For the statistical analysis, one-way ANOVA with Bonferroni post hoc tests was used to compare the stiffness in each situation. In the correlation analysis, the correlation coefficient between the maximum displacement of the sacrum obtained from the FE models and the stiffness acquired via the single loading tests was calculated and evaluated.

RESULTS AND DISCUSSION

The numerical results showed that the injured model significantly deteriorated the stability compared with that of the intact model. All treated models revealed that the loss of stability can be recovered, especially for the SB fixation and PIS fixation. For the implant and bone stresses, both the SB fixation and the PIS fixation showed a lower maximum stress of the fixation devices compared with the LCP fixation. The intact model had the lowest pelvic stress compared with the other situations. The numerical outcomes in the FE models with muscles and ligaments were similar to that in the FE models without muscles and ligaments.

The experimental outcomes showed that the stiffness of the LCP fixation was significantly lower than that of the other two fixation techniques (P=0.00). Additionally, it did not significantly differ from the injured group (P=1.00). In the correlation study, the maximum displacement that was acquired via the FE models was closely related to the stiffness obtained from the biomechanical tests, with a correlation coefficient of -0.98.

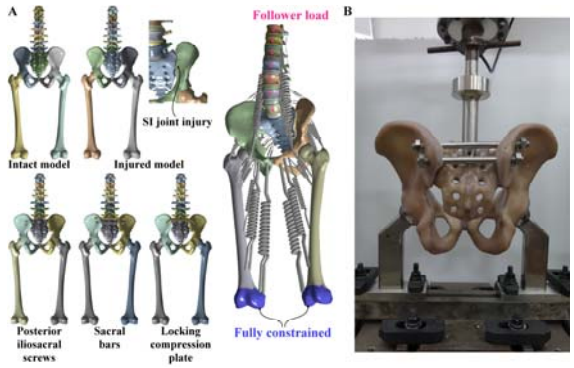

Figure 1: (A) Intact, injured, and treated numerical models. (B) Experimental setup.

CONCLUSIONS

The biomechanics of the intact pelvis, the pelvis with the SIJ injury, and three types of pelvic fixation techniques were investigated using the FE analyses and experiments. The PIS fixation revealed a better fixation stability and lower risks of implant failure and pelvic breakage compared with the other approaches. Therefore, PIS fixation is suggested for treating pelvises with SIJ injury. This study can help surgeons and engineers understand the biomechanics of intact, injured, and treated pelvises.

THE INFLUENCE OF ASSEMBLY FORCE ON THE MATERIAL LOSS AT THE HEAD-NECK JUNCTION OF HIP IMPLANTS IN PHYSIOLOGICAL BODY FLUID SUBJECTED TO CYCLIC FRETTING WEAR

[1] **Khosro Fallahnezhad**, [2]Hojat Badnava, [1]Reza H Oskouei, [1]Mark Taylor

INTRODUCTION

In spite of the benefits of modular design at the head–neck taper junction of total hip replacement (THR), there are problems associated with the release of fretting-wear debris resulting in adverse soft-tissue reactions (ASTR) [1]. To date, there have been very limited studies to investigate the material loss and also the parameters that can affect on the material removal from the junction. These studies are based on major simplifications such as neglecting the mismatch angle between the head and neck. Moreover, all these studies have investigated the interaction between the head and neck in a dry condition, while physiological body fluid could have a significant impact on the behaviour of the contacting surfaces subjected to fretting wear. In this study, a Finite Element (FE) model of the head-neck junction was developed to simulate the fretting wear process. This model was used to investigate the effect of assembly force on the material loss process under a high cyclic gait loading.

METHODS

The material combination used in this study was a CoCr head and a CoCr neck with a distal mismatch angle of 0.024º To model the fretting wear, a FORTRAN code was developed that can control the position of the surface nodes through the ABAQUS UMESHMOTION subroutine within an adaptive meshing constraint. To verify the code, a pin-on-flat model was first developed according to Ding's work [1]. The surface profiles of the flat component were produced and compared with the ones presented by Ding et al. [1]. A good agreement was found between the profiles that successfully verified the UMESHMOTION code and its accuracy used in this study. A three dimensional (3D) model of the CoCr-CoCr head-neck junction was developed and analyzed under walking load profiles. The FE analysis identified the most critically stressed two dimensional section from the 3D model for which the corresponding load components were also determined in order to be used in the 2D fretting wear model of the junction. The wear coefficient and friction coefficient for a CoCr-CoCr contact in a phosphate buffered solution (PBS) were applied to simulate the performance of the head-neck junction in a simulated physiological body fluid. The head and neck models were assembled with 2,000N, 3,000N and 5,000N forces and then subjected to 1,025,000 cycles of walking gait loading.

RESULTS AND DISCUSSION

Figure 1a shows the area loss of the neck during the 1,025,000 cycles of the gait loading for three assembly loads. It is apparent that the area loss versus fretting wear cycles has a linear behaviour. By increasing the assembly force, the amount of area loss increases. After 1,025,000 cycles, models that are assembled by 2,000N, 3,000N and 5,000N forces had 0.0016 mm^2, 0.0027 mm^2, and 0.0053 mm^2 area loss, respectively. Figure 1b demonstrates the depth of fretting wear through the length of the neck, after 1,025,000 cycles. This figure reveals that the wear depth is significantly higher in the distal side, which was understood to be because of the distal mismatch angle between the head and neck. Moreover, the contact length between the head and neck after 1,025,000 cycles, increases with increasing the assembly force. Maximum value of the wear depth for models that are assembled by 2,000N, 3,000N and 5,000N forces were 0.35 µm, 0.49 µm and 0.78 µm, respectively.

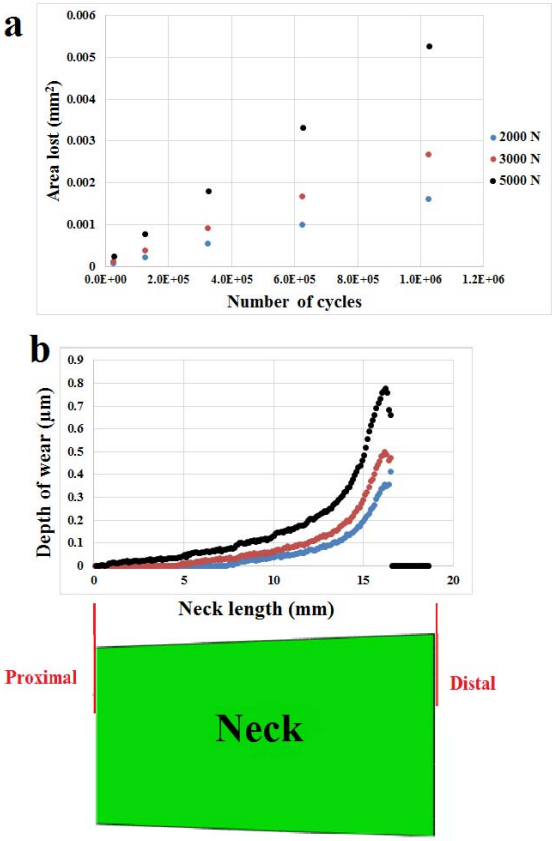

Figure 1: (a) Area loss of the neck versus number of cycles, (b) wear depth versus neck length.

CONCLUSIONS

Based on the Archard equation used in this work, contact pressure, contact length and amplitude of sliding were found as the three parameters that can affect on the material loss in the head-neck junction subjected to cyclic gait loading. Junctions that were assembled with smaller assembly forces (e.g. 2,000N and 3,000N) had higher sliding amplitudes. Higher contact stresses and longer contact lengths produced in 5,000N assembled junction resulted in greater amounts of material loss and depth of wear.

TOWARDS *IN SILICO* ANALYSIS OF TOTAL HIP ARTHOPLASTY MECHANICS

[1] **Karen B FitzGerald**, [1]Philip Cardiff, [1,2]Rob Flavin and [1]Alojz Ivankovic,
[1] University College Dublin,
[2] St Vincent's University Hospital Dublin.

Corresponding author email: *karen.fitzgerald@ucdconnect.ie*

INTRODUCTION

Total Hip Arthroplasty is a surgical procedure that reforms the hip joint, replacing the pathological joint with an artificial prosthesis. Due to post-operative joint instability, complications such as dislocation are still a significant problem. Understanding the mechanics of the hip joint is key in the development of preventative methods to treat post-operative hip dislocation.

As a consequence of the limitations of *in vivo* and *in vitro* hip joint studies, it is proposed that *in silico* (performed on computer or via computer simulation) studies could prove to be an effective tool for the analysis of hip joint mechanics and stability. The development of a faithful, well-verified hip joint model, based on coupled rigid-body dynamics and continuum mechanics would provide unique insight, jointly aiding in the development of complex soft tissue reconstruction procedures and the design of next generation prostheses.

METHODS

Using Computed Tomography (CT) image-sets a patient-specific 3-D model of the hip joint of an adult male was created. This model was then converted into a high-resolution continuum mesh (~6.5 million cells) using commercial software ANSYS ICEM CFD and open-source software cfMesh, see (Figure. 1). A contributing factor to inaccuracy of numerical models of the hip joint may be ascribed to simplifying assumptions with regard to using uniform bone mechanical properties, hence a CT-Based model was chosen in this case. The Young's modulus is assigned based on the apparent density obtained from Hounsfield intensities of the tissue detailed in each voxel of the CT slices, ~~see (Figure. 1).~~

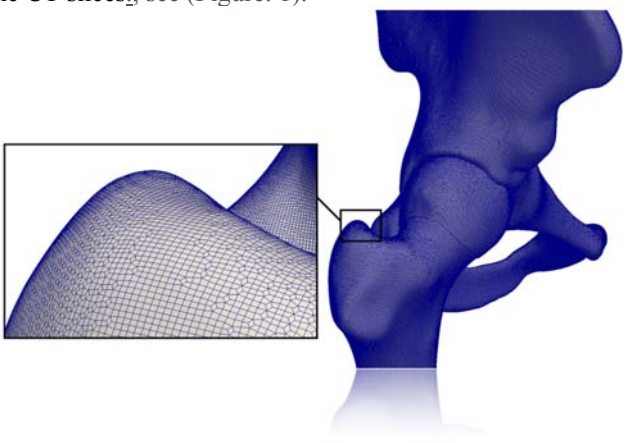

Figure 1 High-resolution continuum mesh.

Gait data of the same adult male was analysed using a rigid-body model of the lower extremity in open source software OpenSIM, thus, the peri-articular loading and reaction forces can be realistically captured for a full gait cycle. The future aim is that muscle forces may be obtained from this OpenSIM model and applied to the continuum model coupling the two modelling approaches.

Preliminary analyses were performed with the continuum model by applying boundary conditions obtained from Gait Analysis. The boundary conditions are as follows; fixing the pelvis at the iliosacral and pubic symphysis joints, and displacing the distal femur in the axial direction into the acetabulum. The femur is displaced such that the resulting total hip force is as measured in [1] that is, at mid-stance and toe-off, the hip joint force is twice body weight, equating to 1,611 N in the femur axial direction and 2.38 times body weight for the heel-strike case, equating to 1,917 N femur axial force.

Displacements and stresses have been calculated using a cell-centred Finite Volume method, implemented in open-source software OpenFOAM, where jobs were run on a supercomputer at the Irish Centre for High End Computing using 24 CPU cores.

RESULTS AND DISCUSSION

The results were compared with a previously developed continuum model [2] that employs a sandwich material distribution. Stresses that are more characteristic of those previously reported in the literature were obtained [3]. A maximum contact pressure of 10.3 MPa is observed in the cartilage of the acetabulum, far less than that predicted in the sandwich model (26 MPa). Contact pressure locations are concurrent in both cases; however, peak magnitudes are significantly different as reported above. A corresponding contact area of 7.32×10^{-4} m^2 is seen in the model, which in this case is larger than that of the sandwich model (3.96×10^{-4} m^2). This is consistent with the difference in contact pressure. Regions of high stress in the pelvis include the ilium directly above the acetabulum, the acetabular roof bone, and near the fixed iliosacral joint.

CONCLUSIONS

The resulting natural hip joint model is the basis of additional work being developed to more realistically capture the physics of the problem. The first of which is the inclusion of a total hip arthroplasty prosthesis into the model, allowing analysis of the mechanics and stability of a reconstructed hip joint. Additionally, incorporation of muscle forces from the OpenSIM model is being undertaken currently. Ultimately, it is hoped that the insights gained will help orthopaedists make confident surgical decisions.

COMPUTATIONAL ASSESSMENT OF THE INFLUENCE ON BONE MASS DENSITY AND BODY MASS INDEX ON THE PRIMARY STABILITY AND STRAIN DISTRIBUTION OF REVISION TIBIAL TRAYS

[1]**Maged Awadalla**, [1]Rami M. A. Al-Dirini, [1]Dermot O'Rourke, [2]Bogdan Lucian Solomon, [3]Mark Heldreth, [1]Mark Taylor

[1] School of Computer Science and Engineering, Flinders University of South Australia, Australia

INTRODUCTION

The survival and satisfaction rate of the revision surgery are inferior and have not yet equaled that of the primary TKR, with 1 in 8 patients require further surgery within 5 years [1]. Modular implant systems (sleeve, stem and augments) are popular in revision surgeries due to their flexibility in addressing various bone defects. Each specific revision bone defect require a particular combination of modular implants. However, patient weight and bone mass density can influence implant primary stability in different ways and alter the expected long term outcome.

The aim of the study is to examine the effect of decreased bone mass density (BMD) and increased body mass index (BMI), separately, on implant primary stability and strain distribution.

METHODS

An FE model (Abaqus, Dassault Systemes) was generated of the non-operated limb of a post TKR 72 year old male patient with body mass index of 25 kg.m^{-2} (weight: 82kg, height: 1.8m). Gray scale values were sampled from CT scan to extract material properties. Hypermesh was utilized to include the patient specific bone defect (AORI type T1 caused by removing the previous TKR implant and cement [2]). Bone cuts and alignment of the tibia implant were preformed following the surgical guide (DePuy Synthes Joint Reconstruction, Warsaw, IN). Joint contact forces for stair descent was applied [3]. The loads and moments were scaled to the body mass of the current subject. The applied forces were scaled based on UK average BMI plus 1 standard deviation ((Obese + SD), BMI = 36 kg.m^{-2}) and plus 2 standard deviations ((Obese + (2 * SD)), BMI = 41 kg.m^{-2}). Bone mass density was varied by using the average and lower bounds of published modulus density relationship [5]. The tibia was rigidly constrained at the distal epiphysis region.

RESULTS

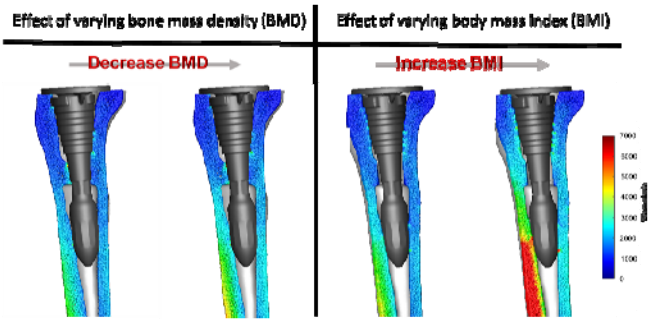

Figure 1: the effect of varying the bone mass density and the body mass index separately on the strain distribution in the tibia.

		Patient weight		Obese + (2 * SD)	
		H-BMD	L-BMD	H-BMD	L-BMD
Micro-Motion (µm)	95prctile	11.4	17.9	22.1	46.2
	75prctile	3.7	5.5	7.4	15.2
	Mean	3.4	5.0	6.5	13.2
	% over 150-µm	0.2 %	1.0 %	1.4 %	4.4 %
	% over 50-µm	0.0 %	0.0 %	8.0 %	1.0 %
Micro-Strain	95prctile	2980	4410	5900	10570
	75prctile	868	1138	1500	2960
	Mean	681	946	1284	2912
	% over 7000	0.2 %	0.2 %	3.5 %	8.4 %

Table 1: The effect of varying BMD and BMI on Micro-motion and strain value. **95prctile** denote 95 percentile. **75prctile** denote 75 percentile. **% over 50-µm** and **% over 150-µm** denote the area of the implant surface that experience micro-motion greater than 50-µm and 150-µm respectively, as a percent of the implant's total surface area that is in contact with the bone. **% over 7000** denote the area of the implant surface that experience equivalent strain greater than 7000 µε (yield strain) as a percent of the implant's total surface area. **H-BMD** and **L-BMD** denote high and low bone mass density respectively.

DISCUSSION AND CONCLUSIONS

The outcome demonstrates that, for a tibia with AORI Type T1 defect, adequate mechanical support and stability was achieved in the sleeve region regardless of BMD or BMI level. This is supported by the current literature [6]. However, strain in the diaphysis was significantly affected by variation in the BMI value (Increase in BMI to (Obese + (2 * SD)) lead to 50% increase in strain). On the other hand, variation in BMD alone did have an effect on the strain distribution (decrease in BMD lead to 30% increase in strain), however it was less compared to variation of BMI (Table.1.) (Figure. 1.). Future analyses should include variation in BMI in order to capture the spectrum of loading likely to be encountered by revision implants. We are currently working on a larger sample size analysis

INTRODUCTION

Pre-clinical testing of orthopedic devices could be improved by comparing performance against established implants with known clinical histories. Corail® (DePuy Synthes, Warsaw) is a femoral stem, with various options for restoring the native femoral anatomy, and has a proven survivorship of 95.1% at 10 years [1], which makes it a good candidate as a benchmark when evaluating new stem designs. Hence, the aim of this study was to establish benchmark data relating to the primary stability of Corail ®.

METHODS

Subject-specific Finite Element (FE) models of implanted femora were run for a diverse patient cohort within the Melbourne Femur Collection. Forty-one femora were selected for this study; 21 males and 20 females. The selected cohort was of joint replacement age (50-80 years old) and represented patients within a broad range of height and BMI. To account for the diversity in shape, the cohort also included femora with the maxima, minima and medians for 14 geometric parameters. Each femur model was implanted with four versions of Corail®; (i) Collared standard offset (STDO) with a 135° neck-shaft angle (NSA) and a standard femoral offset, (ii) Collarless standard offset (STDO) with a 135° NSA and a standard femoral offset, (iii) High offset (HO) with a 135° NSA and an extended (+7 mm in the lateral direction) femoral offset, and (iv) Coxa Vara (CV) with a 125° NSA and an extended femoral offset (+7 mm in the lateral direction and -5mm in the superior direction). The HO variant is a collarless implant, whereas the CV variant is a collared implant. For each femur, an automated algorithm was used to select the size and position of each design variant that achieve maximum metaphyseal fit, without breaching the cortical bone boundaries, while preserving the head centre location. Joint contact and muscle forces were calculated for level gait and stair climbing using an established musculoskeletal model [2] and scaled to the body mass of each subject. Femora were rigidly constrained at the condyles. Risk of failure was assessed based on (i) stem micromotion - a measure of aseptic loosening, (ii) equivalent strains - a measure of peri-prosthetic bone damage and (iii) percentage of the bone-prosthesis contact area experiencing micromotions < 50 µm, micromotions > 150 µm and strains > 7000 µstrains [3].

RESULTS

Stair climb loads resulted in higher micromotion and interface strains, compared to level gait loads. For level gait, the 90th percentile micromotion ranged from 30 µm to 100 µm, for all designs, whereas for stair climb, the range was from 45 µm to 155 µm, for all designs. The 90th percentile interface strains ranged from 1650 µstrains to 6900 µstrains during level gait and from 2200 µstrains to 11700 µstrains during stair climb, for all designs. While most subjects had relatively small differences in micromotion and interface strains when different designs were used, it was noted that the CV design slightly reduced the micromotion/strains for subjects with NSA < 120°, and the HO design slightly reduced the micromotion/strains for subjects with NSA > 130°, compared to other designs.

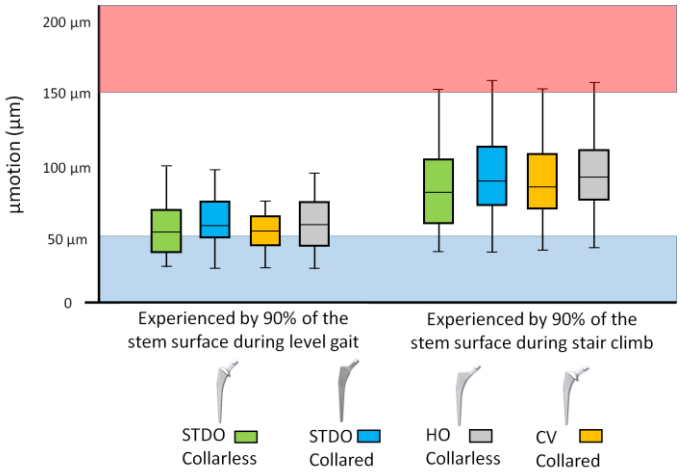

Figure 1: box plots for the 90th percentile micromotion for the four different design variants of Corail®, with the four box plots on the left for level gait loads and four plots on the right for stair climb loads.

DISCUSSION AND CONCLUSIONS

It is desirable for the micromotion/interface strains at the entire contact area to be below 50 µm/7000 µstrains. In our simulations, most of the contact area experienced micromotion/strains below these thresholds, however, a few subjects (<5) had up to 35% of the contact area with higher micromotion/strains. Given the reported survivorship of Corail ® [1], the presented data may be suitable for benchmarking novel femoral stems in the future.

MUSCLE CO-CONTRACTION INDEX IN YOUNG ADULTS WITH AND WITHOUT PREVIOUS KNEE INJURY: INTRARATER RELIABILITY DURING GAIT

Maurice Mohr, Kristin Lorenzen, Luz Palacios-Derflingher, Carolyn E. Emery, Benno M. Nigg

INTRODUCTION

Increased co-contraction between antagonistic knee muscles during gait in post-knee injury populations has been suggested to play a role in the development and progression of post-traumatic knee osteoarthritis [1]. Common measures of co-contraction such as the co-contraction index (CCI), however, rely on the measurement of highly variable electromyographic signals from the muscles of interest [2]. The test-retest intrarater reliability of the CCI during gait in both healthy and post-knee injury populations is currently unknown, which makes it difficult to compare these populations or interpret changes in the CCI in response to interventions. The purpose of this study was to determine and compare the test-retest reliability of the CCI during gait between young adults with and without previous knee injury for the example of *Quadriceps-Hamstrings* co-contraction.

METHODS

Twenty young adults (10♂, 10♀, 20-31 years old) participated in this study; ten (5♂, 5♀) of which had sustained a previous knee injury (cruciate or collateral ligament and/or meniscus) 2-10 years prior to participation and ten controls without a history of knee injury.

Each participant completed two separate testing sessions, 5-13 days apart. During each session, participants performed seven trials of over ground walking at their preferred speed while surface electromyography (sEMG) data of *Vastus Lateralis (VL)* and *Biceps Femoris (BF)* as well as 3D knee joint kinematics were obtained. EMG signals during walking were processed using a wavelet transform to derive the EMG total intensity and amplitude-normalized to the respective peak EMG intensities during a series of isometric maximum voluntary contractions (MVCs). Co-contraction was analyzed for three phases of the gait cycle: 150ms pre-heel strike, early stance (heel strike to peak knee flexion), and mid stance (peak knee flexion to peak knee extension). The CCI [%MVC] between *VL* and *BF* was calculated for each phase as a weighted ratio of the EMG total intensities and averaged across seven strides [2].

For each phase and group (injury/control), the absolute test-retest reliability of CCIs was determined using Bland-Altman 95% limits of agreement, *LoA = bias ± random error*, where *bias* corresponds to the mean of the within-subject differences between days and *random error = 1.96 x standard deviation of the differences* [3]. Relative reliability was assessed according to the intra-class correlation coefficient (ICC, Type [3,1]) and 95% confidence intervals.

RESULTS AND DISCUSSION

95% limits of agreement for *VL-BF* co-contraction indices were wider in the injury group compared to the control group, indicating larger random error and poorer absolute reliability (Table 1). Specifically, during early stance, the injury group showed random error in CCI of up to 11.2%MVC. This result suggests that to attribute a "true change" in *VL-BF* co-contraction during early stance (e.g., in response to an intervention), the observed change in CCI must be at least 11.2%MVC, which exceeds previously reported changes [4]. In contrast, ICCs were similar in both groups and ranged between 0.65 to 0.85, indicating moderate to very good reliability (Table 1). The disagreement between poor absolute and good relative reliability may be due to the higher variance in CCIs among injured compared to control participants (Table 1), which artificially inflates the ICC [3].

CONCLUSIONS

The test-retest reliability of the co-contraction index between *Vastus Lateralis* and *Biceps Femoris* during gait appears to be poorer in young adults with a history of knee injury compared to healthy controls. This has implications for the design and interpretation of co-contraction studies in these populations. Due to the generally large random error between days, the use of the CCI during gait should be restricted to interventions where changes of more than 5% are expected. Further, these results demonstrate that relative reliability may be artificially high despite poor absolute reliability if study samples exhibit large variance.

MUSCLES THAT DO NOT CROSS THE KNEE CONTRIBUTE TO SHEAR AND VALGUS LOADING

INTRODUCTION

Anterior cruciate ligament (ACL) injury remains physically and financially burdensome injury [1]. Whilst the primary role of the ACL is to resist anterior translation of the tibia, non-sagittal loads (particularly the valgus moment) have also been shown to be important contributors to ACL loading and injury mechanisms [1]. Insight into how sagittal (shear force) and frontal (valgus/varus) loads occur during injurious manoeuvres could reveal potential targets for preventative and rehabilitative strategies. Muscles that provide large contributions to both anterior shear and/or the valgus moment may have the propensity to load the ACL, whereas muscles that provide large contributions to both posterior shear and/or varus moment would potentially be most effective in protecting the ACL, and thus would be targets for preventative programs. To date, research has typically focused on muscles that cross the knee joint, such as the quadriceps, hamstrings and gastrocnemius. However, due to a phenomenon known as "dynamic coupling", any muscle in the body can accelerate joints that it does not span [2]. Subsequently, the aim of this study was to investigate how knee-spanning and non-knee spanning muscles contribute to the shear force and valgus moment at the knee joint during side-step cutting.

METHODS

Three dimensional musculoskeletal simulations of unanticipated side-step cutting were generated for five international-level female football players (age, 21 ± 2 years; height, 1.75 ± 0.05m; mass, 67 ± 8kg). Full-body kinematic and ground reaction force (GRF) data were collected using VICON (Oxford Metrics Ltd., Oxford, United Kingdom) and two force plates (AMTI, Watertown, United States) respectively. Each participant completed a 45-degree angled side-step cut in a randomly selected direction indicated via timing gates (Smart Speed, Fusion Sports, Brisbane, Australia). Inverse kinematics and inverse dynamics were then used to determine joint angles and moments, respectively, from a subject-specific scaled musculoskeletal model (25 degrees of freedom, 92 musculotendinous actuators). A static optimisation algorithm was used to decompose lower-limb joint torques into muscle forces. A five-point foot-ground contact model was then used to determine the individual muscular contributions to the GRF via a pseudo-inverse method [3]. The experimental kinematics, individual muscles forces and their subsequent contribution to the GRF were then used to resolve the dynamical equations of motion to determine the muscular contributions to knee joint reaction forces. Peak contributions (mean ± SD) to the shear force and valgus/varus moment across the landing phase (foot contact to peak stance knee flexion) were extracted.

RESULTS AND DISCUSSION

Posterior shear forces were primarily produced by the soleus (351 ± 41N) and biceps femoris long head (285 ± 132N). The anterior shear force was primarily produced by the vasti (243 ± 187N) and rectus femoris (81 ± 75N). The largest peak valgus moments were produced by the soleus (20 ± 4Nm) and vasti (16 ± 12Nm). The greatest peak varus moments were produced by the gluteus medius (53 ± 31Nm) and minimus (9 ± 5Nm).

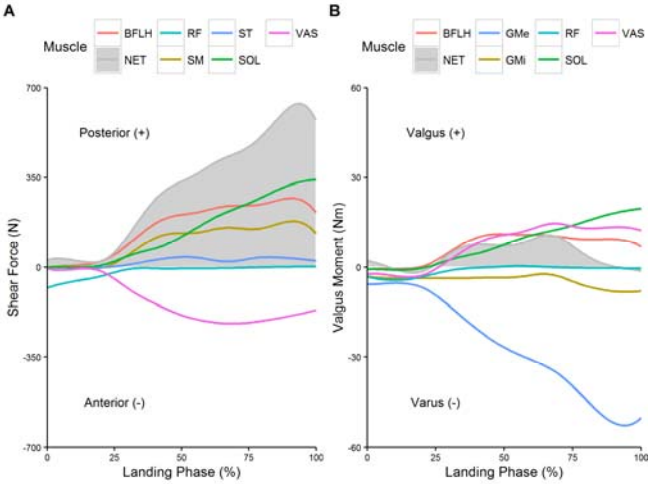

Figure 1: Ensemble averages of muscular contributions to A) shear and B) valgus loading at the knee joint during unanticipated sidestep cutting. BFLH, biceps femoris long head; GMe, gluteus medius; GMi, gluteus minimus; NET, net (total) experimental value; RF, rectus femoris; SM, semimembranosus; ST, semitendinosus; SOL, soleus; VAS, vasti.

CONCLUSIONS

Non-knee crossing muscles were the greatest contributors to the peak valgus (soleus) and varus (gluteus medius) moments. Shear forces at the knee were primarily produced by the quadriceps and hamstring muscle groups, but large contributions were made by non-knee crossing muscles such as the soleus. The data suggests that ACL preventative and rehabilitative programs may benefit from further consideration of non-knee crossing muscles. Variability in the data suggests that participant-specific variations may exist that warrant consideration of individualised strategies.

INTRODUCTION

Increased knee adduction moment (KAM) during walking plays an important role in the progression of medial knee osteoarthritis [1,2]. Gait modifications, such as altering the foot progression angle (FPA), aiming at toe-in during walking, can successfully reduce the KAM and can be taught using real time bio-feedback [3]. To date such gait modifications have been tested only in laboratory environments in a single task condition. Performing gait modifications has been associated with a large increase in perceived cognitive workload at least in the short term [4]. The effectiveness of such gait modifications relies on the cumulative reduction of the KAM during daily activities and therefore requires that the modification can be reproduced without feedback and without additional or with minor cognitive demand. The extent of the learning effect and cognitive demand of the task can be measured when a patient performs a secondary task whilst continuing with the first task. The aims of this study therefore was to determine whether (1) removal of feedback and (2) imposing a dual task would affect the FPA that patients were taught to modify over 6 weeks.

We hypothesized that the removal of feedback and the introduction of the dual task would both result in greater errors in the prescribed FPA, with a tendency to walk with FPA closer to normal baseline values. Secondly, we hypothesized that over the six weeks, the error in FPA would reduce in all conditions.

METHODS

Sixteen patients with radiographic medial knee osteoarthritis (age 61.2 ± 5.8, 12 female) completed the gait training program. All participants received weekly training sessions over six weeks, which focused on achieving a toe-in gait with a personalised FPA for each patient (mean angle 3±2.2° internal rotation). Patients walked on an instrumented treadmill in a virtual reality environment and were provided with quasi real-time feedback on their stance-phase FPA from the previous step. Markers affixed over bony landmarks together with a 10 camera Vicon motion capture system allowed for real-time calculation of the FPA using the Human Body Model [5]. During weeks four, five and six of the program the duration of the feedback provided to the subjects was reduced according to a faded feedback protocol. In week 1 and 6 the Stroop test [6] was performed as a dual task condition while the patient attempted to maintain the modified FPA. Patients were given full instruction on how to complete the dual task and were asked to maintain their modified FPA but were not asked to prioritize one task over the other.

We analysed three different conditions per patient to determine the error and the spread of the error between the actual FPA and the target angle; 1) with feedback on the FPA, 2) without =feedback and 3) during the Stroop test.

Due to violation of the assumption of normality we used the Wilcoxon signed rank test to compare between the two time points (week 1 and week 6) and the Kruskall Wallis test to compare between conditions. Preliminary statistical analyses were undertaken in Matlab 2012a, with α=0.05.

RESULTS AND DISCUSSION

The median error in the FPA was significantly different between conditions in week 1 ($p=0.042$) but not in week 6. Post hoc tests revealed that the differences were between the feedback and no feedback conditions versus the dual task condition ($p<0.001$). Across the two time points, a significant difference existed only in the dual task condition ($p=0.027$), as shown in Figure 1.

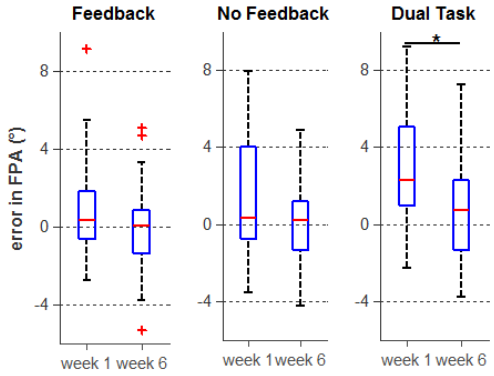

Figure 1: Error in FPA in three different conditions and at two time points. A positive error indicates an angle closer to baseline (externally rotated) and a negative error indicates that the target internal rotation was exceeded.

Interestingly, although not significantly different to week 6, there was a tendency towards baseline values (externally rotated FPA) in all conditions in week 1. In week 6, although the median error remained similar, there was a greater tendency to walk with internal rotation exceeding the target. In the dual tasking condition after 6 weeks training, patients were better able to perform the Stroop task whilst maintaining the required FPA.

CONCLUSION

After a six-week gait training program, patients were able to reduce the error in FPA during walking with dual tasking (significant reduction) and during other conditions (trend observed). This suggests evidence of motor learning and a reduction in cognitive demand; important parameters to ensure successful adoption of a modified gait pattern in activities of daily living.

BIOMECHANICAL DETERMINANTS OF ILIOTIBIAL BAND SYNDROME IN CYCLING

[1]**Mathieu Domalain**, [2]Mathieu Menard and [1]Patrick Lacouture
[1]Institut Pprime CNRS 3346 and Université de Poitiers
[2]Institut d'Ostéopathie de Rennes and M2S Lab, Université de Rennes 2 - ENS de Rennes

INTRODUCTION

Iliotibial band syndrome (ITBS) is a common non-traumatic overuse injury of the lateral knee joint whose incidence is growing following the increase in popularity of endurance sports such as running and cycling. Despite an abundant literature, the treatment of ITBS remains complicated as it lacks evidence-based recommendations [1]. The etiology is commonly acknowledged as "multifactorial". ITBS has been widely described as a friction symptom due to the ITB sliding over the lateral femoral epicondyle (LFE) during repetitive knee flexion-extension. However recent anatomical observations suggested that ITBS would rather be a compression syndrome [2].

The aim was to investigate putative pathomechanisms of ITBS in cycling upon the analysis of experimental conditions (saddle setback) known to exacerbate the potential risk of developing the pathology.

METHODS

Ten well-trained and healthy subjects volunteered to participate in the study. A stationary cycle ergometer SRM "Indoor Trainer" (SRM, Schoberer, Germany) was used. Three-dimensional kinematics were obtained from a 20-camera motion analysis system (Vicon, Oxford, UK). Three saddle setback conditions were compared as this parameter has been recognized as a contributing factor to ITBS [3]. For each of the three conditions, data were recorded during a 30s trial while participants pedaled at a constant pace (90rpm and 200W).

Markers data served as input of a model for the computation of muscle strain, strain rate and ITB-LFE compression force. A musculoskeletal model of the right limb was developed based on an existing model [4]. ITB attachment sites corresponded to the most recent anatomical description of iliotibial band, originates at the iliac crest, passes over the LFE and terminates at Gerdy's tubercle.

The computation process followed Opensim guidelines for inverse kinematics [5]. ITB strain and strain rate calculation were calculated as ITB length (m) and lengthening/shortening velocity (m.s-1) respectively. An arbitrary (100 N) ITB force was fixed for all participants and conditions so that the calculation of ITB-LFE compression force focused on the varying kinematics. A complementary simulation approach was developed to calculate ITB-LFE force over the entire range of motion of the hip and knee joints.

RESULTS AND DISCUSSION

ITB-LFE compression force was the only parameter significantly affected by the experimental conditions, ITB strain and strain rate remained statistically similar. This suggests that ITBS is likely to be a compression syndrome more than a friction syndrome as it is still widely believed. Results of the simulation showed that the intensity of ITB-LFE compression force was higher when the hip was extended and adducted and when the knee was extended and internally rotated (Figure 1). Maximal hip extension had a greater influence (up to 20N) than knee extension (up to 5 N). Inter-individual kinematic differences (5 ± 2°, average across conditions) were higher than inter setback condition differences (1 ± 0.5°, average across participants) for all degrees of freedom.

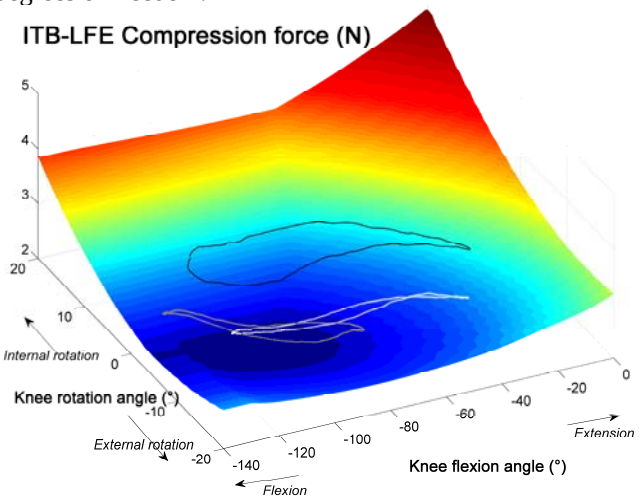

Figure 1: Simulation of ITB-LFE compressive force for combined knee flexion (-140-0°) and external-internal rotation (-20/20°) angles. Solid black, dashed white and dotted grey lines illustrate the kinematics of participant 2, 5, and 8 respectively.

CONCLUSIONS

As suggested by Fairclough [1] and in opposition to what is widely believed, this study argue for ITBS to be more a compression syndrome than a friction syndrome. Furthermore, ITBS potential risk increases in individuals whose pedaling technique exacerbates hip extension-adduction and/or knee extension-internal rotation.

THE ROLE OF THE SURFACE LAYER AND THE INFLUENCE OF EARLY MATRIX DEGENERATION ON THE STATIC AND DYNAMIC PROPERTIES OF ARTICULAR CARTILAGE

Ashvin Thambyah, Richard Park and Neil Broom
University of Auckland
Corresponding author email: ashvin.thambyah@auckland.ac.nz

INTRODUCTION

While the function of articular cartilage in joint lubrication, protection of the bone ends, and load spreading has been well studied, relatively less is known about the damping or energy absorbing properties (non-injurious) of cartilage. Experiments to determine these properties are technically difficult, especially when considering the complex zonally-differentiated microstructure of the tissue [1] and mild degenerative changes that can cause destructuring of the collagen fibrillar network [2]. This study therefore investigates the following two hypotheses. Firstly that by removing the surface layer of cartilage, both the static load response and damping properties will change. Second, that mildly degenerate cartilage will have different static and dynamic material properties compared with healthy-intact cartilage and cartilage with its surface layer removed.

METHODS

A total of 60 bovine patellae were used. From each patellae, a cartilage-on-bone sample block with dimensions of ~14x14x10 mm was obtained. Care was taken to obtain the most flat surface of cartilage in the distal lateral quarter. The subchondral bone of each sample block was embedded in a stainless steel holder with Plaster of Paris, after which the samples were equilibrated in 0.15 M saline for 2 hours at 4ºC. Cartilage thickness was measured prior to testing. The 60 samples were subdivided into three equal groups as follows: (i) Healthy samples (did not stain positive with India ink [3]) with surface layer intact (n=20); (ii) Healthy samples with the surface layer (upper 1/3 ~ 700µm) removed using a microtome (n=20); (iii) Mildly degenerate samples (cartilage stained positive with India ink and corresponding to grade I mild degeneration [3]) (n=20). Static (low strain-rate) stiffness was measured in all samples using a standard 4mm diameter plane-ended polished cylindrical indenter test [4]. The static test was followed by a dynamic test. Here an impact test (non-damaging, 0.5J) was administered to each sample in all three groups, using a 0.55kg mass with 10mm diameter indenter, drop-tower, and ultra-high speed camera, to derive kinematic data for the high strain-rate energy absorbing properties (damping). Energy loss was calculated from the kinematic data, where the proportion of kinetic energy lost from the collision of the impactor to the sample was determined from the known mass and the velocity before and after impact.

RESULTS AND DISCUSSION

From the static mechanical testing, degenerative changes in cartilage resulted in a significant ($p < 0.05$) decrease in stiffness, whilst removal of the surface layer resulted in a significant *increase* in stiffness (Figure 1A).

From the dynamic testing, there were no significant differences in terms of energy absorption properties between all three groups (Figure 1B).

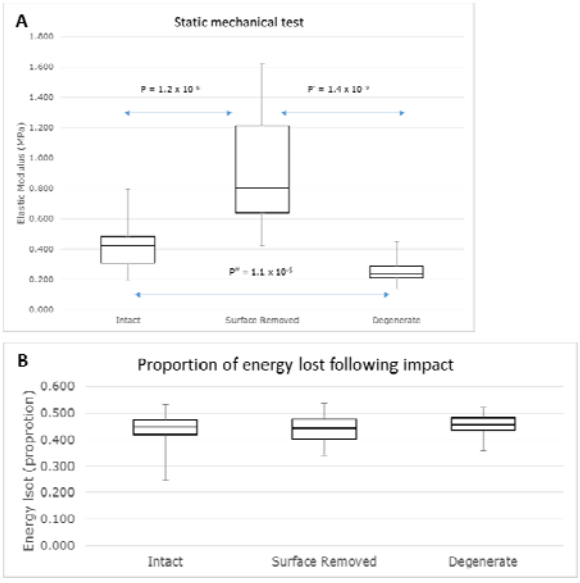

Figure 1: Box-and-whisker plots of data plotted from (A) the static indentation tests, and (B) the dynamic response. In each box, n = 20.

The static mechanical test was essentially a creep test and the difference in elastic modulus between intact and surface removed may be explained in terms of the extent of creep between groups versus the thicknesses with and without the surface layer. It is likely that removal of the upper one third of cartilage thickness does not result in a similar reduction in creep, thus influencing the modulus. The degenerate matrix displays a more compliant response to the indentation test and is similar to findings from other studies [1].

CONCLUSIONS

The data suggests that complex structural details of the surface layer of cartilage, and fibrillar-scale destructuring of the matrix, may have limited influences on the dynamic energy absorption properties of the tissue subject to non-injurious loading.

ESTIMATION OF ARTICULAR CARTILAGE MATERIAL PROPERTIES IN WHOLE KNEES USING IMAGE-BASED FINITE ELEMENT ANALYSIS

[1] Yoonjin Kim, [1]Gangto Lee, [1]Sung Joon Song, [1]Myeong Woo Lee and [1]Yongnam Song
[1]Korea University

INTRODUCTION

Articular cartilage is known to be remodeled by mechanical modulations. Finite element analysis (FEA) is widely used to estimate mechanical conditions in articular cartilage. Accurate material properties are important to successfully describe cartilage mechanical behaviors. Articular cartilage properties were commonly measured by various mechanical tests of cylindrical articular cartilage plugs. However, mechanical response of cartilage plugs may be different from the *in vivo* articular cartilage response due to the differences in boundary conditions. In this study, we developed a loading device which can be operated in a medical image device to measure accurate cartilage deformations under a loading condition. We aimed to estimate cartilage material properties by using the information of CT measured deformation and applied load in FE models. We also compared FE material estimations with conventional unconfined tests.

METHODS

Samples: Five young porcine knees were tested. Surrounding soft tissues were all removed to separate articular cartilage behaviors from other tissues.

Imaging & load application: Prior to the loading application, a CT scan of a fully dislocated knee was done to create 3D meshes of unloaded bone and cartilage for FEA. The sample (flexion: 20°) was then placed in the loading device and a uniaxial compression of 640 N was applied to the sample for 21 min to reach to the steady-state deformation. Another CT scan of the loaded knee was done and 3D models of loaded femur and tibia were created.

Image-based FEA: Neo-Hookean hyperelastic material was used for cartilage while bones were rigid. Initial cartilage material properties (shear/bulk modulus: 0.105 MPa/ 5.3077 MPa) were selected [1]. First, cartilage deformations were calculated by gradually aligning unloaded bone meshes to 3D bone models of a loaded knee which indicated bone positions after 21 min compression. This model was defined as 'displacement controlled FEA'. Second, we applied a uniaxial compression of 640 N to unloaded bone and cartilage meshes and calculated cartilage deformations. This model was defined as 'load controlled FEA'. Since material properties were arbitrary selected, deformation results from 'displacement and load controlled FEA' were not consistent. We iteratively changed material properties and repeated both 'displacement and load controlled FEA' until root mean square differences between cartilage deformations from both methods were smaller than 0.01 mm.

Unconfined cartilage test: Conventional unconfined stress-relaxation tests were done [2] with 4-6 cylindrical cartilage plugs per each knee (plug diameter: 3.5 mm). An impermeable stainless steel indenter compressed the sample with a displacement rate of 1μm/s. 6 stress-relaxation steps were applied until a cartilage plug was compressed by 30% of its original thickness. Sample thickness was measured with a laser sensor and microscopic images of a sample were acquired in every 20 seconds.

RESULTS AND DISCUSSION

We calculated Poisson's ratio and elastic modulus articular cartilage estimated in FEA and unconfined tests (Figure 1). Poisson's ratio estimations in both methods were similar in magnitude for most samples except sample 2. However, elastic moduli of articular cartilages were underestimated in unconfined tests for all tested knees. Elastic moduli in FE analysis were approximately 2.5~6.5 times greater than the unconfined test measurements. Underestimated elastic moduli in unconfined tests may be due to the flow-free surface conditions in cartilage plugs and result in greater cartilage deformations in biomechanical simulations. However, fluid flow in *in vivo* cartilage tissues were restricted by impermeable subchondral bone and adjacent cartilage tissues. Thus, *in vivo* cartilage deformation would be smaller than the deformations estimated by using material properties from mechanical tests.

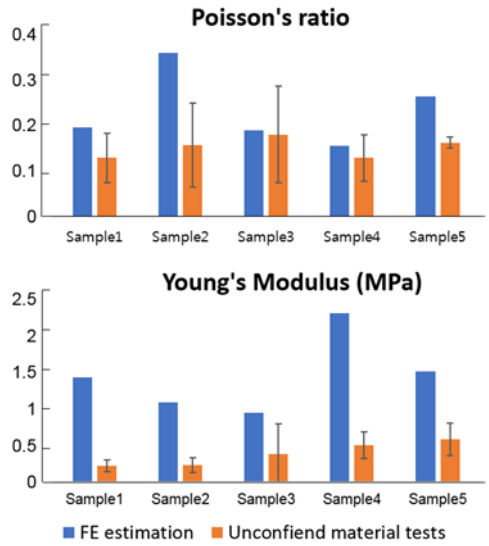

Figure 1: Poisson's ratio and elastic modulus from FE estimation and conventional unconfined material tests

CONCLUSIONS

Our novel image-based FE estimation method utilized 1) accurate cartilage deformations from CT scans and 2) precisely controlled load conditions from a custom loading device to reflect *in vivo* articular cartilage deformational behaviors. Material property estimations by image-based FE method may provide accurate mechanical analysis of the articular cartilage and improve our understandings of joint biomechanics.

THE BIOMECHANICAL EFFECTS OF THE DEFORMATION AND TRAPPING OF THE NUCLEUS ON CELLULAR UV RESISTANCE

INTRODUCTION

DNA damage induced by the radiation, including ultraviolet (UV) light, exerts adverse effects on genome stability, alters the normal state of life, and causes many kinds of diseases. Thus, a biochemical or biomechanical method in DNA damage repair and protection is well required. Recently, we demonstrated that mechanical deformation and trapping of the cell nucleus using polydimethylsiloxane (PDMS)-based microfabricated substrates with an array of micropillars inhibited cell migration and proliferation [1]. Thus in this study, we investigated the effects of mechanical deformation and trapping of the nucleus on UV radiation resistance of DNA in living cells.

METHODS

The epithelial-like cells derived from Xenopus laevis (XTC-YF) were used as a test model. The cells were cultured in a mixture of 50% L-15 medium, 10% fetal bovine serum, and 40% distilled deionized water at room temperature. In order to achieve a mechanical trapping and deformation of the cell nucleus, we used a PDMS micropillar array substrates fabricated by replica-molding [1]. We designed the micropillar substrates with a hexagonal arrangement and with a pillar diameter, length, and center-to-center spacing of 3, 9, and 9 μm, respectively. The both micropillar array substrates and the flat substrates made of the same lot of PDMS were placed in culture dishes. The surfaces of both substrates were exposed to oxygen plasma, and coated with fibronectin to allow cell adhesion. XTC-YF cells were cultured on these two substrates for over 24 h and exposed to UV radiation (250 nm, ~400 mJ/cm^2). Then, the cells were fixed and their intranuclear DNA was stained fluorescently with Hoechst 33342. We also stained phospho-histone γ-H2A.X, a marker for DNA double strand break [2], to estimate UV radiation-induced DNA damages.

RESULTS AND DISCUSSION

Typical fluorescent images of the nucleus in XTC-YF cells cultured on the flat and micropillar substrates are shown in Figure 1. The cell nuclei on the flat substrate had elliptical shapes with smooth surfaces (Fig. 1A), while on the pillar substrates, the nuclei were entirely inserted into the grooves between the pillars and they appeared to be "trapped" mechanically on the array of pillars (Fig. 1B). Following UV radiation, we obtained the confocal fluorescent images of phospho-histone γ-H2AX (Fig. 1C, D) and estimated DNA damages. We found that UV radiation-induced DNA damage, estimated by the fluorescent intensity of phospho-histone γ-H2AX, was significantly inhibited in the nucleus deformed by the micropillars (Compare Fig. 1E and F). The significant positive correlation was observed between fluorescent intensity of intranuclear DNA and γ-H2A.X in the cells cultured on the flat substrates following UV irradiation, while in the cells on the pillar substrate, their correlation became lower. These results indicate that the inhibition of UV radiation-induced DNA damages might be resulted from structural change of DNA caused by the mechanical stress of the nucleus of the cells on the pillars.

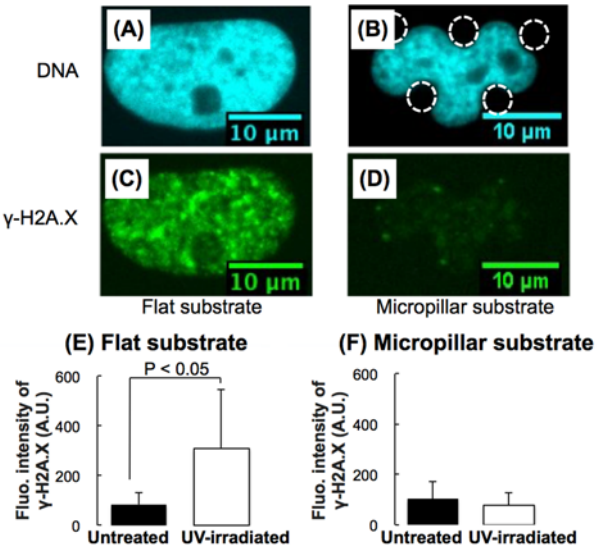

Figure 1: Typical examples of the confocal fluorescent images of the nucleus in XTC-YF cells cultured on the flat (A, C) and the micropillar substrate (B, D). White circles in (B) indicate the micropillar locations. The changes in the fluorescent intensity of γ-H2A.X in XTC-YF cells cultured on the flat (E) and the micropillar (F) substrates following the UV-irradiation.

CONCLUSIONS

We investigated the effects of mechanical deformation and trapping of the nucleus on UV radiation resistance of DNA in XTC-YF cells, and found that UV radiation-induced DNA damage was significantly inhibited in the nucleus deformed by the micropillars. Our study first demonstrated the nuclear stress-induced inhibition of DNA damages in living cells.

MICRO- AND NANO-MECHANICAL EFFECTS OF AGEING AND OSTEOARTHRITIS ON THE HUMAN KNEE JOINT

[1] **Abby E. Peters**, [1] Riaz Akhtar, [1] Eithne J. Comerford and [1] Karl T. Bates
[1]University of Liverpool

INTRODUCTION

Osteoarthritis (OA) is typically associated with degeneration of the articular cartilage; however it is now widely accepted that OA is a whole-joint disease that alters the integrity of multiple tissues of the osteochondral unit and surrounding soft tissues including ligaments. In particular recent research has observed abnormal remodelling and changes in density and separation of bone in the presence of OA. This suggests a synergistic relationship between cartilage and bone; however no material property data exists to understand whether disruption of subchondral and /or trabecular bone structure occurs pre or post initiation of OA. Furthermore a decrease in tensile properties of ligaments is observed during ageing; however this is less well defined in the presence of OA, though histological research has shown adaptations in fibre architecture accompanying disease status. Knowledge of whole joint adaptations during both ageing and disease could be used to improve finite element modelling, therapeutic interventions such as those involving pharmacology or biomimetic materials used to mimic soft and hard tissue during repair, regeneration or replacement. Therefore the aims of this paper are:

1. To compare material properties of cartilage, bone and ligaments from cadavers of varying ages and disease status to help understand the effect of ageing and OA
2. To compare material properties from multiple anatomical locations and tissue types in one knee joint to understand the need for a more subject specific, local approach to treating or representing soft or hard tissues
3. To analyse the relationship between a change in cartilage and bone material properties in the presence of OA

METHODS

Human cadaver knee joints (n=12, 31-88 years) with varying grades of OA (ICRS 0-4) were dissected and eight articular cartilage, and eight subchondral and trabecular bone samples were harvested from the medial and lateral femoral condyle, and medial and lateral tibial plateau. Bone-ligament-bone samples including the anterior cruciate ligament (ACL), posterior cruciate ligament (PCL), medial collateral ligament (MCL) and lateral collateral ligament (LCL) were also harvested from each cadaver. Nanoindentation was used to calculate shear modulus (*G'*) and elastic modulus (*E*), using a dynamic and quasi static method for cartilage and bone respectively. Ten spatially correlated indents were incorporated per sample. Ligament samples were preconditioned and tested to failure at 500mm/min using an Instron 3366. Faster strain rates were used to mimic physiological loading. Biologically realistic hydration status of soft tissue was maintained through submersion in phosphate buffered saline during testing.

RESULTS AND DISCUSSION

Cartilage and subchondral bone material properties are significantly correlated to age (r^2 = -0.307; p = 0.000 and r^2 = 0.366; p = 0.000 respectively) and OA (r^2 = -0.242; p = 0.000 and r^2 = 0.102; p = 0.004 respectively). Additionally a change in cartilage material properties is inversely related to a change in site matched subchondral bone material properties (r^2 = -0.094; p = 0.006: see Figure 1). Trabecular bone lacked a significant relationship to all parameters.

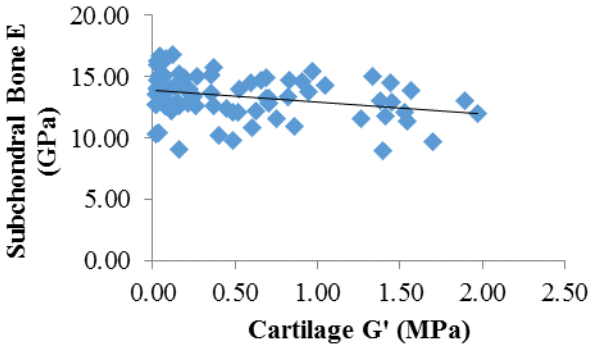

Figure 1: Cartilage shear modulus (*G'*) (MPa) and subchondral bone elastic modulus (*E*) (GPa) correlation.

Preliminary ligament tensile testing showed failure loads between 227-552N within the collaterals and 261-1554N within the cruciate ligaments. Failure sites varied from mid-substance, insertional site and bony avulsion. A young healthy cadaver (37 year old, ICRS 0) showed both the ACL and PCL failed by bony avulsion at 1544N and 1336N respectively. In comparison an old OA cadaver (80 year old, ICRS 4) showed the ACL and PCL failed at 373N and 261N respectively via the mid-substance and insertional site.

CONCLUSIONS

Cartilage, bone and preliminary ligament material property data are correlated to both age and OA. Cartilage *G'*, bone *E* and ligament failure loads vary according to different locations/types in the human knee joint, as well as across individual cadavers. Additionally a change in cartilage mechanics results in a change in subchondral bone mechanics. Such material property data could be applied to finite element models where tissues are often represented as a global structure with one suggestive value. Current research indicates a more local approach should be considered when constructing models, in order to gain more biologically realistic behaviour of the human knee joint in response to mechanical loading, which may aid future therapeutic interventions.

NEUROMUSCULOSKELETAL SYMPTOMS AND BIKE FIT ON DROP BAR 700C ROAD BICYCLES: A RETROSPECTIVE CASE AUDIT INVESTIGATING ASSOCIATIONS WITH SEX AND STATURE.

[1,2,3] **Benjamin P Ward**, [1]Mark J Connick, PhD, and [1]Bill Vicenzino, PhD
[1]The University of Queensland, [2] Queensland Academy of Sport (QAS), [3]Cycle Dynamics

INTRODUCTION

Cycling is associated with a high prevalence of non-traumatic injury with epidemiological evidence that females are at greater risk of neck/shoulder, knee and foot complaints. [1–3] No studies have sought to determine why this may be the case, however, given well-known sex differences in height and the historic male-dominance of cycling, it is plausible that the evolution of adult road bicycle frame designs and standard component sizes has ergonomically favoured males of average stature. It was therefore hypothesised that the absolute deviation (abs dev) from the male mean for height, independent of sex, would best explain neuromusculoskeletal symptom profile. Significant differences in standardised measures of bike fit would be apparent between the sexes and height categories within each sex were also expected.

METHODS

The study involved a retrospective audit of the lead author's clinical records. A mixed recreational and competitive cohort of road cyclists and triathletes (n = 114 M, 48 F; age 40 ± 9 years) using road bicycles without aerobars, gave consent for their pre-intervention data to be used. The prevalence of symptoms at each body region was compared between sexes in contingency tables (Fisher's exact). Poisson regression was used to determine associations and risk estimates (prevalence and count ratios) for height abs dev (in decimeters) adjusting for sex, and vice versa, with the presence of symptoms at each site (using robust standard errors for binary outcomes) and the number of concurrent symptomatic regions. Primary discipline (triathlon vs road), self-reported average weekly kilometres (multiples of 25km) and age (multiples of 5yrs) were also included as control variables. Univariate ANOVAs for standardised bike fit variables were conducted to characterise differences in bike fit between the sexes and by height categories within each sex, based on the male mean and standard deviation (177.7 ± 6.6cm) as follows: <158cm ○; 158–171cm △; 171–184cm ◇; >184cm □. Alpha level was set at $p < 0.05$ and confidence intervals at 95%.

RESULTS AND DISCUSSION

Consistent with previous studies, [1-3] a greater proportion of females reported neck/shoulder symptoms (56% F vs 34% M, p = 0.014). Regression determined height abs dev (PR: 1.65, CI: 1.18–2.29, p = 0.003) and age (PR: 1.12, CI: 1.01–1.24, p = 0.034) to be significantly associated with symptom presence in this region, but not sex (PR: 1.02, CI: 0.60–1.72, p = 0.951). No significant sex differences in symptom prevalence, or significant main effects for height abs dev or sex with regression, were observed for any other region ($p > 0.05$). Females reported more concurrent symptomatic regions with a median of three (IQR 2-4) versus two (IQR 1-3) in males (Mann-Whitney $U = 3397$; p = 0.013), however, regression found no association with sex (CR: 1.11, CI: 0.86–1.45, p = 0.421) or height abs dev (CR: 1.11, CI: 0.92–1.34, p = 0.287). Secondary findings of the regression analyses were as follows: a) wrist/hand symptoms associated with age (PR: 1.20, CI: 1.04–1.39; p = 0.012) and triathlon (PR: 2.34, CI: 1.37–4.00; p = 0.002); and b) lumbopelvic symptoms associated with average weekly km (PR: 1.05, CI: 1.01–1.1, p = 0.025). The latter is consistent with previously reported findings.[3]

Significant differences in standardised bike fit existed between the sexes and between height categories within each sex. The crank length:inseam ratio (CLIR) displayed the largest standardised mean differences (SMDs) of all comparisons. Males had a mean of 20.2 ± 1.0% versus 21.5 ± 1.0% in females (SMD: 1.3, CI: 0.9–1.6; $p < 0.001$). Within each sex the SMDs were even greater between height categories (1.9–2.3, all significant at $p < 0.001$). Absolute crank length ranged from 165-177.5mm (median/mode: 172.5mm M, 170mm F). To better illustrate the extent to which crank length varied proportionally, the CLIR for each category was transformed into average male equivalent crank lengths for presentation in figure 1. Significant differences ($p < 0.01$) with moderate to large effect sizes were found for standardised saddle and handlebar position within and between the sexes. Compared to taller riders of the same sex, shorter riders had: a) saddles that were higher relative to the bottom of the pedal stroke and lower relative to the top; b) steeper effective seat tube angles (females); and c) reduced saddle-to-handlebar reach/drop. These differences are likely to manifest as stature-related variance in riding posture and kinematics and are therefore of clinical interest.

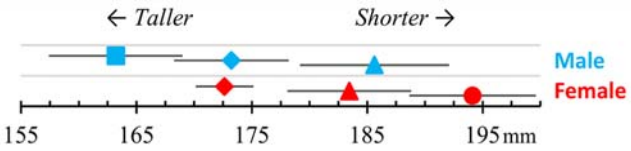

Figure 1: Average male equivalent crank length ± 1 SD by height category in each sex.

CONCLUSIONS

The key finding of this study is that after adjusting for sex, discipline and weekly riding volume, a 65% increase in the prevalence of neck/shoulder complaints is to be expected in road cyclists and triathletes on 700c drop bar road bikes for every 10cm shorter or taller than average males, and 12% for every 5yr increase in age. The retrospective nature of this study precludes the assignation of causality between bike fit and the observed symptom profile. Prospective studies are therefore warranted to determine if causal links exist.

TRIATHLETES LOAD THE PREFERRED LEG MORE DURING RUNNING AFTER CYCLING

INTRODUCTION

Chronic Achilles tendon injuries occur mainly unilaterally and are related to overloading of the tendon tissue. Ankle plantar flexion moment is generated during the stance phase of running through Achilles tendon force transmission to the calcaneus. Plantar foot kinetic variables (e.g. pressure, force) have been used to imply Achilles tendon loading (1). Therefore, the present study investigated if differences in plantar foot kinetic variables exist between the preferred and non-preferred legs of triathletes during a simulated cycle-run transition. The level of asymmetry between the legs during running were also computed. Findings of the present study could enhance prevention strategies for chronic Achilles tendon injury in triathletes.

METHODS

Seven competitive triathletes (mean±SD: age: 32±4 years, body mass: 72±8 kg, height: 1.78±6 cm, maximal cycling power output: 350±17 W) performed 20 mins cycling at 70%VO_{2max} intensity on a cycle-ergometer (LC7, Monark Exercise AB, Sweden) followed by a 5 km running time-trial on a motorized treadmill (RL2500E, Rodby Innovation AB, Sweden). Pressure measuring insoles (Pedar®, Novel GmbH, Germany) were placed inside each running shoe to measure maximal force ($Force_{max}$), total contact area (Area), peak pressure ($Pressure_{peak}$), pressure-time integral ($PT_{integral}$) and force-time integral ($FT_{integral}$) during the running trial. Forefoot maximal force ($Forefoot_{max}$) was analyzed for each leg for the first and last run segments. Analyses were performed based on data acquired during 20 s for each 0.5 km of running. Mean effects were tested with Student's paired t-tests and Cohen's effect sizes (d) (1). The asymmetry index was computed based on previous work (2) as follows:

$$AI = [(NP - P) / ½ (NP + P)] \text{ X } 100\%$$

Where NP = non-preferred leg, P = preferred leg. Leg preference were assessed based on the Waterloo questionnaire (3). Standard deviations (SD) of $Force_{max}$ from both legs were computed for each running segment in order to report intralimb variability.

RESULTS AND DISCUSSION

Mean running speed during the first 0.5 km and last 0.5 km were 15.4±0.86 and 17.0±1.7 km/h respectively. The preferred leg showed higher values of $Force_{max}$, $Pressure_{peak}$ and $FT_{integral}$ ($p<0.01$, $d>0.25$) than the non-preferred leg during running (Table 1). The $PT_{integral}$ increased 17% for the preferred leg from the first to the last run segments in comparison to an increase of 7% for the non-preferred leg. The $FT_{integral}$ increased 7% for the preferred leg while a 6% reduction was observed for the non-preferred leg between first and last segments. The AI for $FT_{integral}$ was less than 1% during the first segment but higher than 10% during the final segment of running. $Forefoot_{max}$ showed an AI of 2.9% ($p=0.7$, $d=0.17$) and 2.6% ($p=0.7$, $d=0.11$) during the first and last running segments respectively. Intralimb variability [mean (SD)] of $Force_{max}$ was 1624 (1.3%) and 1699 (1.3%) for the non-preferred and preferred leg respectively during the first 0.5 km, and 1578 (1.7%) and 1645 (1.6%) respectively during the last 0.5 km.

	NON-PREFERRED				PREFERRED						
	First 0.5 km	Last 0.5 km	5 km	Δ first-last (%)	First 0.5 km	Last 0.5 km	5 km	Δ first-last (%)	d	AI first 0.5 km (%)	AI last 0.5 km (%)
$Force_{max}$ (N)	1649	1608	1629	-2	1716	1677	1686	-2	0.37	4	4.2
Area (cm^2)	174	172	173	-1	174	171	174	-2	0.03	0.1	-0.8
$Pressure_{peak}$ (kPa)	347	380	360	9	352	395	380	12	0.29	1.5	4.0
$PT_{integral}$ (kPa.s)	1587	1694	1638	7	1573	1847	1697	17	0.27	0.9	8.6
$FT_{integral}$ (N.s)	7059	6667	6831	6	7040	7531	7117	7	0.26	0.3	12.2
$Forefoot_{max}$ (N)	1196	1181	-	-1	1232	1212	-	-2	-	2.9	2.6

Table 1. Plantar force and pressure data for non-preferred and preferred legs during running after cycling. Effect sizes (d) are presented for mean values.

Alterations in total contact area between legs were trivial during running and the observed differences can therefore be attributed mainly to increased force and time of force application by the preferred leg during running. Together with the large asymmetry index (12%) observed in the final segments of running, these results indicate greater loading of the preferred leg of triathletes that participated in this study. Based on recent findings showing that Achilles tendon mechanical and structural properties adapt differently due to leg preference (2), coaches and triathletes should account for lower leg preference/asymmetries to prevent tendon overloading and possible subsequent injury. Future studies should investigate Achilles tendon asymmetries in triathletes/runners considering leg preference.

CONCLUSIONS

Triathletes apply larger load on the preferred leg during running after cycling, with a greater asymmetry between legs during the last running segment. These findings have implications for prevention of Achilles tendon overloading in competitive triathletes.

VALIDATION OF A SIMPLIFIED COST FUNCTION FOR THE STUDY OF THE OPTIMAL CYCLING CADENCE

[1] **Giacomo Palmieri**, [2]Giovanni Legnani
[1]Polytechnic University of Marche
[2]University of Brescia
Corresponding author email: g.palmieri@univpm.it

INTRODUCTION

The inspiration of the present study is the well-known experimental evidence that pedaling rates freely chosen by cyclists (80-100 rpm) are higher than metabolically optimum cadences (50-70 rpm) [1]. Several studies supported the idea that cyclists instinctively tend to minimize the muscular stress. A cost function (*CF*) based on average leg joint moments is proposed in [2, 3]. The optimum resulting from the minimization of such *CF* corresponds to the upper limit of preferred cadences chosen by cyclists (in a neighborhood of 100 rpm, increasing with the power output); this confirms that the optimal cadence can be identified in a compromise between a minimum peripheral muscular force and a minimum metabolic cost.

In this work, it is presented an alternative *CF*, based on an equivalent joint moment derived from the power law generated by muscles that is obtained by an inverse dynamics analysis formulated by an energetic approach. The advantage of the proposed method is due to the limited set of experimental data required to define the objective function of the minimization problem. The validation will be given by comparison with the well-established Moment-based Cost Function (*MCF*) of [2, 3], defined as the average of the sum of the absolute value of the joint torques (hip, knee, ankle).

METHODS

Inspired to [2, 4], the leg and the bike have been modeled as a planar five bar linkage characterized on the basis of anthropometric scale factors. Experimental data from [5] have been used to solve the inverse dynamics problem. Two formulations have been implemented: given the experimental forces exerted on the crank and the pedal orientation with respect to the crank rotation, the Newton-Euler formulation has been used to compute the joint torques laws; on the other hand, a power balance formulation has been exploited to compute the overall muscular power law, resulting from the sum of the resistant power at the crank and the derivative of the mechanical energy of the system (potential and kinetic energy). The first formulation allowed to calculate the *MCF*. The second formulation has been used to determine an Equivalent Moment-based Cost Function (*EMCF*), defined as:

$$EMCF = \max(P)/\omega \qquad (1)$$

where P is the power generated by the muscles and ω is the angular velocity of the crank (supposed constant). The comparison between the two *CF* has been done for increasing power outputs; to this purpose, experimental force curves have been fitted by means of Fourier series and then scaled by a linear factor in order to generate the desired mean power.

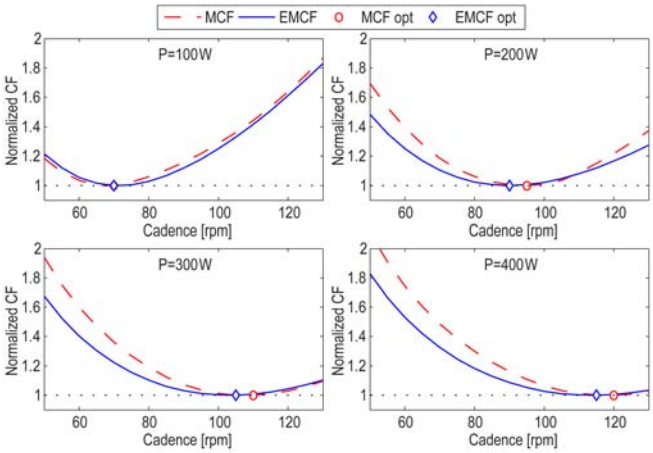

Figure 1: *MCF* and *EMCF* at different power outputs for a cyclist with 70 kg mass and 1.75 m height.

RESULTS AND DISCUSSION

Figure 1 shows the comparison between *MCF* and *EMCF*, plotted versus the pedaling cadence. Optimal cadences are comparable in all cases, with greater values at increasing powers, as evidenced by experiments in literature [1]. Therefore, it can be said that the minimization of the equivalent moment, obtained from the maximum peak of muscular power, gives similar results with respect to the minimization of the average muscular stress. Nevertheless, the proposed *CF* requires much less experimental data: besides the kinematic input data (angle of the pedal vs. crank rotation), the crank torque vs. crank rotation is sufficient.

CONCLUSIONS

The *EMCF* can be used to simply determine the pedaling rate that minimizes the muscular stress, with the advantage of requiring few simple experimental data as input. It follows that it is particularly well suited to create a model that can be easily identified by experiments: the crank torque can be evaluated more easily with respect to pedal forces, e.g. by measuring the ground forces of the rear wheel of the bike over the rollers in a stationary training.

INTRODUCTION

The cycling position with lowering trunk is effective to decrease the air resistance [1], but difficult to maintain during cycling. The stability provided from core muscles is known as an important factor for cycling performance. However, none of the related research mentioned the contribution from upper extremity, which might be intuitively taking part in trunk stability during cycling. Since upper extremity is relatively stable during cycling, the handle contact force (HCF) might be an important indicator to understand the role of the upper extremities during cycling from biomechanical perspective [2]. Although ulnar and median nerve injuries of cyclists are commonly reported [3], the studies regarding the pathogenesis or biomechanics of upper extremities during cycling is still overlooked. Therefore, the purpose of this study was to examine the effect of saddle positions on handle contact force. We hypothesized that more forward leaning of the cyclist would result in more loads acting on the upper extremities. The findings may be critical for proper bicycle fitting to improve comfort, performance, and injury prevention.

METHODS

A bicycle ergometer was designed and fabricated to allow for the full adjustment of bicycle geometry, including saddle position, and hand position etc. Two single-axis load cells were mounted on the left side of handlebars for vertical (HCF_V) and sagittal (HCF_S) forces. Five saddle positions were studied: 0 cm (A), 2cm backward (B), 2cm forward (C), 2cm upward (D), and 2cm downward (E) relative to the setting of the subject's own bicycle, and the handle position were adjusted as a result of the change of saddle.

10 male semi-professional cyclists with more than 3 years of experience with cycling training on a road bike were recruited (height: 177.4±5.99 cm; weight: 72.45±6.37 kg; age: 25.64±4.33 year-old). Participants were asked to place hands on the hook of the handle, and to perform pedaling against constant resistance with constant cadence (100rpm) for 30 seconds per trial, five times per pedal position. The forces were normalized by body weight, and the convex and concave peaks were used to characterize HCF.

A repeated-measures one-way ANOVA was employed for characteristics of HCF_V and HCF_S. Post hoc analysis tests were performed using Scheffe test when main effects or interactions were significant after ANOVA. The level of statistical significance for all analyses was set at 0.05.

RESULTS AND DISCUSSION

The means and standard deviations of characteristics of HCF_V and HCFs for the five seat positions are reported in Table 1. The results of one-way ANOVA and post hoc analysis demonstrated significant difference between settings ($p<0.05$). All peak values of HCF_V and HCF_S in B setting are both significantly lower than other settings, except when compared to C in convex peaks of HCF_V. All peak values of HCF_S in D setting are significantly larger than those in other settings, except when compared to E in convex peaks.

Table 1: Statistical results of HCF_V and HCF_S (% BW)

***p*-value** $p < 0.05$

Since the B setting is the most backward setting, there are lower demands on the upper extremity for trunk stability as shown in our research. It is an interesting finding that vertical adjustment of the saddle resulted in significant increases of the loading on the upper extremity. We suggested that the D setting increases the seat tube angle and lengthens the distance between pedal and saddle. Hence, cyclists tend to use the upper extremities to overcome the unstable status, just as described in previous research [2].

The findings agree with our assumptions that more seat tube angle moves forward, more demands on upper extremity are shown. However, the findings in change of horizontal seat position do not really follow the trend mentioned above. When comparing A to C, no significant difference was shown in both peaks of both forces. The shortened distance between pedal and saddle may increase the difficulty to lean forward, and consequently decrease the load on upper extremity.

CONCLUSIONS

Our results indicate that lowering and moving the seat backward decreases the loading on upper extremity. Further research combining the kinematics and kinetics of upper extremity with controlling seat tube angle and length is suggested and necessary for better understanding the effects of saddle position on upper extremity biomechanics and the mechanism of upper extremity injury.

INTRODUCTION

Stereophotogrammetry has widely used for human movement analysis. Markers placed on the skin moves relative to the underlying bone, so called soft tissue artefacts (STA), could be described as single marker level or marker cluster level. The latter is proposed recently and composed of rigid (translation and rotation) and nonrigid (scaling and deformation) components. Previous study reported that STA affect marker cluster movement mainly on rigid component during walking, hopping and cutting. However, how the marker cluster position and external resistance affect these characteristics of STA remains unknown during cycling. The current study aimed to fill this gap. The purpose of the study was to quantify marker cluster rigid and nonrigid component contribute to STA in different position and resistance during cycling.

METHODS

Twelve healthy young adults (age: 22.5±2.0 years, height: 1.72 ± 0.02 m, mass: 64.8 ± 10.0 kg BMI: 21.7 ± 3.1) participated in the current study with written informed consent as approved by the Institutional Review Board. Total 15 markers placed on the thigh and the shank of each subject were separated into two clusters, around joint and mid-segment, respectively. Each subject performed cycling on an ergometer at 30 rpm both without resistance and with an average resistance of 20 Nm to mimicking rehabilitation conditions. The 3D marker trajectories were measured using a 14-camera motion capture system (Vicon Motion Systems Ltd., UK) at a sampling rate of 120 Hz and the knee was imaged simultaneously at 30 Hz using a bi-plane fluoroscopy system (Allura Xper FD20/20, Philips Medical Systems, The Netherlands). The knees of the subjects were also CT scanned and used to construct CT-based bone models. A subject static calibration was performed while stood in upright posture.

The subject-specific, CT-based bone models were registered to the fluoroscopy images using a volumetric model-based fluoroscopy-to-CT registration method, giving poses of the femur and tibia. Marker cluster initial reference frame with respect to bone-embedded coordinate system acquired through static calibration. Dynamic marker trajectories were all transformed onto bone-embedded coordinate system according to registered bone pose. Two types of marker cluster movement relative to the underlying bone were then decomposed into rigid/nonrigid components following previous study [1,2]. Two-way mixed model ANOVAs were used to test differences in the calculated variables between cluster and resistance condition. Post hoc pairwise comparisons were performed when a main effect was found. A significance level of 0.05 was set for all tests.

RESULTS AND DISCUSSION

Greater position and orientation ranges at the thigh than the shank. Position ranges were the greatest component and shape ranges were the smallest. Between-condition changes were relative small than between-cluster for both thigh and shank. For the thigh, position and size ranges significantly affected by marker cluster position. Significant smaller rigid translation range happened in around joint cluster whereas size range showed the opposite for nonrigid scaling. This could be result from STA of markers around joint displaced toward different directions and error of translations were offset while mid-segment markers moved together and produce greater position range and less size changes. For the shank, all the components of mid-segment cluster were smaller than around joint cluster. It seems bone pose estimated from markers placed on mid-shank could bring more accurate results.

Table. Cluster position, orientation, size and shape ranges due to STA of the thigh and shank under resisted and non-resisted condition during cycling.

Condition	Cluster	Position (mm)	Orientation (deg)	Size (mm)	Shape (mm)
Thigh					
Resisted	Around Joint	19.4 (2.7)*	8.7 (1.6)	8.5 (2.9)*†	5.9 (1.9)
	Mid-Segment	23.9 (3.9)*	9.2 (1.6)	1.9 (1.6)*†	5.8 (1.6)
Non-Resisted	Around Joint	17.9 (2.5)*	7.9 (1.9)	9.8 (3.2)*†	6.2 (1.9)
	Mid-Segment	23.9 (5.2)*	9.3 (1.8)	1.8 (1.1)*†	6.0 (1.6)
Shank					
Resisted	Around Joint	13.6 (2.0)†	6.6 (2.4)*	6.0 (1.9)*†	5.0 (1.3)*
	Mid-Segment	12.6 (2.4)†	4.8 (1.1)*	1.0 (0.3)*†	2.1 (0.5)*
Non-Resisted	Around Joint	12.2 (2.1)†	6.3 (2.4)*	5.4 (2.0)*†	4.8 (1.2)*
	Mid-Segment	10.4 (2.3)†	4.5 (1.6)*	0.9 (0.3)*†	1.9 (0.6)*

*significance was found between-cluster.
†significance was found between-condition.

CONCLUSIONS

Marker cluster rigid and nonrigid movement during cycling were firstly reported. Effects of marker position and resistance condition were also compared. The result provided guidance to choose marker placement and how STA potentially affect computation of bone pose during cycling. For reduce rigid movement purpose, it is suggested around joint marker cluster for thigh and mid-segment markers for shank.

INTRODUCTION

Sport related Traumatic Brain Injury (TBI) has become a major concern. Cycling, skiing and equestrian sport are only some examples of sport where this kind of injury is quite common. Numerical simulations of head impact are used as a valid tool to predict TBI. There are different head models around the world but only some of them include the scalp.

The scalp is the most external part of the head and is the first tissue involved in a head impact. The main function of the scalp is to reduce the severity of the impact by absorbing and distributing external forces. Experimental tests performed on cadavers [1] showed that the presence of the scalp dampens the magnitude of the impact force (up to 35% reduction) by increasing the contact area and the duration of the impact over the skull; therefore the scalp should be taken into account when modelling the head. The scalp is a complex tissue; it is anisotropic, non-linear, viscoelastic and its mechanical properties depend on strain rate. In order to develop effective computational models and to perform realistic simulations of impact, material characterisation at high strain rates is necessary.

In this work, dynamic tensile tests have been performed on porcine scalp at different strain rates (15 – 50 – 100 [1/s]) and at different orientation of the skin tension lines (STLs).

METHODS

Experimental tests have been performed on porcine scalps (22 weeks old, mix gender) at room temperature. Two different sets of samples have been tested; parallel and perpendicular with respect to the STLs. The frozen harvested samples were defrosted a few hours before testing and bathed in saline solution. A total of 34 specimens were tested.

The orientation of the STLs have been identified using the Reviscometer® RVM 600 device (Courage & Khazaka Electronic GmbH, Kln, Germany) [2]. A tensile test rig was developed to perform the test using a Rosand Zwick 5HV impact test machine. The tensile set-up is symmetric and consists of two grips; one moving and one fixed. Sand paper was applied to enhance grip on the sample. Different strain rates were tested: 15, 50 and 100 s^{-1}. Results in terms of Cauchy stress and stretch have been analysed.

RESULTS AND DISCUSSION

Results (Figure 1) showed that the orientation of the STLs affects the mechanical properties of scalp tissue but only at low strain rates. The effect decreases with an increase in strain rate. At 100 s^{-1} there is no difference between samples that are parallel or perpendicular to their STLs. Moreover, the increase in stiffness of scalp tissue is more significant when the sample is loaded perpendicular with respect to the STLs.

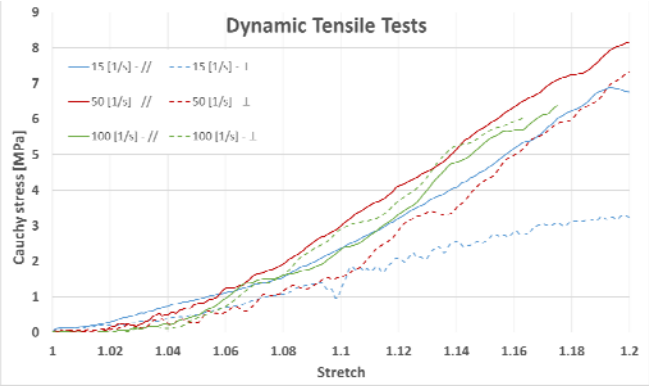

Figure 1: Average of tensile tests performed at 15 (blue), 50 (red) and 100 (green) s^{-1} on specimens parallel (continuum line) and perpendicular (dashed line) with respect to the STLs. The graph reports the data until 1.2 of stretch.

Comparing the values of the stretch at failure, both the orientation of the sample and the strain rate have an effect. Specimens loaded in the perpendicular direction have a higher value of stretch at failure and the stretch at failure decreases with the increase in strain rate.

CONCLUSIONS

The anisotropy of scalp tissue is not evident at high strain rate due to the wide variability of the mechanical properties inter and intra subject. Therefore the scalp can be considered isotropic when subjected to high strain rate loading. The strain rate, instead, affects the mechanical properties and in particular the scalp seems to be stiffer when subjected to higher levels of strain rate.
In order to have more accurate results a bigger number of specimens would need to be tested in a wider range of strain rates.

TRANSDERMAL DRUG DELIVERY ENHANCEMENT BY UNIDIRECTIONAL SKIN EXTENSION

[1] **Sho Suagwara**, [1]Kenji Kikuchi, [1]Shunsuke Shigeta, [1]Keiko Numayama-Tsuruta and [1]Takuji Ishikawa

INTRODUCTION

Transdermal drug delivery systems (TDDS) have been focused as useful methods for drug administration from the skin into the body without pain in the skin as well as metabolism by the digestive organ. Due to barrier function on the top surface layers of the epithelium, which is the stratum corneum, large molecular weight or water soluble drugs cannot permeate well, i.e. low permeability through the epithelium. To overcome these problems, TDDS using microneedles or iontophoresis has been proposed [1,2]. However, there are still some problems on invasive damages, infections from the skin and side effects. From the above reasons, noninvasive TDDS method has been sought. We thus propose a transdermal drug delivery enhancement by mechanical stimulations of the skin. In this paper, we report a novel drug permeation enhancement method by unidirectional skin extension.

METHODS

Experimental materials

We used Yucatan micro pig skin (Charles river, USA), which has similar drug permeation properties with human skins, as a skin model. A water soluble fluorescent probe of fluorescein sodium (molecular weight 376 Da, pH 8.3, maximum absorption wavelength is 490 nm, maximum emission wavelength is 521 nm) was used as a drug model. The fluorescein sodium was diluted to 250 μM by phosphate buffered saline of pH 7.4 (Wako, Japan).

Extensive stimulation & Measurement of drug permeation

The skin model was manually extended for 5 minutes as extensive stimulation by using unidirectional extension stage. The strain was kept at 0.2 ± 0.1 while the skin was extended at room temperature of 25℃. After the extensive stimulation, we put the drug model on the skin surface for 5 minutes. The permeated fluorescence intensity of fluorescein sodium solution in the skin model was measured by a fluorescent stereomicroscope (Leica, Germany).

RESULTS AND DISCUSSION

Figure 1 shows distributions of fluorescein sodium in the stratum corneum with or without the extensive stimulations. The fluorescent patterns showed the configuration of sulcus cutis, *i.e.* the crinkle on the skin surface or edge lines of the skin crista cutis. When the extension was applied, the patterns were stretched to the extension direction. Around the skin crista cutis after the skin extension (cf. Fig1b), the drug permeated regions were recognized inhomogeneously. The results of the maximal fluorescence intensities at the skin crista cutis w/ and w/o the skin extension were 55 and 148, respectively. It was found that the maximal drug permeation was enhanced approximately 2.7 times by the skin extension.

Figure 2 shows the comparison of averaged fluorescence intensities between w/ and w/o the skin extensions. The average fluorescence intensity per the unit area w/ the skin extension is 1.4 times higher than that of w/o the skin extension, with statistically significant propensity ($p > 0.1$). By assuming the proportionality between the fluorescent intensity and the permeated drug per unit area, we can say that the unidirectional skin extension with the strain of 0.2 ± 0.1 enhances the drug permeation approximately 1.4 times. This results suggest that the skin extension would reduce partially the barrier function of the stratum corneum by the structural change at the intercellular junctions of the epithelium.

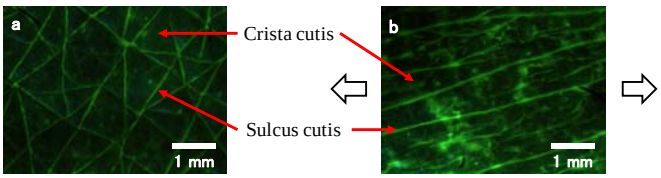

Figure 1: Comparison of the distribution of drug model on the skin surface between a) without extension and b) with extension

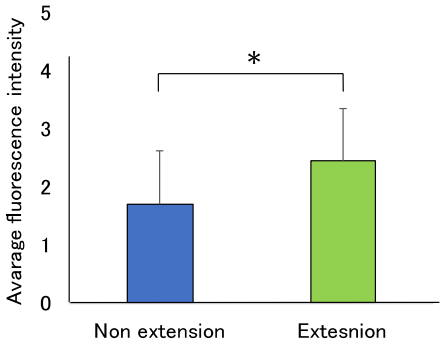

Figure 2: Comparison of the average fluorescence intensity at crista cutis between w/ and w/o the skin extensions. * indicates $p < 0.1$.

CONCLUSIONS

We investigated experimentally the transdermal drug delivery enhancement by unidirectional skin extension. As results, the extended skin was not only elongate in the extensional direction and compressed in the perpendicular direction, but also enhanced the maximal drug permeation. The unidirectional skin extension with the strain of 0.2 ± 0.1 enhanced the average permeated drug per the unit area about 1.4 times.

INTRODUCTION

Recently, clinical treatments applying Drug Delivery System (DDS) have been being developed. However, it is quite difficult to *in vivo* diagnose spatiotemporal distribution of drug infiltration. An example of chemical substance, "water", has significant influence on human body due to physiological carrier media. Therefore, *in vivo* quantitative measurement of moisture content is necessary to classify skin mechanics. In this study, we propose 2C-OCM (2-Color Optical Coherence Moisturegraphy), which is composed of two-band light sources having different optical absorption properties of moisture content. RSOD (Rapid Scanning Optical Delay line) is implemented as a depth scanner of interferometer, which can modulate the two-band lights to different frequencies. In order to verify 2C-OCM, it was *in vivo* applied to the dorsum of hand skin with varying moisture condition of tissue.

METHODS

A schematic view of 2C-OCM is shown by Fig. 1. This is constructed around an optical fiber interferometer based on Time-domain OCT [1], and can simultaneously acquire two interference signals only by a single channel. Two super luminescent diodes with respective center wavelengths of 1317 nm and 1421 nm are used as dual light sources. Water molecule has a larger peak of the absorption spectrum around 1400 nm than that around 1300 nm, so the signal intensity of 1400 nm band decreases exponentially to the direction of depth. On the other hand, the signal around 1300 nm does not decrease even with a rise of water content. This spectral difference in these light absorption properties can determine water content quantitatively with high contrast. While, RSOD was implemented as a depth scanner in reference arm so that it can provide video-rate tomography by rotating a galvanometer mirror. In addition, light of each wavelength, which is diffracted by a grating, is focused on different position on the surface of scanning mirror by an achromatic lens, so can modulate lights of the two-band wavelength to respective different frequencies. Hilbert transform is applied in the frequency domain to both interference signals frequency-separated by digital band-pass filter. Two axial-scanning envelope signals are calculated as tomographic intensity distributions of two-band wavelength. The ratio can be calculated by division between these intensity signals. Wavelength gap of two-band have no more than 100 nm difference, so the scattering coefficient and the reflectivity of them can be assumed to be equal. Therefore, the logarithmic ratio can be just an integral function of depth-profile of absorption coefficient around 1400 nm band, because water absorption around 1400 nm is much larger than that around 1300 nm. The water absorption coefficient can be obtained locally by calculating the depth-gradient. The depth-profile of moisture content can be given by means of pre-experimentally calibrated relationship between water content and depth-gradient logarithmic ratio. The optical specification, e.g. the depth and horizontal resolution, Δz = 18 μm, 16 μm respectively. Galvanometer mirror in RSOD was driven at 500 Hz, and the image acquisition rate was set to 1.67 fps under the condition of 300 scanning lines. 2C-OCM was applied to the dorsum of hand skin under the condition of control and moisture saturated skin for 30 minutes.

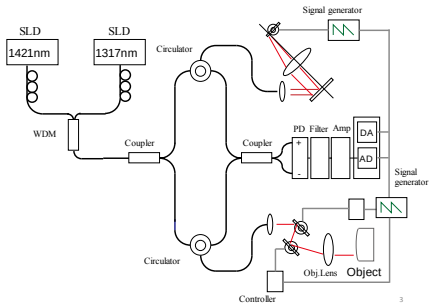

Fig. 1 2C-OCM system based on a low coherence interferometer with a rapid scanning optical delay line using dual light sources

RESULTS AND DISCUSSION

Figures 2 (a) and (b) show moisture content distribution under the condition of control and moisture saturated skin, overlapping OCT image of 1300 nm. Skin surface is visualized as a horizontal blight line at Z = 100 μm. Tissue layers of epidermis and upper dermis are shown from Z = 100 to 250 μm, and below Z = 250 μm, respectively. As shown by these figures, moisture content was distributed from 30% to 60% under control condition, whereas from 50% to 90% under moisture saturated condition. There are some artifacts in moisture content, which are caused by the positioning mismatch of two-band signals. It is possible to decrease by means of aligning adjustment with sub-pixel accuracy.

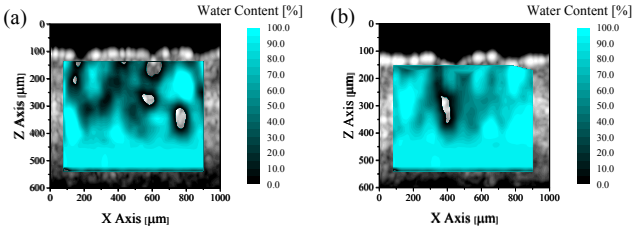

Fig. 2 1300 nm OCT images and moisture content distributions by 2C-OCM; (a) control; (b) moisture saturated condition

CONCLUSIONS

This paper presents the 2C-OCM system with RSOD, which was *in vivo* applied to the dorsum of hand skin with varying moisture in tissue. As a result, this could offer tomographic moisture content in micro scale. It was suggested to be an effective modality as *in vivo* tomographic diagnosing tool of DDS concentration in tissue.

MECHANICAL AND FLUID DYNAMICAL CHARACTERIZATION OF 3D POROUS CERAMIC MATERIAL – APPLICATION TO BAGHDADITE SCAFFOLDS FOR LARGE SEGMENTAL BONE DEFE€TS

INTRODUCTION

Identifying suitable 3D scaffolds for repair and regeneration of bone in critical size defects is challenging due to different, often contradictory, requirements imposed on these materials. Ceramic materials have gained increasing use in bone tissue engineering due to their biocompatibility and similar chemical composition as bone. Recently, calcium silicate ceramic containing zirconium, patented under the name Baghdadite, has shown very promising results in terms of biocompatibility [1] and excellent mechanical properties [2]. While scaffold mechanical properties are essential to support the defect at the repair site, the success of the bone graft is strongly governed by the ability of blood vessels and cells to invade the scaffold. Permeability has been shown to play a major role in the promotion of vascularization and bone regeneration *in vivo*. Material properties of ceramic scaffolds (and bone) decrease with increasing porosity. On the other hand, the permeability of scaffolds (and bone) increases with increasing porosity. Consequently, an optimum range of porosities needs to be identified where both the mechanical properties and the permeability are sufficiently high to warrant efficient bone repair. Identification of this porosity regime is challenging. Here we propose a novel experimental-computational approach to characterize the dependence of material properties and permeability on porosity using Baghdadite as scaffold material.

METHODS

In order to assess dependence of permeability on porosity, Baghdadite scaffolds with dimensions 10 mm in length and 7 mm in diameter with porosity varying from 65 to 95% have been scanned using a desktop microCT scanner. After reconstruction, the volumes are segmented into three phases (solid, fluid, interface). An in-house algorithm maps the segmented images into a 3D mesh. The Stokes equation is solved at the porescale by means of the open source software **arb** [3]. The porescale velocity and pressure fields are upscaled in order to calculate the full anisotropic permeability tensor.

Furthermore, the stiffness and strength of the samples was investigated by performing uniaxial compression tests with the ElectroForce 5500, Bose. Tests were run under displacement control at 0.5 mm/min with loading until 0.5%, followed by unloading, followed by reloading until fracture. Based on these tests both material stiffness and strength can be calculated. Also the fracture mode was determined based on the obtained load-displacement curves.

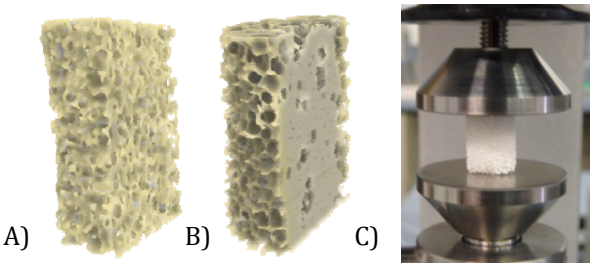

Figure 1: 3D reconstruction of specimen cut in the long axis: A) from a high porosity specimen and B) from a low porosity specimen. C) Compression testing apparatus.

RESULTS AND DISCUSSION

The anisotropic permeability tensor is computed for 12 specimen from each group of porosity. The eigenvalues of the upscaled tensor indicate the preferential flow directions of the microstructure. While the low porosity scaffolds exhibited a typical brittle behaviour, the highly porous scaffolds showed a damageable, cellular-like behaviour from the rupture of individual ceramic struts.
The functional advantages of different scaffold morphologies are discussed in term of permeability and mechanical strength properties.

CONCLUSIONS

Both the mechanical properties and permeability need to be considered for selection of optimal scaffold porosities for application in critical size bone defects. The experimental-computational approach proposed here provides important information on selection and design of ceramic scaffolds with particular microstructures and mechanical properties to mimick host bone tissue.

INTRODUCTION

The intervertebral disc is a complex, composite structure that possesses both elastic and energy absorbing properties, which may result from interactions between the solid phase and fluid flow (poroelasticity), as well as from intrinsic viscoelasticity in the solid phase itself. Similar behaviour has been demonstrated for normal discs [1], however the time-dependent behaviour of degenerated discs and the relative contributions of the solid and fluid phases in each of six degree of freedom (DOF) loading directions has not been studied. Degenerated discs generally do not have a hydrated functional nucleus, and we hypothesized that the poroelastic behaviour of degenerated discs would play a minor role compared to the solid-phase intrinsic viscoelastic behaviour of the disc tissue.

The aim of this study was to determine the 6DOF frequency-dependent changes in disc stiffness and phase angle and compare the poroelastic and viscoelastic behaviour of degenerated discs.

METHODS

Fifteen intact human lumbar segments were dissected from human lumbar spines (mean (SD) age 76 (11) years, Thompson grades 3 (N=6), 4 (N=6), 5 (N=3)). Each segment was tested along 6DOF directions under hybrid position-load control at four dynamic loading frequencies (0.001 Hz, 0.01 Hz, 0.1 Hz and 1 Hz) while subjected to a physiological preload, hydration and body temperature conditions in a hexapod robot [2,3]. Non-destructive cycle amplitudes were 1.1 MPa compression, 0.6 mm shear, 3° lateral bending, 5° flexion, 2° extension and 2° axial rotation. Average stiffness over the entire final load-unload cycle and phase angle over all loading cycles was calculated. DOFs were divided into two groups: the poroelastic (poro) group expected to favor fluid flow during loading (compression, bending, flexion/extension), and the viscoelastic (visco) group expected to exhibit primarily intrinsic (solid phase) viscoelastic behaviour (shears and axial rotation). Stiffnesses and phase angles for each DOF were normalized and expressed as %change relative to 0.001 Hz for the other frequencies. Separate repeated measures ANOVAs were performed on the within-subjects effects of frequency and between-subjects effects of the poro and visco groups (poro-visco) and their interactions.

RESULTS AND DISCUSSION

The overall within/between-subjects effects of frequency, frequency x poro-visco and poro-visco were highly significant ($p<0.001$, Figure 1). No significant differences existed between the poro-visco groups at 0.01 Hz ($p>0.05$) for stiffness or phase angle. Significant differences between poro-visco groups were observed at 0.1 and 1 Hz for stiffness and phase angle ($p<0.05$). Overall, the visco DOFs exhibited larger %changes in stiffness and phase angle at 1 Hz relative to 0.001 Hz, compared to the poro DOFs ($p<0.05$).

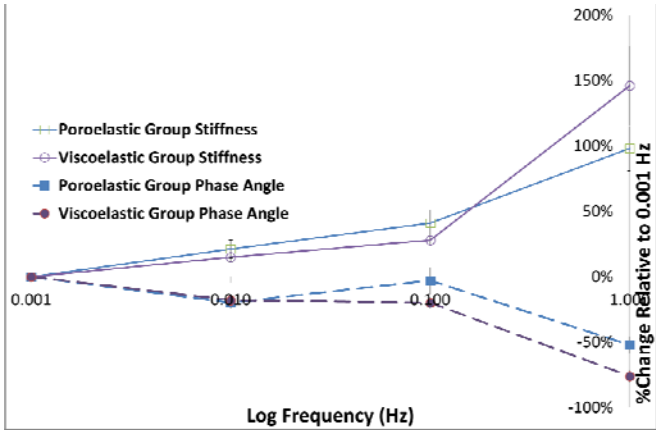

Figure 1: Mean (95% CIs) stiffnesses and phase angles plotted as a percentage of those at 0.001 Hz as a function of frequency for those DOFs thought to be dominated by poroelastic behaviour and DOFs thought to be dominated by intrinsic viscoelastic behaviour.

CONCLUSIONS

Stiffness increased and phase angle decreased with increasing loading frequency for both poro and visco groups, where the effects were more pronounced at 1 Hz compared to the slower frequencies. Strong biphasic differences occurred at 1 Hz as viscoelastic effects were significantly greater than poroelastic effects for both stiffness and phase angle, which could be attributed to a desiccated nucleus.

TOWARDS DEVELOPING AN INTEGRATED FRAMEWORK TO PREDICT SUBJECT SPECIFIC SPINE MECHANICS

INTRODUCTION

There is a growing interest in the field of computational biomechanics to combine the two simulation approaches of finite element (FE) analysis and neuro-musculoskeletal (NMS) models. Together, these two synergistic modelling methodologies provide a more intrinsic understanding of physiological biomechanics, giving an insight into the internal dynamics of the tissues for physiologically authentic motions.

This study will outline the steps involved in adapting an established NMS model of the spine (demoa, [1]) to include subject specific anatomical geometry and mechanical parameters in order to provide temporal data for muscle forces. FE considerations relevant to modifying a validated subject-specific, thoracolumbar spine model [2] in order to apply individual muscle fascicle forces will be outlined.

METHODS

Both the NMS and FE models were individualised to simulate thoracolumbar spinal anatomy for the Visible Man (VM, Visible Human Project, NIH) using custom-developed image processing software, Dicomtilt [2], in order to generate models with compatible anatomy and initial conditions. The following sections detail the specific steps employed for both models.

FE model: A series of specific, user-selected landmarks defined both the osseous anatomy for the thoracolumbar vertebrae/ribcage and the insertions for spinal muscles active in the lumbar spine. These muscles matched those already included in the NMS model and included attachment/origin points in the thoracolumbar spine, sacrum and pelvis. Using custom-developed FE pre-processing software, VirtuSpine [2], these landmarks were used to create an osseoligamentous FE model of the spine with individual muscle fascicles modelled using axial connector elements (tension-only) overlaid with non-linear spring elements. The spring elements will permit the contribution of the passive muscle stiffness to be investigated and the connector elements enable quasi-dynamic loading conditions to be applied via force amplitude data for the temporal change in muscle forces during a specified motion.

NMS model: Muscle attachment points and ligament initial lengths for the VM were obtained using Dicomtilt and inertial parameters for the VM vertebrae were derived from the FEM. These data were used to adapt the model structures in the NMS model to simulate subject-specific muscle fascicle origin/insertion points for the VM. Ligament force-displacement properties were the same in both models and were derived from the literature [2]. Using an advanced coupling algorithm, the elastic response of the L2/3 intervertebral disc during multi-axis loading was solved using an FEM of the VM lumbar joint and the mechanical response homogenized to derive the NMS link element for the disc [3].

Initial Conditions: Both models were initiated from a comparable state, which represented the intrinsic hydrostatic nucleus pressure in the intervertebral disc in the unloaded condition [4]. Similarly, the pelvis was spatially constrained.

RESULTS AND DISCUSSION

The NMS modelling workflow was successfully adapted to morph the typical anatomical representations for the thoracolumbar spine, sacrum and pelvis in order to simulate subject-specific anatomy and inertial properties. By individualizing the NMS model parameters, this ensured the mechanical response of the NMS soft tissue elements were discretized to a specific spine.

Similarly, the established image analysis and FE pre-processing method was successfully modified to incorporate additional capability for deriving subject-specific osseous attachment points for lumbar muscle fascicles and the capability to mesh/analyze >100 individual muscle fascicles.

CONCLUSIONS

With this newly established workflow, the capability of simulating physiologically feasible muscle forces in an FEM of the thoracolumbar spine (including ribcage) and pelvis is the next phase, such that an osseoligamentous model can be used to investigate the tissue level mechanics associated with realistic physical motions of the spine. Further to this, the influence of spinal motion and muscle activation strategies on tissue level mechanics can be more deeply investigated. We now have the significant and relevant structures included in both modelling methodologies to embark upon novel approaches to studying spinal biomechanics, permitting a finer resolution in discovering the influence of muscle synergies on mechanics of joints and in exploring the biomechanical implications of spinal pathologies which involve atypical muscle activation.

MECHANICAL LOADS WITHIN THE HUMAN LUMBAR SPINE - A NEURO-MUSCULOSKELETAL SIMULATION OF THE LOAD SHARING BETWEEN LIGAMENTS, INTERVERTEBRAL DISCS AND MUSCLE-TENDON UNITS

INTRODUCTION

Looking into the human body is difficult as long as the human is alive. Several attempts have been successful in temporarily inserting measurement devices to read out actual signals while the human is moving. In particular, the data of instrumented implants help in the observation of the joint loading, for example, in the intervertebral discs.

Additionally, implanted pressure sensors in the inter-vertebral disc increase the knowledge of the physiological range of joint loading. However, no measured data of real humans is available of simultaneous recordings of the forces in the intervertebral discs, the ligaments and the muscle-tendon units, which together form a spinal segment. The facet joint is thereby very often neglected.

Computer simulations of digital human body models can help to get a deeper insight in the dynamics of inner body parts. Especially structural models which let all relevant parts interact mechanically according to their physiological properties allow to gain realistic estimations of the internal loads.

In this contribution, we will report on a study of the passive mechanics on active mechanical loading of the human lumbar spine. We ask for the individual load the most relevant biological parts carry in specific quasi-static conditions. For example, lying on a table for several minutes leads to a relaxation of the muscles, with their activity continuously decreasing. Internal forces of each single part acting within the body level out. After a certain settling time the human body reaches a state of equilibrium. In that situation, the load sharing between the three most relevant force bearing structures of a spinal segment and their single effects on joint loads are unknown so far. Using computer simulations with our digital human body model, we can now give a physiologically based approximation of the contribution of each single structure and their combined effect on the mechanical loads within the lumbar spine.

METHODS

We carried out real experimental measurements using a specific testing machine. The machine was constructed of two table parts which can move around a hinge joint together forming one table on which the subjects were asked to lie on. In the joint axis, we are able to measure rotational moments. The subjects had to lay in a right lateral position on the testing machine and we asked them to relax for at least 30 minutes. The subjects were positioned on the testing machine such that the rotation axis was aligned to represent the L4/5 joint level. Due to the fact, that they were fixed with straps on both table parts and initially positioned in a certain posture, a resultant rotational moment stemming from the passive and active contributions of the joint could be observed. After relaxing, we assumed to have measured only passive contributions of the respective body parts. The measurement was repeated for body postures between 0° and 90° in 5° increments.

Using our previously published human body model [1] including 13 rigid body parts and a detailed lumbar spine with 58 non-linear ligaments, 5 homogenised intervertebral discs [2] and 202 muscle-tendon units [3], we run the same experimental protocol as we did with the real humans. In the numerical experiment, we adjusted the initial conditions of the passive elements such that the rotational moment of the real experiment was mapped. We turned the active contributions from the muscle fibres off and analysed the load sharing of the passive components of the muscle-tendon units, the ligaments and the intervertebral discs.

RESULTS AND DISCUSSION

The study revealed a continuous increasing load share in the ligaments on the lumbar spine while progressing flexion of the body. Additionally, starting at an angle of approximately 60° the ligaments are stretched longer than the elastic region reported from literature.

CONCLUSIONS

We hypothesize, that in the human body when flexed for a certain amount of time in a specific range, the ligament takes over most loads and is due to over-stretch. A potential risk of changes in the ligaments mechanical characteristics seem possible.

OBTAINING STRAIN RATE DEPENDENT MATERIAL PROPERTIES OF THE HUMAN INTERVERTEBRAL DISC USING AN INVERSE FINITE ELEMENT APPROACH

[1] **Nicolas Newell**, [1]Grigoris Grigoradis, [1]Alexandros Chirstou, [1]Diagarajen Carpanen, [2]J Paige Little and [1]Spyros Masouros

INTRODUCTION

Intervertebral discs (IVDs) are situated between vertebral bodies (VBs) in the spine and function to distribute loading while allowing the spine to flex and bend. Within the IVD, the anulus fibrosus (AF) surrounds the fluid-like nucleus pulposus (NP), both of which are enclosed above and below by the cartilage endplates (CEP). Finite element (FE) models of the IVD have become common in biomechanical analysis of the spine. Their precision is dependent upon accurate material properties that have traditionally been obtained experimentally by excising tissue and loading it in tension, confined compression, or through indentation tests. This method can lead to inaccurate results as the disruption of the material continuity can affect its structural behaviour. To counter this problem, inverse FE modelling has been used since properties of constituent components can be characterised without removing them from their surrounding tissue. The method involves creating a geometrically accurate mesh, replicating the experimental boundary conditions, and then optimizing the material properties of each component until computational and experimental results match. The aim of this study was to characterise strain rate dependent material properties of the most influential components of the human IVD in axial compression using an inverse FE method.

METHODS

For this initial investigation one human L3-L4 motion segment (male, aged 58) was used. VBs were sectioned transversely half way along its height, and posterior elements and surrounding soft tissue was removed. 5mm of the superior and inferior VBs were fixed with bone cement in mounting cups with the transverse plane of the IVD aligned parallel to the workbench.

The specimen was then axially compressed at three strain rates (0.001, 0.01, 0.1/s) up to 15% strain. Strain, and strain rate calculations were made based on initial IVD height measured from CT images. Specimens were preconditioned by performing three loading precycles prior to each strain rate test. A five minute relaxation period between tests was found to be sufficient for a repeatable response.

Geometry of the subject-specific FE model was obtained using a custom developed image-processing software (Matlab R2007b). Landmarks, manually selected by the user, were imported into a custom pre-processing tool (Python 2.5) which generates the IVD FE model. More detail on this technique can be found elsewhere [1, 2]. Initial material properties were based upon existing literature values for adult tissue. The AF ground matrix was modelled as a non-linearly elastic material with 14 layers of embedded rebar elements, able to respond linearly in tension and buckle in compression, to represent collagen-fibre bundles. The NP was modelled as an incompressible fluid with an initial pressure of 70 KPa [3]. Endplates, cortical bone, and trabecular bone had linearly elastic material properties. The lower VB was fixed and the upper VB was displaced at the same rate, and by the same amount as in the experiment.

Sensitivity to the material properties of all components of the model were investigated by adjusting each property in turn by ±20% of the initial value. The peak force, measured at the upper VB was then compared to the original, baseline computation. The most influential material properties were then selected for optimisation. An in-house inverse FE modelling optimisation algorithm (described in more detail elsewhere [4, 5]) was then used to adjust these properties until a close match was found between the experimentally and numerically measured force at the upper VB.

RESULTS AND DISCUSSION

Experimentally, the IVD exhibited a non-linearly elastic behaviour, and a stiffening effect was seen as strain rate was increased. The behaviour of the FE model was most sensitive to the AF ground matrix (8% change from baseline) and AF fibre bundle material properties (5% change from baseline), and therefore it was these properties that were optimised. A Mooney-Rivlin material model was used to describe the AF ground matrix. The strain energy function for this material is shown in Equation 1, where W is the strain-energy density function, I_1 and I_2 are strain invariants, and C_{10} and C_{01} are material constants:

$$W = C_{10}(I_1-3)+C_{01}(I_2-3) \quad [1]$$

The material properties for each strain rate obtained using the optimisation algorithm are shown in Table 1.

Strain rate (/s)	0.1	0.01	0.001
Fibre Young's Modulus (MPa)	239	227	168
AF Matrix C_{10} (MPa)	0.039	0.012	0.001
AF Matrix C_{01} (MPa)	0.001	0.008	0.021

Table 1: Optimised material properties for each strain rate

CONCLUSIONS

The material properties of a human IVD were successfully quantified across strain rates using an inverse FE technique. This technique can now be used on multiple specimens to determine average material properties of the IVD.

EVALUATION OF JOINT ANGLES AND NET JOINT MOMENTS IN ROPE JUMPING

[1] **Triveni Shetty**, [1]Bela Agarwal, [1]Bindya Sharma, [1]Rajani Mullerpatan

INTRODUCTION

In space and time constrained urban areas, compliance to routinely recommended physical activities like walking, and running is difficult. Negligible requirement of equipment and space make rope skipping (RS) an attractive alternative form of physical activity that can be prescribed to adults even in rural parts. Bounce skipping is popular with children as a recreational play activity globally; however exploration of physiological and biomechanical demands of the activity needs to be considered prior to prescription of rope jumping for adults.

Physiological responses to rope skipping are well documented. However, limited knowledge regarding biomechanical demands of rope skipping limits understanding of its scope in health promotion. Being a high impact activity like running, load encountered by knee joint is a concern. Therefore this study was designed to study joint angles and net joint moments during RS with reference to known activities like walking and running.

METHODS

An exploratory study was conducted on 10 healthy female participants aged 18-25 yr following ethical approval. Five trails of walk, run and bounce RS at self-selected pace were captured after practice sessions for each activity. Thirty-nine reflective markers were used and data were captured using 12-camera Vicon system (Oxford Metrics Group, UK) and 2AMTI force plates. Sampling frequency for digital data was set at 200 Hz. Butterworth filter with cut off frequency of 10 Hz was used to filter trajectory and analogue data [1] from RJ and standard filter settings for walk and run.

Three best trails were averaged using mid-gait, mid-run and mid-skip data.[2] For purpose of description left side was considered as there was no significant difference between right and left side ($p>0.05$). Joint angles of hip, knee and ankle in sagittal plane were analyzed at instances of loading, take-off and flight (mid-air) during RS. Hip adductor moment, knee adductor moment and ankle dorsi-flexor moment during walk, run and RS were analyzed in plug-in gait model.

RESULTS AND DISCUSSION

Kinematic demands during RS were highest on knee followed by hip and ankle. Maximum knee flexion occurred during flight (72.2º) and minimum during take-off (10.8 º) resulting in total motion of 61.4 º. Similarly greatest hip flexion was observed during flight (32.7 º) and least during take-off (11.6 º). Hip joint moved through a total of 21.0 º of motion. Maximum ankle dorsi-flexion occurred during landing (32.7º). Ankle plantar flexion (-13.4 º) was observed during take-off, moving through a total movement of 46.1 º at ankle in one skip cycle. (Figure1a)

With respect to peak joint moments, walk and run followed a similar pattern. Highest moments were recorded at ankle followed by hip and lowest moment was encountered by knee. Whereas during RS; knee moment was higher than hip moment but lower than ankle moment.

With reference to run (1.89Nm/kg), peak knee adductor moment was highest during run (1.89Nm/kg) followed by RS (0.96 Nm/kg) and least in walk (0.60 Nm/kg). Interestingly, peak hip adductor moment was highest during run (2.06Nm/kg) followed by walk (1.02Nm/kg) and least in RS (0.72Nm/kg).

Peak hip moment was 65% lower in RS with reference to run and 29% lower compared to walk. Peak knee moment was 49% lower than run and 60% higher than walk. Peak ankle moment was 28% lower than run and 29% higher than walk. Skipping involved landing softly on toes and not on heels resulting in lower load on knees, as the feet and calf muscles absorb the impact.

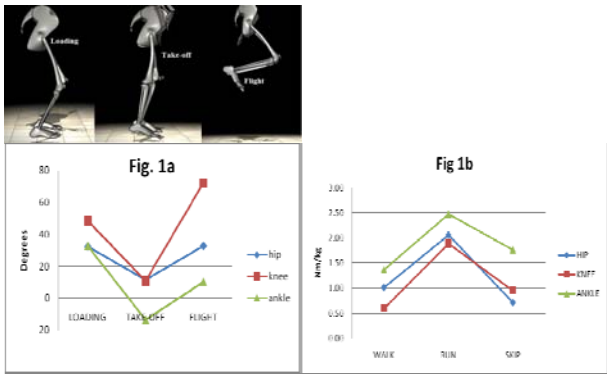

Figure 1a: Hip, knee and ankle peak joint angles during different instances of RS.

Figure 1b: Peak net joint moments of hip knee and ankle during walk, run and RS.

CONCLUSIONS

In RS load on lower extremity joints are minimal as implied by lower net joint moment results with respect to run. As knee joint moves through a 60 º range and net joint moments are lower than run. With further research, RS holds potential for prescription as a safe exercise for young adults along with people who have knee and hip joint pathology.

HUMANS GENERATE POSTURE-SPECIFIC CONTROL FOR MAXIMUM HEIGHT VERTICAL JUMPS WITHIN 200 MS

Maarten F. Bobbert and Axel Koopman
Research Institute MOVE
Vrije Universiteit Amsterdam
Amsterdam, The Netherlands
Corresponding author email: m_f_bobbert@fbw.vu.nl

INTRODUCTION

When humans are asked to perform a maximum height squat jump they do so from their own preferred initial posture. However, in many team sports the dynamics of the game require players to jump from other initial postures as well, and preparation time may be limited by actions of the opponents. In a previous study, it has been shown that humans adjust their control signals when they perform maximum height jumps from equilibrium postures different from the preferred posture [1]. The purpose of the present study was to determine how much time humans require to generate control signals for a maximum height vertical jump.

METHODS

We had 10 healthy male subjects perform maximum height vertical jumps in various conditions. We measured full body kinematics at 200 Hz (OPTOTRAK 3020) and ground reaction forces at 200 Hz (Kistler 9281B force plate). We also collected surface electromyograms at 1000 Hz from hamstrings, glutei, rectus femoris, vastus lateralis, gastrocnemius and soleus of the right leg (Porti-17t). In one condition the subjects performed countermovement jumps with the instruction to perform the downward movement slowly and to initiate the push-off for a maximum height jump as quickly as possible upon an auditory cue (condition CC). The auditory cue was generated when the height of the hip during the countermovement dropped below one of three preselected values following in random order: H (high), M (medium), L (low). Hence, the subjects were uncertain about the posture from with the jump had to be initiated until the auditory cue was given. In another condition, we had the subjects reproduce with the help of online feedback the lowest posture they had reached during a CC jump, and perform a maximum height squat jump from that position as quickly as possible following an auditory cue (condition SC) or whenever they felt like it (condition SF). Electromyograms were rectified and smoothed at 10 Hz to yield srEMG. For each muscle, we detected the onset of the rise in srEMG by fitting a line to the rising phase of the srEMG time history, and extrapolating this line backwards in time to the srEMG reference level (in CC the level in a 100 ms interval around the instant that the auditory cue occurred). A similar procedure was used to detect the onset of the increase in the ground reaction force.

RESULTS AND DISCUSSION

It was found that jump height was not less in CC jumps than in SC jumps (Figure 1, top panel), and not less in SC jumps than in SF jumps (Figure 1, bottom panel). If we assume that subjects generate optimal control in SF jumps, we may conclude that they also generated optimal control in SC jumps, despite the fact that control in CC was generated as quickly as possible following the auditory cue from a posture that was unknown in advance. We found that muscle stimulation patterns in CC varied depending on the height at which the auditory cue was given; just as in the corresponding SC and SF jumps, a 'plantarflexion shift strategy' was found [1]: the onset of srEMG in m. gastrocnemius and m. soleus relative to the onset of srEMG in m. gluteus occurred later ($p<0.05$) when the auditory cue was given at a lower posture. From this we concluded that posture-specific adjustments were made in control signals. Finally, it was found that in CC the onset of the increase in ground reaction force occurred within 200 ms from the auditory cue.

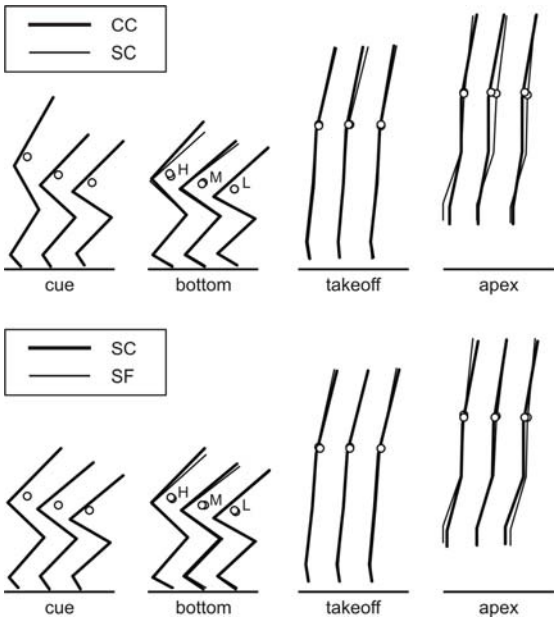

Figure 1: Average stick diagrams of body postures for different jump conditions at the instant that an auditory cue was given (in CC and SC), and when the bottom of the jump, takeoff and the apex of the jump occurred. The small circle represents the center of mass.

CONCLUSIONS

Combining all findings of this study we conclude that it takes humans only 200 ms to generate a posture-specific muscle stimulation pattern for a maximum-height vertical jump.

EFFECTS OF GRAVITY ON HUMAN MOTOR CONTROL

Dinant A Kistemaker, Martijn van der Sar, Rick Staa and Rob van Beers
[1]VU University Amsterdam
Corresponding author email: dinant.kistemaker@gmail.com

INTRODUCTION

The influence of gravity on human motor control is typically studied by comparing movements performed either with or against gravity (e.g. moving the arm up vs down). Observed differences have been used to support the claim that gravity is 'optimally integrated in motor control' by the CNS, for example through minimization of (mechanical) energy[1].
However, straightforward comparison of such movements is not without difficulties because they not only differ with respect to gravity, but i) are performed with different muscles that ii) operate differently (e.g. eccentric vs concentric), and iii) have different sensory inputs to the motor system. The goal of this study was to 1) investigate the effect of gravity on the control of movements in identical movement tasks and 2) to investigate whether the observed motor behaviour is consistent with minimizing mechanical energy.

METHODS

To study the effects of gravity, we used an experimental setup that could be inclined backwards from a horizontal position (0°) to a complete vertical position (90°) in steps of 15° (see Fig.1). Attached to the frame and chair was a surface with two markers, placed 30 cm apart. The task was to move the index finger from one marker to the other in 400 (±100)ms. Auditory feedback was given about the timing. Per (randomized) chair angle, 13 participants made 50 outward and 50 inward movements.
A model of the human upper and forearm actuated by 6 Hill-type muscle models was used to predict optimal muscle activation patterns for minimal positive mechanical muscle work using a Sparse Nonlinear Optimizer (SNOPT).

Figure 1: Overview experimental setup and arm model.

RESULTS AND DISCUSSION

Participants were equally successful at meeting the task requirements across all chair angles (~89%). From the movement data, maximal lateral deviation (P_{dev}) was calculated as well as the relative time to peak velocity ($\%t_{Vpeak}$), shown in Fig. 2. A two-way rmANOVA revealed that P_{dev} was not significantly affected by chair angle ($F(2.7,24.5) = 2.2$, $p = .126$), but did show a significant effect of movement direction on P_{dev} ($F(1,9) = 12.3$, $p = .007$). The results for $\%t_{Vpeak}$ were similar: no significant effect of angle on $\%t_{Vpeak}$ ($F(2.4, 21.8) = .36$, $p = .739$), yet a significant effect of direction on $\%t_{Vpeak}$ ($F(1, 9) = 9.9$, $p = .012$). These results support the claim that 'simply' comparing movements with and against gravity is problematic. For example, by only comparing inward ('with gravity') with outward ('against gravity') movements at 90°, one may find significant differences that can falsely be attributed to gravity. As such, these data may explain the inconsistencies found in the literature about the (magnitude of) gravity dependent curvature and symmetry.

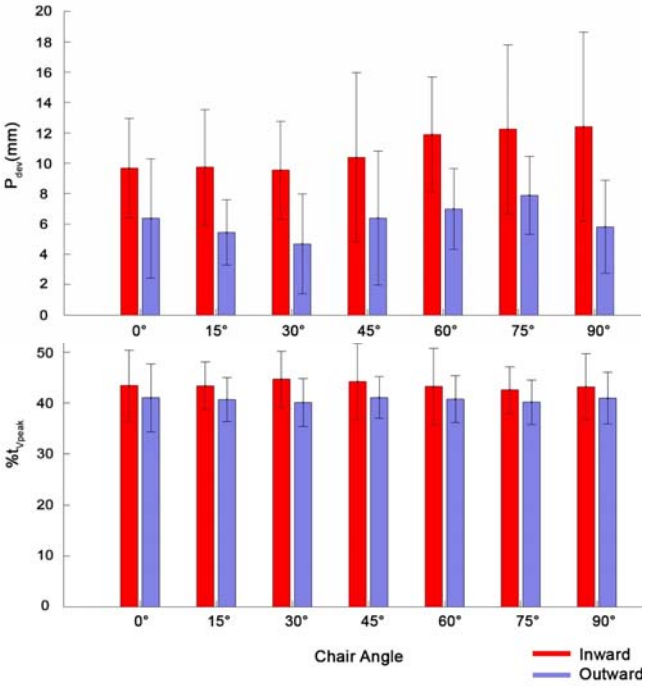

Figure 2: Average (±sem) P_{def} and $\%t_{Vpeak}$ across subjects.

Preliminary results with the arm model optimized for positive mechanical muscle fibre work show that (outward) movement paths are affected by gravity such that P_{def} increases with gravity and $\%t_{Vpeak}$ decreases. Only minimizing jerk and torque change led to (outward) movements similar to those observed experimentally.

CONCLUSIONS

This study provides clear data that gravity alone does not influence arm movement kinematics. Movement curvature and time to peak velocity was significantly different for outward and inward movements. Preliminary data obtained from an optimal control model of the arm shows that the experimental data is inconsistent with minimizing mechanical energy.

AN INCREASE IN OXYGEN CONSUMPTION ARE ASSOCIATED WITH CHANGES IN GAIT PROFILE SCORES IN HEALTHY ADULTS BUT NOT ACHRONDOPLASIA (DWARFISM)

[1]David Sims, [1] Adrian Burden, [1] Hannah Jarvis,[1] Gladys Onambele, [1] Carl Payton and [1] Chris Morse
[1] Health Exercise Activity Living Research Centre, Manchester Metropolitan University, Cheshire

INTRODUCTION

Achondroplasia is the most prevalent type of Skeletal Dysplasia in humans and is characterised by disproportionate limb and torso length [1]. Whilst shorter stride length, increased pelvic tilt and varus movement of the knee are observed in Achondroplasic children [2], no kinematic data exist in Achondroplasic adults. Gait Profile Score (GPS) uses kinematics to derive a quantifiable measure of an individuals' gait variability [3]. It is therefore a useful measure in comparing gait pathologies to healthy groups [4]. Changes in gait patterns are associated with changes in oxygen consumption (VO_2); measures of which allude to the energy cost associated with gait speed [5] and/or efficiency of movement. To our knowledge however, VO_2 and GPS have not been measured in Achondroplasia. The aims of this study were to measure VO_2 and GPS in Achondroplasic and healthy average statured (controls) adults during walking and running at incremental speeds

METHODS

Ten Achondroplasic adults (mean [SD], age: 22 [3] yrs, mass: 61.8 [8.5] kg, stature: 137.8 [4.7] cm) and seventeen adult controls (age: 22 [2] yrs, mass: 78.3 [10.7] kg, stature: 178.7 [8.3] cm) completed a full body gait analysis at a self-selected walking speed (SSW), 6 absolute walking speeds (0.56 - 1.94 $m \cdot s^{-1}$; increments of 0.28 $m \cdot s^{-1}$) and 6 absolute running speeds (1.67 - 3.33; 0.28 $m \cdot s^{-1}$), determined using two timing gates 1 m apart. Lower limb kinematics were collected and used to calculate GPS in accordance with Baker et al. [6]. VO_2 ($ml \cdot kg^{-1} \cdot min^{-1}$) was also collected using expired gas analysis at each gait speed during the kinematic analysis on a treadmill. Two-Way ANOVA was used to assess the difference in VO_2 and GPS between participant groups and gait speeds. Respective central tendencies of VO_2 and GPS at each gait speed were analysed using a Spearman's correlation.

RESULTS AND DISCUSSION

Compared to controls, Achondroplasia VO_2 was greater at each gait speed ($P < 0.05$) apart from SSW ($P = 0.494$, Figure 1). Averaged walking and running VO_2 were 19% and 10% greater in Achondroplasia, respectively ($P < 0.05$). Achondroplasia GPS scores were greater than controls at all gait speeds ($P < 0.05$), and 64% greater at SSW ($P < 0.001$). There was no difference in GPS between any locomotion speed in Achondroplasia ($P > 0.05$), whereas controls' running GPS were greater than their walking GPS ($P < 0.05$). VO_2 and GPS did not significantly correlate ($P > 0.05$) in Achondroplasia, whereas controls showed a significant positive correlation between VO_2 and GPS ($R^2 = 0.803$ $P < 0.01$).

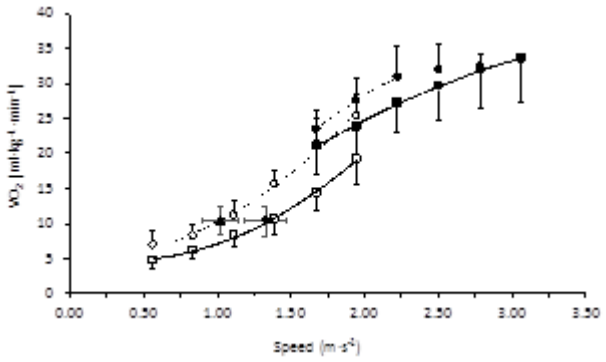

Figure 1: VO_2 for Achondroplasia (○) and control (□) when walking (open) and running (closed). SSW speeds are presented for Achondroplasia (▲) and control (◆) respectively. Values presented as means and standard deviation (error bars).

CONCLUSIONS

The greater GPS and VO_2 in Achondroplasia is likely due to differences in limb length, gait kinematics, muscle and tendon factors or segment inertial properties between Achondroplasia and controls, however this remains to be determined experimentally. The similar VO_2 at SSW is likely to be due to a matching of stride frequency at these speeds between Achondroplasia and controls. Unlike controls, Achondroplasia did not increase GPS with gait speed. It is possible that a lack of joint congruence in Achondroplasia [7] limits the change in kinematics throughout walking and running.

THE NEUROMUSCULAR RECOVERY PROFILE OF A FULL BODY RESISTANCE EXERCISE SESSION

[1] **Paul W Marshall**, [1]Rebecca Cross and [1]Michael Haynes
[1]Western Sydney University
Corresponding author email: p.marshall@westernsydney.edu.au

INTRODUCTION

Fatigue may be defined as a potentially disabling symptom for an individual, where physical and cognitive function is limited by the interaction between neuromuscular and perceived fatigue [1]. The fatigue and recovery from a resistance exercise session is not well understood, leading to confusion in real-world practice about how to best schedule this type of training between other activities. We designed this study to examine the time-course of changes in central motor output, including measures of quadriceps afferent excitability [2], contractile fatigue, and perceived fatigue in the 48 hours following a full body resistance exercise session.

METHODS

Eight resistance trained men volunteered for the study (mean ± SD; age 27.0 ± 6.0 years, height 1.79 ± 0.05 m, weight 81.8 ± 6.8 kg, training experience 7.8 ± 5.0 years). Experimental measures around the training session included; quadriceps maximal voluntary torque (MVT) and rate of torque development (RTD), voluntary activation (VA), maximal and rate of rise in quadriceps surface electromyograms (EMG), contractile function was measured from potentiated twitch torque (Q.pot.tw) as well as time to peak and ½ relaxation time, and H-reflex curve modelling from vastus medialis (VM) in addition to examining homonymous presynaptic inhibition via paired-pulse stimulation.

Perceived fatigue measures included session rating of perceived exertion (RPE), in addition to wellness, sleep quality, mood, stress, and quadriceps muscle pain (VAS).

The training session was approximately 60-minutes duration and included nine different exercises. The session was modelled after that used within-season in Australasian contact field sports.

Measurements were performed before (PRE), immediately (IP) and 1 hour after the session (1H), as well as after 24 and 48 hours recovery (24H, 48H). Linear mixed model ANOVA procedures were used for data analysis, with Bonferroni corrections used for post-hoc analysis of main effects (significance set at $p \leq 0.05$).

RESULTS AND DISCUSSION

Reductions in MVT were observed after training ($p<0.002$), with values reduced from PRE by 25% 1H after training (Figure 1). RTD was reduced from PRE at the IP measurement only by 13.6% ($p=0.05$), with full recovery after 1H rest. Both MVT and RTD were recovered by 24H. Contractile function was reduced up to 1H after exercise between 25-40% ($p<0.001$), but recovered by 24H. VA was only different between IP and 48H measures ($p=0.008$), with VA scores higher after rest. No changes were observed for EMG measures. The maximal amplitude ($p=0.024$) and slope of the H-reflex ($p=0.002$) were higher immediately after exercise, and gradually returned to PRE levels after 48H rest.

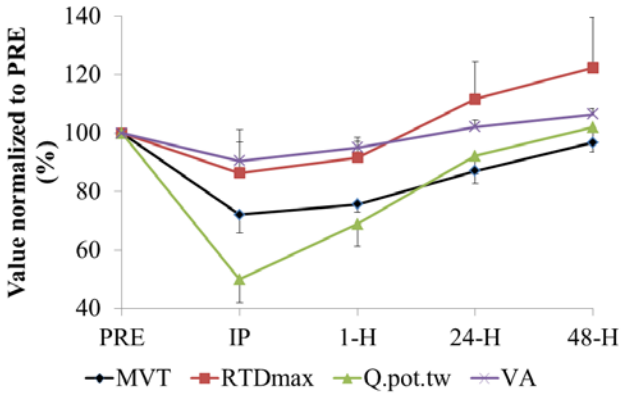

Figure 1: Changes in key neuromuscular variables after the full body resistance exercise session.

The session training load, based on RPE multiplied by time of session, was 465.2 ± 7.6. Perceived fatigue, wellness, general soreness, and quadriceps VAS scores increased after exercise and only returned to PRE exercise levels following 48H rest.

CONCLUSIONS

There was a mismatch between the recovery of neuromuscular and perceived fatigue that must be taken into account when prescribing multiple training sessions within season in sport. While neuromuscular recovery is generally complete after 24H rest, activities requiring full voluntary effort (maximal effort field training; a match) should probably wait 48H after such as session because of the delayed recovery in perceived fatigue. Short duration explosive activities that do not induce contractile fatigue could be considered later on the same training day as the session tested here, owing to the maintenance of RTD and early muscle activation. Increased gain of the α-motoneuron response to afferent input is a likely mechanism explaining the maintenance of RTD. The increased H-reflex does not appear to be from a change in homonymous presynaptic inhibition.

ACKNOWLEDGEMENTS

We thank the volunteers for taking part in the strenuous training session and testing in this study.

INTRODUCTION

High tibial osteotomy (HTO) is a well-established procedure for the treatment of medial-compartmental osteoarthritis (OA), which aims to offload the medial compartment of the knee through re-alignment of the lower limb. The goal of this surgery is to reduce the severity of OA symptoms, particularly medial compartment pain, and to slow the progression of arthritis.

This study determines the efficacy of HTO surgery in modifying knee loading using 3D motion capture and patient reported outcome measures (PROMS). It also examines the relationships between the changes in clinical estimates of load distribution (the mechanical tibiofemoral angle (mTFA) defined from long leg x-rays) with changes in biomechanical indicators of loading and PROMS.

METHODS

Gait was evaluated for 18 HTO candidates (BMI 27.0 ± 7.8 kgm^2; age 51.3 ± 7.3 years) using 3D motion capture, at two time points: pre-operatively (average 1.7 ± 1.6 months), and post-operatively (average 14.0 ± 3.3 months). OA severity determined using the Kellgren-Lawrence radiographic score ranged from 2 to 4 (2(*n*=1), 3(*n*=13) and 4(*n*=3) with one score missing). Varus deformity was determined as mTFA (see Table 1). The PROMS Oxford Knee Score and Knee Outcome Survey were taken at each assessment point. Approval was granted by the Research Ethics Committee for Wales and Cardiff and Vale University Health Board.

Subjects walked at their self-selected speed and wearing a modified Cleveland Clinic marker set [1]. Joint kinematics, kinetics and temporal parameters were calculated within Visual 3D (C-Motion, USA). A Butterworth fourth order lowpass filter was used on raw marker coordinate data (cut-off frequency 6 Hz). Joint angles were calculated using the Cardan/Euler x, y, z sequence to find the orientation of the distal segment with respect to the reference proximal segment. Inverse dynamics was used to calculate net external knee joint moments represented in the tibial reference frame [2].

The two peaks of the external knee adduction moment were calculated for the first and second half of stance phase (EKAM P1, EKAM P2), along with the minimum (EKAM trough) between the two peaks. In cases where the EKAM did not appear biphasic, the timing of the peak internal knee rotation moment was used to define EKAM P2 [3]. Knee flexion/extension moment (FMom/EMom) and internal knee rotation moment (IntMom) at the time of the two EKAM peaks were calculated to identify further knee loading changes as a result of re-alignment. All joint moments are normalised to %BW.h. Knee Adduction Angular impulse was calculated for the positive portion of EKAM to provide information on average loading over the stance phase. Paired samples t-test and Pearson's correlation were performed (SPSS Statistics).

RESULTS AND DISCUSSION

Reduction in frontal plane loading following HTO did not significantly increase transverse or sagittal plane knee loading (Table 1). In fact a significant reduction was also seen in the transverse plane moment at the timing of EKAM peaks 1 and 2, and in sagittal plane moment at the timing of EKAM peak 2. The change in mTFA and EKAM peak 1 significantly correlated (r=0.54, p=0.031) (n=16), as did the change in mTFA and Oxford Knee Score (r=-0.544, p=0.044) (n=14). Subjects significantly increased their gait speed (p=0.032) following HTO surgery.

Table 1: Key changes in knee loading, varus angle and PROMS pre to post HTO surgery (Mean ± Std. Deviation)

Variable	n	Pre-HTO	Post-HTO	Sig.
EKAM P1	18	3.02 ± 1.30	2.11 ± 0.92	p=0.002
EKAM P2	18	2.37 ± 1.23	1.50 ± 0.80	p=0.002
EKAM trough	18	0.76 ± 0.14	0.73 ± 0.09	NS
KAAI (%BW.h.s)	18	1.32 ± 0.60	0.81 ± 0.38	p=0.001
FMom P1	18	1.75 ± 1.09	2.01 ± 1.31	NS
EMom P2	18	1.06 ± 1.06	0.58 ± 0.99	p=0.030
IntMom P1	18	0.14 ± 0.19	-0.01± 0.12	p=0.005
IntMom P2	18	1.03 ± 0.52	0.67 ± 0.37	p<0.001
Gait Speed (m/s)	18	1.02 ± 0.22	1.07 ± 0.17	p=0.032
mTFA (°)	16	7.5 ± 3.4	2.3 ± 1.7	p<0.001
OKS	16	25.3 ± 7.7	36.8 ± 6.8	p<0.001
KOS	15	46.7 ± 12.9	58.9 ± 12.8	p=0.016

CONCLUSIONS

Both mTFA, EKAM and KAAI indicate significant reduction in medial compartment loading following HTO. Reductions in sagittal and transverse planes also result from the surgery. These findings, along with the significant improvement in PROMS, provides evidence of HTO efficiency in alleviating symptoms of OA and fulfilling the aims of surgery.

INTRODUCTION

Varus malalignment of the knee joint can result in increased mechanical loading, pain, inflammation and joint degradation within the medial compartment. High tibial osteotomy (HTO) is a joint realignment surgery which aims to restore the mechanical axis of the lower leg, and hence reduce medial contact forces. Whilst clinical studies have suggested that in certain patients, there is a biological effect with reversal in degenerative processes and regeneration of cartilage [1], there is a lack of evidence for this.

The neurotransmitter, glutamate is present at increased concentrations in arthritic synovial fluids and the glutamate transporter EAAT1 is mechanically regulated in bone [2]. Glutamate receptors (GluRs) and transporters are present and function in various musculoskeletal tissues, including bone, cartilage, meniscus and synovium [3]. Activation of GluRs influences inflammation and destruction of cartilage and bone, which contribute to arthritic joint degeneration [3,4]. Glutamate also acts on nerves within the joint to cause pain. Thus glutamate signaling represents a mechanism whereby mechanical load through the joint can directly influence joint pathology and pain. This study, aimed to evaluate, in individual patients, whether regional changes in glutamatergic signals in subchondral bone for pre- HTO are correlated with biomechanics, function, clinical measures or pain.

METHODS

Clinical measures: The knee varus angle was taken pre-operatively from standing long leg X-rays (VARUS), alongside OA grade (Kellgren Lawrence, KL), Pain (VAS) and Oxford Knee Score (OKS) from 13 patients undergoing HTO surgery (12 male: 2 female; 1.73m ± 0.089; 83.9Kg ± 19.4; 46.3yrs ± 4.66).

Biomechanical measures: Human motion analysis was performed pre-operatively (38.8±45.6 days). Subjects were asked to walk barefoot over ground at a self-selected pace. Biomechanical indicators of dynamic joint loading were calculated within Visual 3D (C-Motion, USA): External Knee Adduction Moment Peaks 1 and 2 (KAM1 and 2); knee adduction angular impulse in the 1st and 2nd half of the Stance (KAAI1 and 2) [5]; knee flexion at KAM Peaks 1 and 2 (KF1 and 2); max knee flexion moment and max knee extension moment.

Biological measures: Sub-chondral bone cores were taken from Anterior, Posterior Medial, Lateral joint quadrants, at time of surgery 1 cm below the surface. RNA was extracted, reverse transcribed and GluRs (NR2D, GRIK4), and transporters (EAAT1 and 3), normalized to HPRT1 (RefFinder of 3 genes) quantified using quantitative polymerase chain reaction (RT-qPCR). Gene expression data was analysed in all four quadrants, or combined across Medial M, lateral L, or Anterior A and posterior P or combined for all (ALL).

Statistics: Data were tested for normal distribution (Shapiro Wilkes Normality Test) and tested for correlations using the Pearson's correlation coefficient (parametric data) or Spearman's Rank Correlation Coefficient (nonparametric data) (SPSS).

RESULTS AND DISCUSSION

The relationship between static alignment and dynamic frontal plane joint loading, often complicated by compensatory off loading mechanisms such as trunk lean, appears strong within our cohort: increased static mal-alignment (VARUS) was associated with increased dynamic frontal plane knee loading; KAM1 (0.67, $p=0.006$), KAM2 (0.75, $p=0.002$), KAAI1 (0.82, $p<0.001$), KAAI2 (0.77, $p=0.001$).

EAAT1, shown to be mechanically-regulated in animal studies [2] was not related to static or dynamic indicators of joint loading in this cohort. A strong negative relationship between EAAT1ALL and body mass ($r=-0.618$, $p=0.016$). suggests that the widely-used technique of normalizing joint moments to bodyweight might not be appropriate when exploring mechanical regulation of biomarkers. Our data included two patients with VARUS scores outside the normal clinical range (1.9 and 18.7 deg.) and exclusion of these revealed that increased VARUS is potentially associated with increased NR2DALL (0.64, $p=0.046$) and increased PAIN is associated with increased in EAAT3ALL (0.76, $p=0.03$).

The stability of reference genes and the low ratio between the cohort size and the number of parameters analysed means that statistical significance of associations should be treated with caution.

CONCLUSIONS

Our combined, data in individual patients pre HTO surgery, reveals that clinical measures such us VARUS, PAIN and body mass associate with biomechanical and biological factors. Thus, medial OA with altered loading at the knee (varus alignment) may regulate glutamatergic signaling in sub-chondral bone to influence pain, inflammation and pathology. Linking biological signals to biomechanics in humans pre HTO is challenging, however may reveal new mechanically driven disease mechanisms that explain the profound protection offered by glutamate receptor antagonists in animal models of arthritis [4].

INTRODUCTION

One of the main surgical goals when performing a total knee replacement (TKR) is to ensure the implants are properly aligned and correctly sized; however understanding the effect of alignment and rotation on the biomechanics of the knee during functional activities is limited. Cardiff University has unique access to a group of local patients who have relatively high frequency of poor alignment, and early failure [1]. This has provided a rare insight into how mal-alignment of TKR's can affect patients from a clinical and biomechanical point of view to determine how to best align a TKR. Aim: To perform an in-vivo analysis investigating the relationship between alignment and biomechanical function to assist surgeons by determining the optimum alignment. Objectives: Comparing patients with neutral (-2° to 2°), varus (≥2°) and valgus alignment (≤-2°). To perform an exploratory statistical analysis to find any significant relationships with clinically relevant surgical measures.

METHODS

Twenty-five patients with 27 Kinemax (Stryker) TKR's were recruited. Patients undertook gait analysis of level walking using 8 Qualysis Pro-Reflex cameras with an instrumented walkway (Bertec, USA) using a modified Helen Hayes marker set. Visual3D (C-motion, Inc.) was used to compute lower limb kinetics and kinematics. Single plane video fluoroscopy of the knee was taken for a step-up and step-down task to determine TKR kinematics. Joint Track image registration software (University of Florida, USA) was used to match CAD models of the implant to the x-ray images. This technique is known to have high accuracy in measuring TKR kinematics [2]. Further processing using JointView software (University of Florida, USA) calculated 3D joint kinematics and the tibio-femoral contact points. Bespoke code developed within MATLAB (The Mathworks Inc, USA) was utilised to calculate the centre of rotation (CoR) using the contact point data. Long-leg radiographs and CT scans were used to define component alignment and rotation. Hip-Knee-Ankle (HKA) angle was measured from the radiographs to determine long leg alignment in the frontal plane. The CT scans were used to calculate each components rotational alignment and inter-component rotation. Angle of tibial slope was calculated using radiographs. HKA was compared with the output variables of the biomechanical analysis using independent sample t-test and Pearsons correlations. The exploratory analysis was carried out using Pearson's correlations comparing the surgical measures against the outputs from the two different biomechanical analysis. Shapiro-Wilks test was performed to check for normality (SPSS Statistics V23).

RESULTS AND DISCUSSION

The mean age 74 (range 60-89), mean Oxford score 35 (13-47) and mean KOOS score 72 (15-98). Mean Hip-Knee-Ankle measurement was 1.1° varus (10° varus to -9.5° valgus) and mean femoral and tibial rotation was 1° internal and 4° external respectively. There was found to be a significant difference of flexion range of motion (ROM) during level gait (P=0.044) between valgus (41.84° (5.08)) and neutral (51.44° (7.95)) groups. There was also a significant difference (P=0.002) between valgus (44.72° (7.78)) and neutral (56.00° (3.61)) for peak knee flexion during swing phase. HKA was found to significantly negatively correlate with several kinetic motion analysis metrics (table 1). However HKA was not correlated with peak vertical ground reaction force and no significant differences between groups or correlations were found with any of the dynamic fluoroscopy analysis outputs.

Table 1: Correlations between frontal plane alignment and fluoroscopy movement and gait analysis metrics

	HKA (r)	Sig
Medial/Lateral position of COR during step down (Fluoroscopy)	0.323	NS
Peak Lateral GRF	-0.535	P=0.04
Peak Adduction Moment	-0.709	P<0.001
Peak Internal Rotation moment	-0.488	P=0.01

During the exploratory analysis tibial rotation was found to significantly correlate with anterior posterior (AP) translation max (r=0.405 P=0.034) and min (r=0.504 P=0.007) in the medial compartment during the step up activity and tibial slope was also highly significantly correlated with superior/inferior translation (SI) ROM on both medial and lateral sides during step up (r=-0.610 P=0.001) and step down of fluoroscopy (r=-0.542 P=0.04).

CONCLUSIONS

The primary focus of the study on the effect of long leg alignment has shown a reduced ROM of flexion during gait for valgus aligned patients and increased frontal plane loading for varus aligned patients. Frontal plane alignment does not appear to influence joint kinematics measured with video fluoroscopy, with no relationship between HKA angle and any of the kinematic data that was analysed. Exploratory analyses have found other relationships that are worthy of further research and may be more important in optimizing function.

INTRODUCTION

Hip and knee osteoarthritis is the 11th highest contributor to disability in Australia and ranks amongst the top ten causes of disability worldwide[1]. The lifetime risk of the disease is now 14%[2]. Knee osteoarthritis (OA) produces pain and loss of joint function, a slow erosion of the ability to perform activities of daily living. Those with OA knee avoid high-flexion tasks such as kneeling--finding it one of the most difficult activities. This research is a cross-sectional, case-controlled inductive study of the kinematics of knee motion while kneeling. It aims to, for the first time; quantify the differences in *vivo* kneeling knee kinematics in 6 degrees-of-freedom between those with and without OA knee

METHODS

.Twenty OA knee and twenty healthy knee participants who were gender, BMI-matched (26.9 ± 3.6 and 27.3 ± 3.6 kg/m^2), and age-matched (69.4 ± 8.7 and 70.1 ± 8.6 years) were recruited for this study. All participants had their single-plane fluoroscopy movie recorded while dynamically kneeling-. All started at 90° and used their body weight to kneel as deeply as possible. A CT static 3D image of their knee was also taken. Their CT data was registered onto the 2D fluoroscopy image using the in-house bespoke 3D/2/D registration algorithm called Orthovis—producing kinematic data in 6 degrees-of-freedom by the Grood and Suntay co - ordinate system[3]. A calibration grid was used to minimise out-of-plane errors. Descriptive statistics were used to compare and contrast the groups.

RESULTS AND DISCUSSION

With increasing flexion, from 90° through to 150°, descriptive healthy and OA knee kinematics respectively were (mean ± SD) 122.1° ± 15.2° and 114.0° ± 13.4° flexion; -9.7° ± 4.8° and -5.9° ± 3.78° external/internal rotation; 2.0° ± 1.9° and 2.4° ± 4.5° abduction/adduction; -3.1° ± 3.9° and -1.1° ± 3.4° mediolateral shift; 15.4° ± 2.8° and 13.6° ± 2.7° anterior/posterior translation, and 35.9 mm ± 2.7 mm and 30.6 mm ± 3.3 mm superior/inferior translation.

Osteoarthritis restricts range-of-motion in all 6 degrees-of-freedom. It appears that healthy knees initially distract and then compress towards deeper flexion whereas OA knees after approximately 128° continue to distract.

CONCLUSIONS

The comparison of these groups has demonstrated dampened motion in all 6 degrees-of-freedom. This is the first time such a large number of participants so strongly matched for age, BMI and gender have been compared and contrasted. Future analysis will include exploring the relationship between the variables and determine the confounding and lurking variables that drive these differences.

THE EFFECT OF THIGH COMPRESSION GARMENT ON ISOKINETIC KNEE EXTENSION AND FLEXION TORQUE DEVELOPMENT

Yuki Kawagoe, Shun Otsuka, Yasuo Kawakami
Faculty of Sport Sciences, Waseda University
Corresponding author email: goetta88@akane.waseda.jp

INTRODUCTION

Recently, compression garment (CG) has attracted attention in the athletic field to enhance performance. Matsumoto et al. (2013) suggested the existence of the optimal interface pressure (20mmHg) for thigh muscle to increase electrically-evoked knee extension torque [1]. This suggests that the optimal interface pressure on the thigh could enhance the maximal voluntary knee joint performance as well. Zhang et al. (2016) reported negligible effect of CG on isokinetic knee extension torque [2]. However, they did not measure actual CG pressure, thus the result might have been due to the interface pressure that was not optimal. This study sought to determine the effects of thigh CG with the pressure of 20mmHg on the torque profile during maximal voluntary isokinetic knee extension and flexion.

METHODS

Nine healthy males (21 ± 3 years, 175.9 ± 5.8cm, 70.7 ± 8.0 kg; mean ± SD) participated in this study. Each subject wore CG on the right thigh that was manufactured individually based on his dimensional data to match the interface pressure of 20mmHg over the thigh. The participants were seated on the custom-made seat of a dynamometer to avoid pressure on muscle bellies of hamstrings. They performed unilateral (right side) isokinetic knee extension and flexion [range of motion: 90°- 0° (full extension)] at 100°/s with CG (CGC) and without (CON). Peak torque, knee joint angle at which peak torque was observed (Angle-PT), and the maximal rate of torque development (RTD) were measured. Two attempts were made routinely in each condition and the best value of the two was used for analysis. Additional trials were performed if peak torques were substantially different (more than 5% between first two trials). The order of conditions was randomized. Interface pressure was measured from 12 positions (30%, 50%, and 70% of thigh length × anterior, lateral, medial, and posterior sites) on the thigh in a standing posture.

Paired *t* tests on peak torque, Angle-PT and RTD were performed to compare CGC with CON. In order to assess the deviation of the interface pressure values obtained at each measurement position from 20mmHg, one-sample *t* tests were performed. Significance level for all comparisons was set at $p < 0.05$.

RESULTS AND DISCUSSION

There was no significant difference between CGC and CON in peak torque or Angle-PT. On the other hand, RTD was higher in CGC (489.5 ± 83.6 Nm/s) than in CON (441.9 ± 46.1 Nm/s) for extension but not for flexion (Figure 1). The pressure of 20mmHg was attained at 30% of anterior and medial sites, 50% of all sites and 70% of medial site of the thigh.

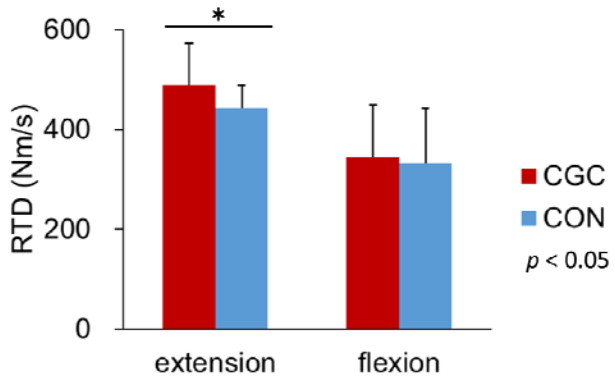

Figure 1: Rate of torque development in each condition

Previous studies suggested reduction of muscle oscillation to be one of the reasons for CG to enhance exercise performance [3,4]. Matsumoto et al. (2013) presumed that the quadriceps femoris force was more effectively transmitted to the patellar tendon through the reduction of muscle oscillation, leading to greater knee extension evoked torque [1]. In the present study, the bellies of major quadriceps (vastus lateralis and rectus femoris) [5] were under compression of the optimal pressure that was proposed by Matsumoto et al. [1], thereby leading to "brisk" torque production eliminating unnecessary muscle oscillation. The CG did not affect knee flexion torque profiles although the pressure was kept at 20mmHg at the muscle bellies of hamstrings. But the proximal and distal sites of hamstrings may have already been under pressure in the sitting posture during the measurement, leading to a negligible effect of CG on these muscles.

CONCLUSIONS

The compression garment with the pressure of 20mmHg did not affect the peak torque or Angle-PT during maximal voluntary isokinetic knee extension and flection, but increased the rate of torque development of knee extension.

GAIT STABILITY IS AFFECTED BY ANTIPARKINSONIAN MEDICATION IN PARKINSON'S DISEASE SUBTYPES

INTRODUCTION

People with Parkinson's disease (PD) have been categorized into two subtypes: Tremor Dominant, with a predominance of resting and postural tremor, and Postural Instability and Gait Difficulty (PIGD), with a predominance of postural instability, gait impairment and falls [1]. People with PD have more irregular head movements in anteroposterior (AP) and mediolateral (ML) planes when walking, as recorded from accelerometers, suggestive of decreased gait stability [2, 3]. However, whether it is also more apparent in the PIGD subtype is unknown. Moreover, the effects of antiparkinsonian medication on gait stability in PD subtypes require clarification, since the PIGD patients have a lower absorption of, and response to, dopamine. This may be manifested as decreased gait stability, which could explain why PIGD patients are more susceptible to falling. Thus, the aim of this study was to compare PIGD and non-PIGD groups across measures of gait stability and in their response to levodopa treatment.

METHODS

Thirty eight people with PD split in two groups: PIGD group (n=23) and Non-PIGD group (n=15) participated in this study. Gait analysis was performed using linear accelerometers attached to the participants' head and pelvis. Participants performed 2 walking trials ("off" and "on" status of antiparkinsonian medication) at a self-selected speed along a 20m corridor. The middle 15 meters of steady state walking were analyzed. From the accelerometry data, measures of pelvic and head gait stability were derived using harmonic ratios (HR) of accelerations in the three orthogonal planes [3, 4]. HRs along the AP and vertical (VT) axes were calculated over multiple two-step windows [2] and HR along the ML axis was calculated over multiple eight-step windows [5]. Two-way analysis of variance was used to identify subtype (PIGD vs non-PIGD group) and medication ("off" vs "on" levodopa) main effects and interactions. Where significant interactions were found, main effects were not calculated but post hoc tests were conducted. Significance levels were set at 0.05.

RESULTS AND DISCUSSION

There was a main effect of subtype for head AP HR, demonstrating that the PIGD group had worse head stability in the AP plane than the non-PIGD group ($p<0.001$) irrespective of phase of levodopa therapy. There were also main effects of medication for head AP ($p=0.008$) and VT ($p=0.002$) HRs. For both subtypes, levodopa intake improved AP HR but reduced VT HR at the head. Significant interactions were evident for pelvic ML ($p=0.003$), head ML HR ($p=0.048$) (Fig 1) and head VT HR ($p=0.01$). In each case, HRs improved in non-PIGD group and deteriorated in the PIGD group following levodopa intake.

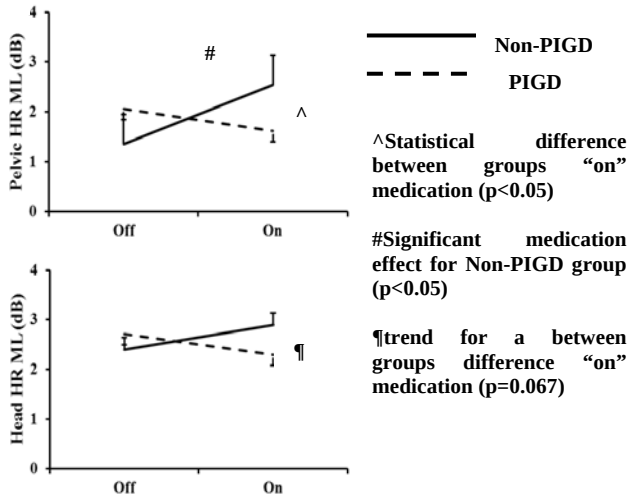

Figure 1: Post hoc on mean gait stability measures. Error bars represent standard deviations.

CONCLUSIONS

The PIGD subgroup was more likely to have reduced gait stability following levodopa, possibly because: (i) levodopa may not be effective at improving gait stability for all people with PD; (ii) levodopa could be detrimental to the sensory organization of postural control; (iii) in the PIGD group, the net effect of levodopa might be to reduce postural control. When people with postural instability walk, they may increase ML centre-of-pressure displacement, and reduce ML stability, to help maintain forward motion; (iv) the PIGD subtype may be more likely to have widespread cerebral white matter disease, interrupting cortical-subcortical tracts involved in the control of balance and gait, and lesions in the putamen, which may result in impaired control of gait; (v) PIGD patients might have more non-dopaminergic lesions compared to non-PIGD patients.

DETECTING FREEZING OF GAIT IN PEOPLE WITH PARKINSON'S DISEASE WITH WEARABLE DEVICES

INTRODUCTION

Parkinson's Disease (PD) is a degenerative neurological condition that affects over 10 million people worldwide. Symptoms include tremor, stiffness, muscle rigidity, slowness of movement. Freezing of Gait (FOG) affects 50-80% of patients with PD and leads to reduced quality of life and increased risk of falling. FOG may be reduced through various strategies including auditory and visual cues. However, before strategies to prevent FOG can be optimised for the individual more accurate identification of FOG episodes during daily life is required.

Currently no gold standard exists to measure FOG using wearable devices. FOG during daily life can be measured using a self-report questionnaire [1] (which may risk bias) or by a skilled assessor (requiring greater resources). Several small to medium sized laboratory studies using wearable devices have been undertaken in the past.

Here we present the first large study using gait data from 130 people with Parkinson's disease to develop algorithms to detect FOG using wearable devices. A range of walking, turning, postural transfer, single and dual task conditions were assessed.

METHODS

Participants were from a randomised control trial conducted in North Bristol NHS Trust Hospital, UK [2]. Data from 130 people with PD aged between 46 and 90 years, with a disease duration ranging from 5 and 13 years were used.

Participants wore a device containing 3D accelerometers and gyroscopes (Dynaport Hybrid, McRoberts, Netherlands). The device was attached to a waist belt and located between the posterior superior iliac spines. FOG was invoked by a FOG protocol. This comprised several classes of activity including a sit-to-stand, a 6m walk between two chairs placed 50cm apart, a 360° turn to the right, a 540° turn to the left, the return walk back, a 180° turn and a stand-to-sit into the starting chair.

All walks were videotaped, synchronized with the wearable device data and annotated by a skilled assessor for FOG, cognitive stops, walking, turns, postural transfers, standing and sitting.

Gait data were processed in MATLAB. The Daubechies 5 wavelet was used to detect features associated with FOG in the accelerometer signals (Fig 1A). The Morlet wavelet was used to detect FOG in the gyroscope data. An ensemble of decision trees was constructed to detect FOG and four-fold cross validation used to assess the algorithms accuracy.

RESULTS AND DISCUSSION

The FOG protocol invoked 212 episodes of freezing: 67% episodes occurred during turning, 12% were destination hesitation, 9% were during gait initiation, 9% in open spaces and 3% between the chairs. Two participants were unable to complete to FOG protocol within 10 minutes and excluded.

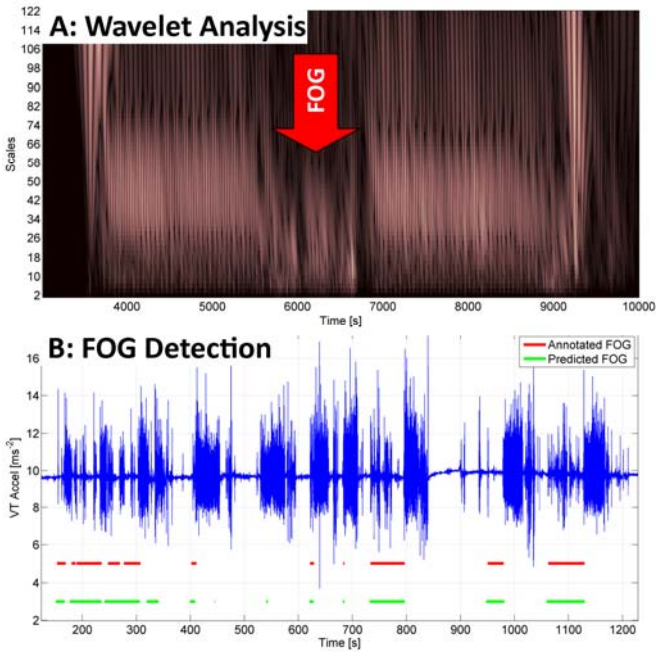

Figure 1: Panel A; wavelet detection of FOG during a turn while walking (red arrow). Panel B; Detected FOG (green) versus annotated FOG (red) while walking. For this participant, 20 FOG steps were missed and 122 shuffling steps were misclassified as FOG.

The ensemble used wavelet features (Fig 1A) to detect eight classes of activity with 90% overall accuracy after 4-fold validation. Sensitivity to FOG steps was 82% and specificity 75%. Slow shuffling steps by some people were misclassified as FOG and reduced the specificity (Fig 1B).

CONCLUSIONS

FOG episodes can be detected with a wearable device which may help optimize strategies to prevent FOG in daily life. We are working on improving the algorithm's specificity.

POSTURAL STABILTY DURING A DUAL TASK IN PARKINSON'S DISEASE: THE INFLUENCE OF CORTICAL CONTROL

[1] **Roger Pegoraro**, [1]Ian Stewart and [1]Graham Kerr
Queensland University of Technology
Corresponding author email: roger.pegoraro@hdr.qut.edu.au

INTRODUCTION

Parkinson's disease (PD) is a progressive neurodegenerative disorder initiated by loss of dopaminergic neurons in the basal ganglia. Those with PD are reported to have increased postural instability, particularly during dual task performance [1]. PD patients often have cardiac dysautonomia which can cause alteration of middle cerebral artery (MCA) blood flow velocity (BFV) and hypoperfusion of the cerebral cortex. Hypoperfusion has been associated with executive dysfunction, postural instability and movement difficulties [2]. Additionally, those with PD have an increased incidence of orthostatic hypotension which also influences postural stability [3]. This study investigated postural stability, bilateral MCA BFV, oxygenated (O_2Hb) and deoxygenated (HHb) haemoglobin concentrations in the pre-frontal cortex (PFC) of people with PD during a standing serial subtraction task (SST).

METHODS

Early stage PD (Hoehn & Yahr Staging I – III) and control participants with and without orthostatic hypotension (PD No OH: N = 6, 65.2±3.4 y; PD OH: N = 14, 66.5±2.4 y; CON No OH: N = 9, 54.2±2.7 y; CON OH: N = 13, 65.1±2.7 y) serially subtracted 7 from a randomly assigned 3-digit number while standing on a force platform. Path length and 90% confidence ellipse (C90) area were calculated for the subtraction task duration and subsequent rest period. The number of subtractions performed and the percentage of subtractions correct were recorded. Transcranial Doppler ultrasound was used to measure bilateral MCA BFV. O_2Hb and HHb were recorded bilaterally over Fp1, Fp2, F7 and F8, according to the 10-20 Electroencephalography system (10-20 IEEG), throughout the task using near-infrared spectroscopy (NIRS). The relative change for MCA BFV measurements, O_2Hb and HHb during the SST was calculated.

RESULTS AND DISCUSSION

Postural stability indices show a significant difference between rest and SST condition for CON groups only (**Figure 1**). Further, PD No OH had a significantly larger C90 area during rest compared to other groups. The PD groups have similar path length and C90 area regardless of task condition. SST performance was similar between groups for number of subtractions and percent correct responses. PD No OH had a significantly smaller increase in left MCA BFV compared to all other groups. There were no differences between groups for right MCA BFV. PD OH had significantly smaller increases in O_2Hb compared to CON OH at Fp1, Fp2, F7 and F8 and also compared to CON No OH at Fp2 and F8. PD No OH had a significantly smaller increase in O_2Hb compared to CON No OH at Fp2. PD OH had a significantly smaller decrease in HHb compared to CON No OH at Fp1 only. Postural instability within the PD and CON groups does not appear to be influenced by clinically defined orthostatic hypotension. However, the PD cohorts are equally unstable at rest and during performance of a cognitive task. The CON groups have an increase in postural instability when subjected to a cognitive dual task.

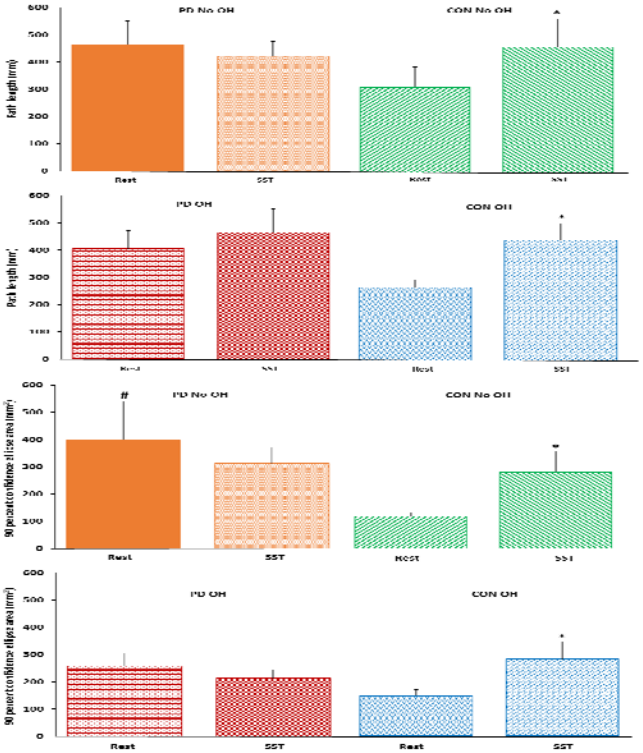

Figure 1: Path length and C90 area for Parkinson's and Controls during serial subtraction task and rest.

CONCLUSIONS

Postural instability is a well-known consequence of PD. The present results indicate some differences in cortical blood flow and in cortical oxygenation for people with PD during dual tasks. However, the influence of cortical and cerebral mechanisms which contribute to balance control in PD are not fully understood. The contribution of cerebral blood flow and cortical oxygenation to postural stability during dual task performance in this population needs further investigation.

EFFECT OF DISTAL MUSCLE WEAKENING DURING DIABETIC GAIT: A PREDICTIVE SIMULATION STUDY

INTRODUCTION

Diabetic neuropathy leads to a massive and progressive reduction in the lower limb muscles strength, mainly in the ankle extensors and flexors [1]. Predictive simulations can provide valuable insights into adaptation strategies in diabetic gait by enabling the investigation of the effects of individual biomechanical parameters in a perfectly controlled, non-invasive fashion. This study investigates the effects of distal muscles (tibialis anterior and triceps surae) weakness on the compensatory adaptations observed in diabetic gait using an optimal control framework.

METHODS

The musculoskeletal system model contains seven rigid bodies (HAT- head, arms, trunk; both thighs, legs, and feet) in the sagittal plane with 9 degrees of freedom and includes eight muscles bilaterally: iliopsoas, glutei, hamstrings, rectus femoris, vasti, gastrocnemius, soleus and tibialis anterior. The lower limb joints (hip, knee and ankle) are modeled as ideal hinge joints and the muscles as Hill-type [2], including the contractile element (muscle fibers) and an inextensible tendon. The combined effect of all passive tissue is represented by passive joint moment expressions from [3]. The resulting dynamic model has 34 states (9 generalized coordinates, 9 generalized velocities and 16 muscle activations) and 16 controls (16 neural excitations). The cost function of the optimal control problem includes an effort (sum of activations squared) and a tracking term. The tracking term is included in the cost function to avoid an excessive divergence of the solution compared to normative patterns reported in [4] (shaded area in Figure 1 with ± 1 SD). A gait velocity of 1.1 m/s was prescribed. We simulate 4 conditions to represent the weakening of the distal muscles of diabetic individuals: 1) reference (no changes in reference parameters); 2) maximal isometric force of the triceps surae (gastrocnemius and soleus) (TS) was reduced in 15% and of the tibialis anterior (TA) in 10%; 3) 30% reduction in TS and 20% reduction in TA; 4) 40% reduction in TS and 30% reduction in TA. The reference simulation was used as initial guess for the other simulation conditions. The optimal control problem was solved using the PROPT package and SNOPT was used for solving the large-scale optimization problem.

RESULTS AND DISCUSSION

The reduction in the maximal isometric forces of the TS and TA has a major impact on the push-off phase (Figure 1). The weakening of these important distal muscles leads to a delayed action of the TS and a progressive decrease of the gastrocnemius peak force in the push-off phase. This distal deficit appears to be compensated by a larger hip flexion moment resulting from an increase in the iliopsoas muscle group force in this phase, a measure reported in the literature as the hip strategy [5] Another noticeable adaptation strategy of the model is the increase in ankle flexion as distal muscles get weaker. The larger ankle excursion increases passive ankle extension moment at push-off, compensating for part of the decrease in active moment.

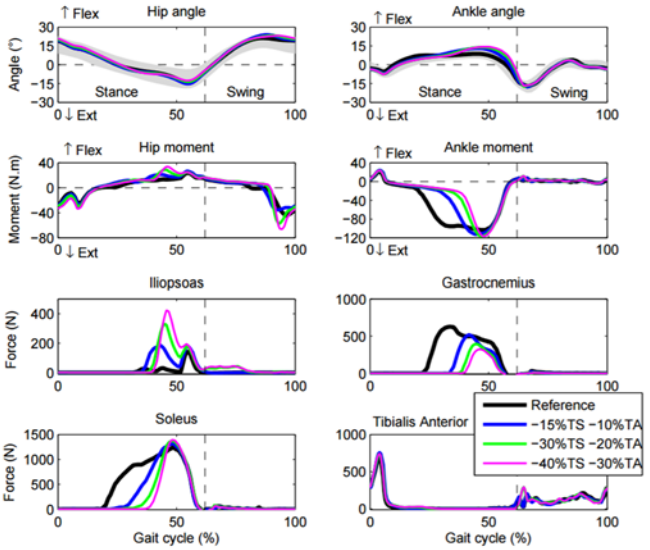

Figure 1: Joint angles, net joint moments and muscle forces predicted for different TS and TA weakening degrees.

CONCLUSIONS

The decrease in the isometric force of the distal muscles due to diabetes leads to clear gait adaptations. Among the most important are a delay in the TS action, a decrease in gastrocnemius peak force, an increase in iliopsoas peak force and a larger ankle flexion, all during the push-off phase. The increase of hip flexion moment along with the reduction of ankle extension moment may be interpreted as the hip strategy described in the literature. The increase in ankle flexion, in turn, is linked to an increase in passive moment to compensate for the lower active extension moment at push-off. This result suggests that passive properties of the ankle may play a major role in diabetic locomotion and should be further investigated.

MECHANICAL MODELS FOR INSECT WING MARGIN SHAPES

[1] **Yukitaka Ishimoto** and [2]Kaoru Sugimura

[2]Kyoto University
Corresponding author email: ishimoto@akita-pu.ac.jp

INTRODUCTION

Insect wings are diversified with respects to their sizes, margin shapes, venation patterns, pigmentation. While gene networks governing the *Drosophila* wing development have been well characterized, the diversity of insect wing margin shapes remains a mystery. Among such margin shapes, smoothly curved margin is the most frequently found, implying a highly organized multicellular mechanical structure. In this work, we developed mechanical models of the wing margin shape where nonuniform bending stiffness of the margin plays an important role. We showed a variety of the bending stiffness may produce diversified wing margin shapes and inferred bending stiffness from experimental images may provide some insight on the differentiated margin cells of the insect wings. We further studied the influence of the cellular properties of the blade to the margin shapes. The models would serve as a basic ingredient of an integrated model for wing development.

METHODS

A naïve and one of the simplest mechanical models of smooth margin shapes is the Euler's elastica – a mechanical model of a thin rod and its resulting curves. However, this uses the constant bending stiffness along the margin and it seems to be unnatural to expect such. Therefore, we develop a model with the generalized bending stiffness – the non-uniform bending stiffness (model A). The corresponding deterministic equation with the stiffness leads to a mathematically distinct highly non-linear form, so that one cannot expect to obtain an exact, analytic solutions. Instead, we invoke a numerical calculation to find a margin shape for a given distribution of the bending stiffness. We use the pinned boundary condition, which is consistent with the system considered, such as fruit fly.

The insect wing consists of blade, margin, and hinge. In fruit fly development, while the hinge keeps contracting, the cells in the blade are pulled and dragged. While the margin is pinched at the end points, the blade is stretched towards the hinge. Therefore, we develop the above model with the tensile forces from the blade (model B). This may create a buckled margin shape under a certain condition. Both models provide a reverse engineering of the bending stiffness: geometric profiles of experimental images enable us to infer the stiffness along the margin.

RESULTS AND DISCUSSION

We successfully simulated the margin shapes (Figure 1). The first example shows a veinless mutant of *D. melanogaster* [1] and our simulation result. The following three sets of examples in Figure 1 (b1-d1, b2-d2) show the drawings of Zygaenidae, Tortricidae, and Crambidae in [2] and our simulation results. The last example shows an elongated shape of wings in Eustheniidae [3], which can be also found in dragonfly.

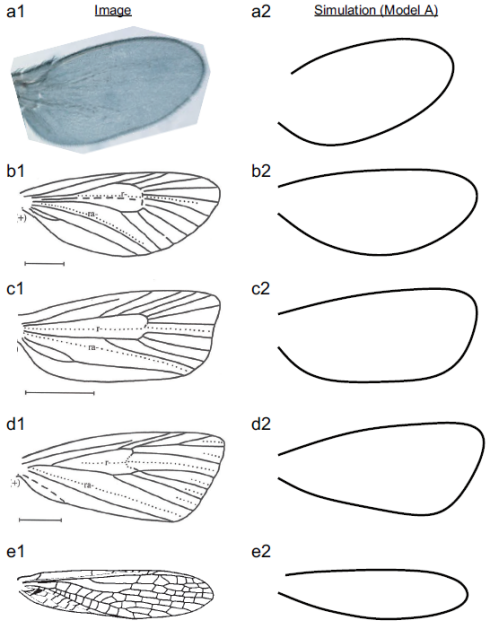

Figure 1: A photograph (a1), drawings (b1-e1) of various insect wing, and simulated wing margin shapes (a2-e2).

In our simulation, the shapes were sufficiently robust against small perturbations in the stiffness in most part of the margin, while some seemed sensitive, giving a potential source of the morphological diversity. Buckling solutions of model B (Figure 2) may give another source of the diversity.

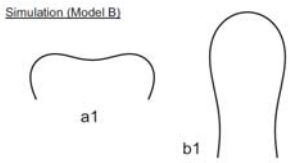

Figure 2: Typical buckling solutions of model B. A case with tensile force (a1), and with pressure (b1).

CONCLUSIONS

We have constructed mechanical models for the insect wing margin shapes with nonuniform bending stiffness. Our simulations showed the nonuniform stiffness was sufficient to reproduce diverse wing margin shapes found in nature.

TOWARDS A REALISTIC BIOMECHANICAL SIMULATION OF HAND FORCE CAPABILITY IN FOSSIL HOMININS AND NEW INSIGHTS ON THE ROLE OF THE 5TH DIGIT

[1]**Mathieu Domalain**, [2]Guillaume Daver

INTRODUCTION

The recent discoveries of the Lomekwian stone tools (3.3 Ma) support the hypothesis that early hominins were able to make and use stone tools around 500.000 years before the first occurrences of the genus *Homo* [1]. Furthermore, the lithic reduction techniques inferred from Lomekwian tool replication experiments suggest that forceful grips, rather than enhanced hand dexterity, was a major prerequisite for making such tools. Then, assessing gripping abilities of contemporaneous hominin, i.e. *Australopithecus afarensis*, is necessary. To date, the *A. afarensis* hand has been described as being both human-like due to axial asymmetry of the metacarpal bones and the derived morphology of the distal pollical phalanx, and ape-like with regards to its radial intercarpal and carpometacarpal joints. More specifically, the 5th digit (whose morphology is rather unique for *A. afarensis)* has been deemed crucial to ensure forceful grips [2].

This study had two aims: 1) to develop, present and evaluate a simulation framework that includes a musculoskeletal model of *A. afarensis* hand, and 2) to propose new insights on the putative role the 5th digit may have played in the development of Lomekwian tools production capabilities.

METHODS

Three musculoskeletal hand models were developed for each of the following taxa: *H. sapiens*, *P. troglodytes* and *A. afarensis*.

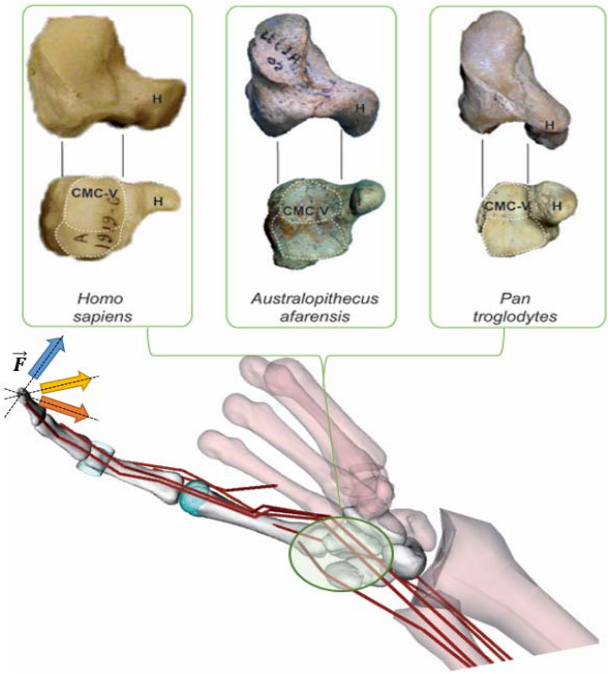

Figure 1: Flow chart illustrating the integration of the bone geometry of the 3 taxa into the musculoskeletal model of the 5th digit and the 3 directions of the simulated external force.

All models were adapted from the same original model [3]. Bone geometry was derived from published dimensions [4] together with authors 'personal 3D scans of the original fossils for *A. afarensis*. Given the absence of existing model, two versions of the 5th Carpometacarpal joint (CMC-V) were tested. *A. afarensis* musculoskeletal geometry was adapted from the *H. sapiens* model based on qualitative observations on *P. troglodytes*. Three databases of Physiological Cross sectional Area (PCSA) were also tested. The sensitivity of simulation outcomes to those constitutive factors of the modelling was assed.

Simulated input data were 1) CMC-V joint posture and the resulting 5th digit orientation and 2) External force direction. Those two factors mimicked the diversity of hand configuration while holding a stone. Outcome data were muscle forces computed through static optimization.

RESULTS AND DISCUSSION

The %RMSD between muscle forces estimated from simulations based on the anatomical model of *H. sapiens* and simulations based on an anatomical model of *P. troglodytes* is 13% (average across force direction; CMC-V posture and PCSA database conditions). Overall, simulations run by using an anatomical model based on *P. troglodytes* demonstrated a higher capacity of external force, but muscle force patterns were rather similar. Outcome data were sensitive to both the kinematic model of CMC-V and the direction of the external force (Table 1).

Table 1: Magnitudes of the maximal external forces possible to exert as a function of CMC-V kinematic model and direction of the external force (see Fig 1).

DoF	**Palmar** (N)	**Palmar-radial (N)**	**Radial (N)**
0-DoF	9	17.8	8.6
2-DoF	9.3	18.1	9.8
3-DoF	4.2	16.2	7.2

CONCLUSIONS

Our first results suggest a limited influence of muscle parameters (e.g., PCSA) and support the value of simulations for studying extinct taxa even in absence of soft-tissue data. Given the difficulty for the pulp of the 5th ray to face the surface of a large-sized object, the *A. afarensis* hand would have had limited possibility to exert sufficient force to make Lomekwian tools.

INVERSE ANALYSIS OF LINGUAL MUSCLE STRESS FROM A 3D DEFORMED SHAPE OF TONGUE

[1]Shigeo Wada, [1]Narihiko Koike, [1]Tsukasa Yoshinaga, [2]Nozaki Kazunori, and [1]Ii Satoshi

INTRODUCTION

Tongue is one of the important articulatory organs, which produces speech sounds by changing its shape quickly in the oral cavity with contraction of the lingual muscles. Recently, in order to understand the detailed mechanisms of the tongue deformation during speech, computational mechanics studies have been conducted using a continuum model of tongue including muscle fiber elements [1,2]. In those studies, two-dimensional shapes in the median sagittal plane of the tongue obtained by MRI measurements were used for estimation of the lingual muscles activation when vowel sounds were pronounced. However, the deformation of tongue creates a complex 3D shape necessary for the correct pronunciation in speech including consonant and sibilant sounds. Thus, in this study, we develop a computational model of tongue including nine major lingual muscles and investigate whether the constriction stress of each muscle can be identified from the 3D shape of deformed tongue by means of inverse analysis.

METHODS

A configuration of the tongue at a rest position was obtained from the CT image of a subject. The tongue model was divided into tetrahedral elements including the muscle fibers that produce a contraction stress in the direction of their orientation. The tongue muscles were classified into five types of extrinsic muscles (Fig. 1 (a)-(e)) and four types of intrinsic muscles (Fig. 1 (f)-(i)). The orientation of each muscle fiber was determined from the anatomical data [3].

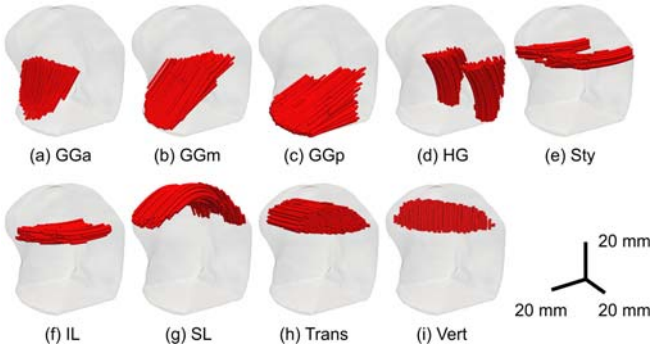

Figure 1: Configuration of the tongue and muscle fiber orientation. (a)-(c) Anterior, middle and posterior part of genioglossus, (d) hyoglossus, (e) styloglossus, (f) inferior longitudinalis, (g) superior longitudinalis, (h) transversalis, and (i) verticalis. The red lines indicate the position and direction of each muscle fiber.

The deformation of the tongue was represented by the Cauchy's first law of motion. The tissue was assumed to be a hyperelastic body expressed as a 2nd-order Mooney-Rivlin model. The Cauchy's stress was calculated by the sum of the isotropic elastic stress of tissue (σ_{elas}) and the anisotropic contraction stress of muscle fibers (σ_{fiber}). The contraction stress was calculated as $\sigma_{fiber} = F(e \otimes e)$, where F is muscle fiber stress and e is a unit vector of the fiber orientation. The muscle fiber stress F was assumed to be constant in each muscle. The material constants obtained by experiments [1] were used in the calculation.

Here we consider an inverse analysis to identify the muscle fiber stress F of each muscle from a deformed target shape and an undeformed reference shape of the tongue. The difference in those shapes can be evaluated by the surface distance φ from the reference shape. Then the problem is formulated as

$$\text{Minimizing } J = (\varphi_t - \varphi_d)^2 / 2 \quad \text{with respect to } F \qquad (1)$$

where φ_t and φ_d are the surface distance of the target shape and the deformed shape obtained by inverse analysis, respectively. The problem was discretized by the Galerkin finite element method, and muscle fiber stress was identified by the least square method.

To validate the proposed method of inverse analysis, a reference shape of the deformed tongue was provided by solving a direct analysis of the tongue deformation under given muscle fiber stresses. The displacement at the bottom of tongue was fixed to zero. The contraction stress of each muscle fiber was assumed as shown in Table 1(a). The values were determined so as to cause a forward protrusion of the tongue [4]. Then, the deformed shape was used as the target shape in the inverse analysis to identify the contraction muscle stresses. We verified the method by comparing the muscle fiber stresses given in the direct analysis and those identified by the inverse analysis.

RESULTS AND DISCUSSION

The tongue shape obtained by the inverse analysis well agreed with the target shape. Table 1 (b) shows the values of muscle fiber stress identified by the inverse analysis. It was found that the muscle fiber stresses were identified within an error range of about ±250Pa, which was more than 10% of the maximum stress applied at the GGp. The error was caused by the shape matching in the inverse analysis in which the corresponding points were unknown between two shapes. However, the stress distribution in the 9 muscles was successfully reproduced, taking relatively high values at GGp, Trans, and GGm and low values at IL, Sty, and HG. These results indicate that the contraction stresses of multiple muscles inside the tongue can be identified from the three-dimensional shape of tongue which can be obtained by the CT or MRI measurements.

Table 1: The values of muscle fiber stress F [Pa] (a) given to direct analysis and (b) estimated by inverse analysis.

	GGa	GGm	GGp	HG	Sty	IL	SL	Trans	Vert
(a)	60	1100	2000	15	0	0	500	1000	600
(b)	216	861	2026	-129	-102	2	728	1031	382

INTRODUCTION

Rheumatoid arthritis (RA) patients often have pain in the lower extremity, which in some cases can be caused by foot deformity and foot pain. With the intention to stabilize and align the foot patient-specific foot orthotics (FO) are often prescribed to this patient group. A limitation of the previous literature on FO to treat RA and related diseases is that it has focused exclusively on clinical outcomes of FO such as pain and physical function, while overlooking the biomechanical principles on which the rationales for FO is based [1].

The aim of this study was to investigate the effect of patient-specific FO on ankle, knee and hip loading during gait. This was accomplished by developing patient-specific (PS) musculoskeletal models (MS) capable of estimating joint mechanics with and without the FO.

METHODS

Four early stage RA patients were recruited for this study. A pair of FO was developed for each patient using a weight bearing casting technique. PS bone geometry was obtained from magnetic resonance imaging (MRI) images and segmented in an image analysis package (Mimics 19, Materialse, Belgium). Motion capture was performed with an eight-camera setup (Qualysis, Sweden) with reflective markers together with three force plates (AMTI, USA) sampling at 100 and 1000 Hz respectively. The gait trial consisted of two conditions: one with the PS FO and one with a control insole (C).

PS MS models of each patient were developed using the AnyBody Modeling System (AnyBody Technology, Denmark), Figure 1B. Muscle attachments were made PS based on the Twente Lower Extremity Model version 2.0 dataset using advanced morphing to customize a generic cadaver-based model with respect to PS morphology acquired from MRI [2].

Accurate joint centres and axes were calculated with analytical surface fits to the segmented MRI bones. Joint reference systems were defined based on the ISB recommendations.

RESULTS AND DISCUSSION

Resultant joint forces for the ankle, knee and hip joints are presented in (Figure 1) for the C and FO. The results showed that the ankle force is reduced with FO. Meanwhile, the resultant knee and hip joint forces increased with FO. Additional data from the model showed that, despite an increase in the total resultant forces in the knee and hip, change in the different joint moments and muscle forces still occur. These changes may potentially contribute to the reduction in pain. Further studies are needed to confirm this.

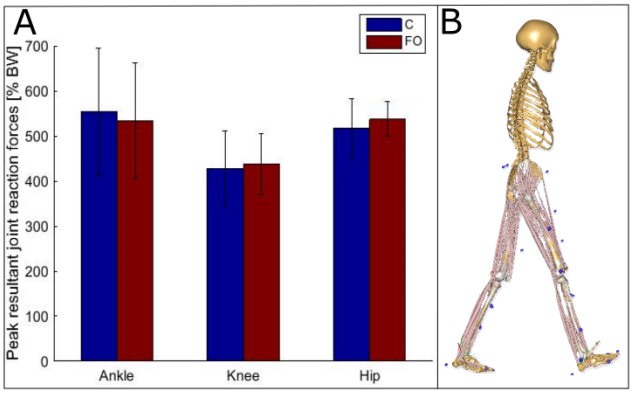

Figure 1: A: Mean peak resultant joint forces for the Ankle-, knee- and hip joint during the stance phase of gait with ± one standard deviation. B: Patient-specific AnyBody model

CONCLUSIONS

The results of this study indicate that FO can change the load distribution in the lower extremity. MS modeling is appealing for studying biomechanics due to the challenging nature of directly measuring the internal loading of the complex structure of the human body that occurs during motion. Further studies are needed to investigate if there is a relationship between changed loading in MS models and pain for RA patients.

ADJUSTABLE MEDIAL LONGITUDINAL ARCH HEIGHT FOOT ORTHOSES AND BIOMECHANICAL SIGNIFICANCE

[1] **Haihua Ou**, [1]Zeeshan Qaiser, [1]Liping Kang and [1,2]Shane Johnson*

INTRODUCTION

Lower Extremity Injuries (LEI) in the foot and ankle region are the most common injuries experienced by physically active groups (including sports and military personnel). Classical treatment for LEI involves the fabrication of custom moulded or fitted foot orthoses. The arch height is a critical parameter for an orthosis at mid-stance. Typically, the standard procedure for fabricating a custom made foot orthoses starts with using moulds or surface data captured in a neutral position of the foot based on Root's Subtalar Neutral (SN) theory [2, 3]. More recent research [1], however, reported a significant difference in forefoot and rearfoot geometric measurements between different casting techniques (plaster cast, foam cast and laser scan), and arch height varied up to 2cm among fabrication techniques.

A low arch height would lead to an orthosis with no functional orthotic benefits, and a high arch height would injure the subject instead of providing injury prevention or rehabilitation benefits. In all, an objective means of obtaining or forming orthotic shape has yet to be developed.

The hypothesis of this research is that there exists a small range of optimum arch height and the optimal orthotic medial longitudinal arch shape is not necessarily the custom moulded shape. Instead, in the process of forming the orthotic profile, foot/orthosis interactions including soft tissue deformations and foot bone kinematics needs to be considered and plantar pressure distribution serves as an indicator.

In this study, we propose an objective technique and orthotic system to form/design an optimal orthotic shape.

METHODS

In this research an adjustable arch height orthoses is developed. A fiberglass/epoxy orthosis is fabricated through the vacuum bagging method. A longitudinal cutout is made just lateral to the first ray of the foot. The adjustment of flexible orthosis height is achieved by adjusting the length of the arch span through a lead screw mechanism under the hallux.

An experimental parametric study is performed on a range of individuals by varying the arch height. Displacement of the navicular is measured during balance standing with the orthotic changes. Plantar pressure redistribution is measured during walking by Novel plantar pressure measurement system.

RESULTS AND DISCUSSION

Mean pressure in forefoot, midfoot and rearfoot is evaluated and the mean mean pressure (MMP) over the walking cycles is shown in Figure 1. Significant pressure redistribution is observed from forefoot to midfoot as the arch height is increased.

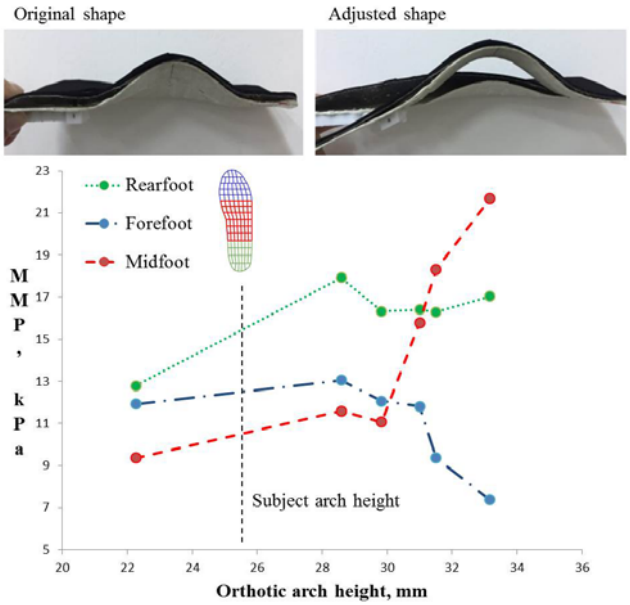

Figure 1: Mean mean pressure over all frames in forefoot, midfoot and rearfoot with varying screw lengths.

The navicular displaces vertically downward when the orthotic arch height is low compared with the subject's arch height. Alternatively, when the orthotic arch height is high, the navicular displaces vertically upward, causing discomfort.

CONCLUSIONS

The findings and results of this study guide foot specialists to design orthoses with effective arch heights for skeletal foot control and therefore better treatment of the LEI. The adjustable arch height system can assist practitioners to select appropriate arch height through testing plantar pressure and navicular drop in addition to subjective ratings.

INTRODUCTION

The human foot is a complicated mechanism, with 26 bones, numerous tendons, ligaments and muscles, functions of which are not yet totally understood [1]. The foot plays a crucial role as the initial contact point with the environment during human locomotion, including impact absorption while landing and rigid energy transfer during pushing-off [1, 2].

However, foot morphology and biomechanics can be altered due to ill-fitted footwear and shoes with different material properties. Further, numerous studies have illustrated that altered foot morphology presented different locomotion characteristics from normal gait. A particular one is the motion of human toes, as toes were reported to have prehensile and ambulatory functions. These toe functions were believed to increase running economy and reduce forefoot loading and hence forefoot injuries.

Previous research into footwear with unstable perturbations showed different kinematics, plantar pressure and muscle activity characteristics [3]. In this study, we evaluate hallux rocker shoes to investigate the immediate response of running biomechanics.

METHODS

Twenty-five male habitual shoe runners were recruited to join the test (mean age: 23.6±2.1 years, mean height: 173±4.6cm, mean weight: 68±5.8kg, mean foot length: 255±4.8mm). They had no history of wearing any unstable or rocker shoes. No illness, deformation or motor disorders in the prior half year were exhibited before the experiment. This study was approved by the Ethics Committee of the Research Academy of Grand Health in Ningbo University. Participants were informed of the purpose, requirements and process of this experiment and provided written consent. Normal flat shoes were chosen as control shoes, and experimental shoes (Hard-H & Soft-S) were formed with an unstable hemisphere (4cm diameter and 1cm height) to the hallux region based on material properties (hardness scale) (Hard-67.92 & Soft-8.44). All shoes were EU size 41.

Tests were conducted with an eight-camera Vicon 3D motion capture system to collect and analyze kinematics, with frequency of 200Hz. Plantar pressure measurements were taken using a Novel Pedar insole system, with frequency of 50Hz. Lower extremity joint kinematics, range of motion during stance, peak pressure and force time integral were measured to analyze the biomechanical response.

The repeated measures ANOVA with post hoc Bonferroni test from SPSS 17.0 were taken to analyze the significance among control shoes, experimental shoes-H and shoes-S, with significance level at 0.05.

RESULTS AND DISCUSSION

In the stance phase, shoes-H presented greater ankle ROM in the coronal and transverse planes than control shoes ($p<0.05$) and shoes-S ($p<0.05$). The peak pressure and force-time integral in the lateral forefoot (LFF) and other toes (OT) regions were greater than control shoes ($p=0.016$ & 0.018) and shoes-S ($p=0.015$ & 0.005). Shoes-S presented significantly reduced peak pressure and force time integral in the medial forefoot (MFF) and central forefoot (CFF) ($p=0.008$, 0.015 & 0.038, 0.027), and increased in the big toe (BT) region ($p=0.000$, 0.003 & 0.000, 0.000) compared with control shoes and shoes-H. Figure 1 summaries this.

These results suggest that the softer rocker stimuli (shoes-S) exhibited reduced ankle ROM, and reduced peak pressure and force time integral for all regions of the foot except the big toe. Conversely, shoes-H with intensive stimuli presented abnormal kinematics, plantar pressure distribution and force time-integral, which might increase the injury risk to the lower extremity and foot.

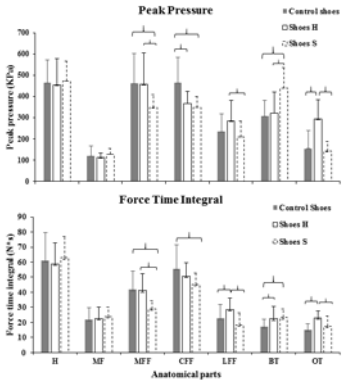

Figure 1: Illustration of peak pressure and force time integral while running with control shoes and shoes H & S.

CONCLUSIONS

Soft rocker shoes introduce reduced ankle ROM, peak pressure and force-time integral and may be useful for rehabilitation training and reducing the impact of injury. The increased pressure on the big toe and quicker response may prove, counter-productive, however. Hard rocker shoes highlight that ill fitted shoes with stiff material properties may increase injury and pathology in the foot.

ASSESSMENT OF LONG BONE FRACTURES UNDER DYNAMIC BENDING AND PINCHING LOADINGS

INTRODUCTION

Long bone fracture due to contact with an object often occurs in various accidents, e.g., traffic accident, domestic accident and sport accident. Investigations on the mechanical responses and fracture behavior of long bone under external loading have been conducted in the past. However, they commonly focused on the large-diameter long bones, e.g., femur, tibia, humerus and radius. Furthermore, although studies on the fracture criterion of a small-diameter long bone under quasi-static loading can be found in the literature [1], it was difficult to find an experimental study under dynamic loading (impact velocity of the order of 1 m/s). Therefore, a fracture criterion for a small-diameter long bone under dynamic loading was considered important in predicting the risk of fractures in an accident.

In this study, mechanical responses of porcine fibula under dynamic bending and pinching loadings were investigated using a custom-made drop-weight testing machine equipped with several measurement devices. A fracture criterion based on the combination of three different physical parameters was then proposed based on the experimental data.

METHODS

Mechanical test was conducted using a custom-made drop-weight testing machine [2]. Impactor had a mass of 4.59 kg. An anvil with tip curvature radius of 1.0 mm was fixed to the inferior surface of the impactor. Specimen fixation table was equipped with two anvils having a tip curvature radius of 5.0 mm for three-points bending test, and with an additional anvil fixed between the two anvils for pinching test. An accelerometer (Kyowa Electronic Instruments Co., Ltd.) was attached on the superior surface of the impactor. A load cell (Kyowa Electronic Instruments Co., Ltd.) was also fixed between the specimen fixation table and the base of the testing machine. Furthermore, laser displacement meter (Keyence Corp.) was fixed to the top of the testing machine to measure the drop distance of the impactor.

Fresh porcine fibulae obtained from slaughterhouse were utilized as test specimens. In order to identify the initiation of fracture, a wide band AE sensor (NF Corp.) was attached on the distal end of the specimens. A total of 64 specimens with maximum thickness at diaphysis of 9.0-12.0 mm were prepared for this study.

Two different tests: bending and pinching, were conducted in this study. Drop heights of the impactor were set to be 20 mm (impact velocity of 0.30 m/s), 40 mm (impact velocity of 0.43 m/s), 60 mm (impact velocity of 0.78 m/s), and 80 mm (impact velocity of 0.95 m/s). Eight specimens were tested under each drop height condition. Signals from the measurement devices were acquired using a data logger (Keyence Corp.) at 20 kHz. Moreover, a high-speed video camera (Photron Ltd.) was used to record the fracture behavior of the specimen at 2,000 fps.

RESULTS AND DISCUSSION

In the bending test, fracture was observed in 19 specimens (drop height of 80 mm: 8 specimens; 60 mm: 7 specimens; 40 mm: 4 specimens). The fracture pattern was similar to butterfly fracture. In the pinching test, fracture was observed in 26 specimens (drop height of 80 mm: 8 specimens; 60 mm: 7 specimens; 40 mm: 8 specimens; 20 mm: 3 specimens). The fracture pattern was comminuted fracture.

Comparisons of load and displacement at fracture as well as impulse and work to fracture among the test results were conducted. The pinching test results showed greater fracture loads than the bending test results. However, the differences were not statistically significant. The pinching test results also showed lower fracture displacement, lower impulse to fracture and lower work to fracture compared to those in the bending tests. Significant differences ($p < 0.05$) could be confirmed at most conditions.

Figure 1 indicates the relationships between impulse/displacement and impact velocity in the test results with fracture. Both results showed a similar trend with high correlation coefficients. Considering that the two results almost overlapped each other, Figure 1 may indicate the fracture threshold of porcine fibula under dynamic loading regardless of the loading condition.

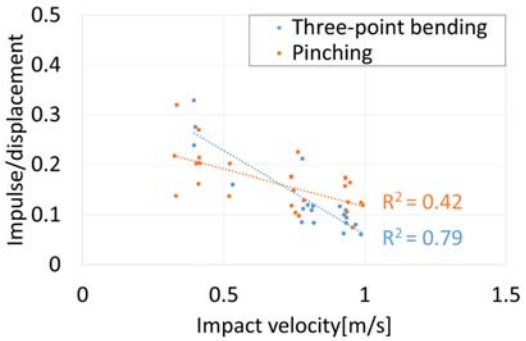

Figure 1: Relationships between impulse/displacement and impact velocity in the test results with fracture.

CONCLUSIONS

Mechanical responses and fracture behavior of porcine fibula under dynamic bending and pinching loading were investigated using a drop-weight testing machine. Impulse/displacement versus impact velocity showed a similar trend and almost overlapped each other, indicates a possibility to develop a fracture criterion of a small-diameter long bone regardless of the loading condition.

CONTRIBUTIONS OF METATARSAL ANGLE AND METATARSAL HEAD FORCE TO INCREASED STRAINS OBSERVED IN MINIMALIST SHOE RUNNING

INTRODUCTION

Stress fractures are considered overuse injuries associated with the mechanical fatigue of bone. Long periods of repetitive loading can lead to the formation of bone microdamage [1] which can accumulate and propagate to form a stress fracture. The number of loading cycles that a bone can withstand prior to stress fracture is strongly correlated with the magnitude of deformation (i.e., strain) it experiences. The metatarsal bones in the foot are susceptible to stress fracture during long distance running, presumably because they are exposed to repetitive strains with each step. Current work in our group has shown that during running, strain magnitudes are greater in minimalist (uncushioned) shoes for all five metatarsal bones compared to traditional (cushioned) shoes. The purpose of this study was to investigate whether the cause of these higher metatarsal strains was from larger forces acting on the metatarsal heads or from altered metatarsal angles during ground contact.

METHODS

Fourteen male recreational runners (age: 26.2 ± 4.2 years; height: 178.4 ± 5.4 cm; body mass: 75.6 ± 5.6 kg, means ± SDs) participated in this study. Participants ran 10 km/week, had no lower limb injuries within the previous 3 months of the study, were self-reported rearfoot strikers, and had no prior experience running in minimalist footwear. Computed tomography (CT) scans were taken of each participant's right foot in both the traditional and minimalist shoes to obtain neutral sagittal-plane metatarsal angles (Discovery 610, General Electric Healthcare; USA). Next, participants ran overground in the traditional and minimalist shoes at their preferred speed for a 5-km run (±5%) while motion capture (Motion Analysis Corp.; USA) and plantar pressure (Pedar-X, Novel; USA) data were collected for the right lower limb. Preferred running speed was determined from warm up trials performed with the traditional shoe.

Seven retro-reflective markers were adhered to each shoe to separate the foot into rearfoot and forefoot segments. The sagittal angle of the rearfoot segment was added to the neutral metatarsal angles from the CT scans to obtain sagittal-plane metatarsal angles throughout ground contact. These metatarsal angles were then combined with plantar pressure data to calculate metatarsal head forces using a musculoskeletal model of the metatarsophalangeal joint [2]. Repeated measures ANOVAs were used to test for differences in metatarsal angle and metatarsal head force at the instant of maximum strain on each bone ($p \leq 0.05$).

RESULTS AND DISCUSSION

At the instant of peak metatarsal strain, metatarsal angles were on average 18.6% greater ($p < 0.001$) in the traditional shoe compared to the minimalist shoe (Table 1). Metatarsal head forces were on average 2.5% greater in the minimalist shoe compared to the traditional shoe ($p \leq 0.65$), but differences were only significant at the fourth metatarsal. An average effect size of $d = 1.95$ and $d = 0.19$ was observed for metatarsal angle and force magnitude differences between footwear conditions, respectively. Positive effect sizes represent larger angles/forces in the traditional shoe.

These results suggest that increased strains in the minimalist shoe are due to decreases in metatarsal angle and not increases in force. A smaller metatarsal angle at the instant of peak strain causes the long axis of the bone to be more perpendicular to the applied load, producing a greater bending moment and thus a greater strain magnitude. It may be possible that metatarsal strains, and therefore the risk of metatarsal stress fracture, could be lowered by designing footwear that supports the metatarsals during ground contact, thus increasing the metatarsal angle, making these bones more resistant to the applied loads.

CONCLUSIONS

Increased strains observed when running in the minimalist shoe were caused by a lower sagittal-plane metatarsal angle at the instant of peak strain. These findings are valuable as they offer insight into shoe design properties that may reduce metatarsal strains and the risk of stress fracture.

ELASTIC MODULUS AND HYDROXYAPATITE CRYSTAL ORIENTATION IN A SINGLE TRABECULA

[1] **Satoshi Yamada**, [2] Koichi Fukasawa, [1] Masahiro Todoh and [3] Shigeru Tadano
[1] Faculty of Engineering, Hokkaido University
[2] Graduate School of Engineering, Hokkaido University
[3] National Institute of Technology, Hakodate College

INTRODUCTION

The mechanical properties and nanostructure of each trabecula are important factors in determining the strength of the cancellous bone. On diaphyseal cortical bone, the c-axis of hydroxyapatite (HAp) crystals aligned along the bone axis, and the degree of crystal orientation was correlated with the elastic modulus [1]. However, the mechanical properties and nanostructure in a single trabecula have not been elucidated. The authors have attempted to investigate the elastic modulus and crystal orientation in a single trabecula using the trabecular specimens at least 3 mm in length by tensile test and X-ray diffraction (XRD); however, the specimens were larger than the standard size and existed in the edges of the cancellous bone [2]. Hence, the micro-cantilever bending (MCB) test has been proposed to investigate the elastic properties of a single trabecula with the standard size [3]. The present study aims to investigate the elastic modulus and HAp crystal orientation in a typical single trabecula inside the cancellous bone by MCB and XRD measurements.

METHODS

A total of 10 rod-like trabeculae were dissected from the proximal epiphysis of an adult bovine femur (two years old). A specific single trabecula was randomly selected and isolated, while keeping one extremity connected to the cancellous bone. The specimen was fixed into a holder almost vertically by embedding the cancellous bone portion in epoxy resin. The trabecular length was 1.12 ± 0.17 mm. Each specimen was fixed onto a testing device and the load was perpendicularly applied to the free end in a stepwise manner. Specimens were loaded and then unloaded three times under air-dried conditions. The elastic modulus in the longitudinal direction was calculated from the force-deflection relationships. The specimen was assumed to be a vertical circular cylinder of orthotropic material and shear stress was considered to be negligible in the calculations. Then, the specimen was perpendicularly irradiated with characteristic X-rays of Mo-Kα with a collimator of 1 mm diameter, at a tube voltage of 40 kV and a tube current of 40 mA (Ultima IV, Rigaku, Japan). The XRD pattern was detected by X-ray imaging plate. The degree of c-axis orientation of the crystals with respect to the longitudinal direction, $\langle\cos^2\beta\rangle$, was calculated from the pattern of the (002) planes [2]. The measurements were conducted three times, and the average value was used for each specimen.

RESULTS AND DISCUSSION

The elastic modulus of the trabeculae inside the cancellous bone was 9.1 ± 5.4 GPa [3]. There was no significant difference with the large trabeculae in the edges of the cancellous bone in the same age bovine femurs [2]. These were 42% of the value of the cortical bone specimens [1]. The c-axis of the crystals aligned along the longitudinal direction, not the bone axis, and $\langle\cos^2\beta\rangle$ was 0.343 ± 0.002. A specimen was broken before the XRD measurement. There was no significant difference with the large trabeculae; however, it was smaller than that of the cortical bone. Figure 1 shows the elastic modulus and $\langle\cos^2\beta\rangle$ in the trabecular and cortical bone specimens. In the trabeculae, elastic modulus was not correlated with $\langle\cos^2\beta\rangle$, although there was a statistically significant correlation in the bone tissue including single trabecula and cortical bone ($r = 0.75$, $P < 0.01$). It suggests that the bone tissue in a single trabecula may have a particular elastic modulus and nanostructure and the variations are relatively small locally. Furthermore, the difference of the mechanical properties between trabecular and cortical bone tissue depends on the degree of crystal orientation as well as bone mineral density.

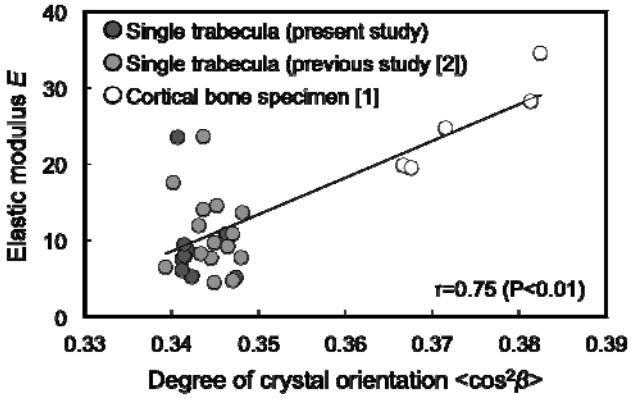

Figure 1: Elastic modulus and $\langle\cos^2\beta\rangle$ of the trabeculae inside and in the edges of the cancellous bone [2] and cortical bone specimens [1] taken from two-year-old bovine femurs.

CONCLUSIONS

The average elastic modulus of a single trabecula in the proximal epiphysis of adult bovine femurs was 10.6 ± 5.2 GPa and 42% of the value of the cortical bone specimens. The c-axis of the crystals aligned along the longitudinal direction of the trabecula, and $\langle\cos^2\beta\rangle$ was significantly smaller than that of the cortical bone. There was no statistical correlation between elastic modulus and $\langle\cos^2\beta\rangle$ in the trabeculae.

UNIQUE CONTRACTILE PROPERTIES OF INDIVIDUAL STRESS FIBERS MAY EXPLAIN TENSION-INDUCED IMMOBILIZATION OF FOCAL ADHESIONS

[1] **Shinji Deguchi** and [1]Tsubasa S. Matsui
[1]Osaka University
Corresponding author email: deguchi@me.es.osaka-u.ac.jp

INTRODUCTION

Contractile forces generated by stress fibers (SFs) play crucial roles in regulation of focal adhesions (FAs) [1]. Although contractile properties of whole cells have been extensively studied, those intrinsic to individual SFs remain unclear. Here we isolate SFs from cells to directly characterize the relationship between the shortening rate and forces generated by individual SFs. These isolated SFs are associated with various proteins that include phosphorylated myosin regulatory light chain (MRLC) required for non-skeletal myosin–actin cross-bridge cycling. Thus, contractile shortening of the structurally and functionally non-impaired SFs is induced upon reactivation with exogenous ATP. We then evaluate their contractile rates and forces using functionalized microneedles for physical manipulation. SFs shorten quickly at a rate of ~3.5 μm/s in the absence of loading, whereas, interestingly, the shortening rate is drastically decreased by more than two orders of magnitude upon tensile loading. Thus, a highly steep shortening rate–load relationship was observed, which is distinct from the hyperbolic Hill curve of striated muscles although the contractile properties of skeletal muscles have been assumed in other studies to be valid for SFs that possess sarcomeric patterns along their lengths [2]. FRAP experiments on cells expressing several MRLC mutants indicate that the binding lifetime of nonmuscle myosin II on SFs is elevated with increased tension, thus being consistent with the unique contractile properties at the level of SFs. These results suggest that the tension-induced arrest of nonmuscle myosin II suppresses shortening of the whole SFs and thus immobilizes FAs while sustaining isometric tension.

METHODS

SFs were isolated from smooth muscle cells that were cultured in DMEM supplemented with 10% fetal bovine serum. Cells were treated with low ionic strength solution containing triethanlamine and then with a buffer containing a gentle detergent to extract ventral SFs. Individual SFs were physically manipulated with a functionalized glass needle to which proteins on the SFs nonspecifically adhere. The glass needle has a bending stiffness comparable to that of single SFs, thus from the deflection of the glass needle and its known stiffness we can evaluate the force required for stretching or sustaining forces generated in the manipulated individual SFs. Mg-ATP of physiological concentrations was applied to the SFs to induce their contraction and characterize the biophysical properties.

RESULTS AND DISCUSSION

We extracted SFs by de-roofing cells with low ionic strength solution containing triethanolamine. Myosin regulatory light chain in the resulting extracted SFs is kept highly phosphorylated so that application of exogenous ATP readily reactivates their extensive contraction without addition of any recombinant proteins. We found that individual SFs have a unique shortening rate–load relationship that is distinct from the hyperbolic Hill curve. SFs exhibit marked shortening in the absence of external loading, whereas the shortening rate is drastically decreased by more than two orders of magnitude upon external tensile loading. We confirm in a separate experiment using live cells that nonmuscle myosin II keeps binding to actin in SFs rather than cross-bridge cycling as tension is increased, which is thus consistent with the arrest of shortening under tensile loading that we found with the isolated individual SFs. We suggest that the contractile properties intrinsic to SFs with a non-Hill curve are suited for exerting a constant tension on FAs. Meanwhile, an upward-convex relationship between the actively generated force and degree of actin–NMII overlap, similar to that of muscles, is observed in SFs as well, suggesting that it is a universal feature common to the sarcomeric architecture. We also provided direct evidence that isometric contraction is realized for individual SFs without new actin incorporation, and furthermore they can reestablish an equilibrium isometric tension following repeated changes in their length. Thus, the contraction of SFs occurs without structurally irreversible process, and even after shortening the original structure is restored without new protein incorporation just by mechanically stretching back.

CONCLUSIONS

Despite increasing knowledge regarding how finely focal adhesions are regulated by the cellular tension, it remains unknown how the isometric contraction of individual SFs is maintained in stationary cells to exert a level of tension on immobilized cell adhesions. The present study provided isometric contractile properties intrinsic to SFs. We found that they are distinct from those of striated muscles that have been assumed in other studies to be valid for SFs.

A LOGISTIC MODEL FOR ESTIMATION OF BONE ADAPTATION PATTERN IN MOUSE TIBIA

[1,2]**Yuzhu Guo**, [1]Lingzhong Guo, [1]Enrico Dall'Ara, [3]Yongtao Lu and [1]Marco Viceconti

INTRODUCTION

In vivo micro-computed tomography (microCT) imaging can be used for longitudinal monitoring of bone adaptation in mice. However, the continuous, even if small, bone growth in mice makes the quantification of local bone adaptation challenging. In vivo imaging provides accurate measurements on the same mice and can reduce the number of animal tests required to answer a research question. Still, inter-mouse variability is an issue and a large number of data is needed to characterize the biological process of bone adaptation. Computational models can be used to further reduce the number of animal experiments, and the time and cost associated to them.

In this study, a spatio-temporal one-dimensional model is developed to describe the dynamics of bone mineral content (BMC) over both time and space. Based on the model, virtual mice can be created by adjusting the associated parameters.

METHODS

Five wild type C57BL/6J (BL6) mice were used. The detailed information on animals and in vivo microCT scanning can be found in [1, 2]. Briefly, eight scans of the whole mouse tibia were conducted at the week 14, 16, 17, 18, 19, 20, 21 and 22 of age. After rigid registration, the fibula was removed. Each image of the tibia was cropped between the growth plates and was divided into 20 sections along its axial direction. After proper densitometric calibration the BMC was calculated in each section.

Assuming that the BMC distribution is continuous with respect to both space and time, the BMC data were smoothed with cubic spline functions by using the Matlab function 'csaps' (smoothing parameter set to 0.968 considering that the precision error of the in vivo data is less than 3.2% [2]).

A logistic growth model was used to describe the BMC dynamics over time:

$$\frac{dBMC}{dt} = r(x)\left(1 - \frac{BMC}{b(x)}\right)BMC \qquad (1)$$

where r and b are two parameters, which characterize the change of BMC dynamics over space x. Logistic growth model is widely used for representing the population growth. The value of *BMC* grows in a varying rate. The initial stage of growth is approximately exponential; then as saturation begins the growth slows and at maturity, growth stops. Parameter b represents the asymptotical value of *BMC*. Elastic net algorithm is used to estimate the parameters in the model. The ranges of each parameter were obtained by finding the envelope of identified parameters for the five mice. Using the model, 'virtual mice' can be created by choosing parameters randomly in the range of the parameter space.

RESULTS AND DISCUSSION

The identified parameters at critical locations are show in Table 1. The range of parameters indicates the inter-mouse variability.

Table 1 Model parameters

[illegible]			
0.1309±0.0582			
b([illegible]			

Using the average value of the parameters, a virtual mouse was created. Using the same initial conditions, the comparison of virtual mouse BMCs (Fig 1a) with a real mouse (Fig 1b) is shown in Figure 1. It can be observed that both mouse BMCs have higher values at the proximal, distal end and also the joint point of the tibia and fibula (TFJ). By randomly selecting the model parameters in the parameter range, infinitely many virtual mice can be created. The model will be validated with data from independent experiments which are currently ongoing.

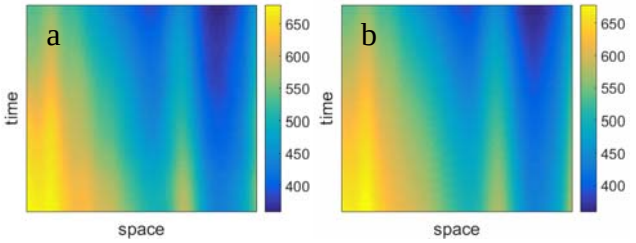

Figure 1 Comparison of virtual mouse and real mouse BMC

CONCLUSIONS

A one-dimensional spatio-temporal model is proposed to characterize the bone adaptation process. The results enable the in silico augmented animal trails. We can generate 'virtual mice' based on the identified models which obtained from the scans of real mice to reduce the number of animal used. This model can also help to reduce the number of scans to be performed on the mouse, refine the procedure and reduce the costs. The proposed model suggests that a minimum of 3 time points should be acquired. The same methodology can be used to mice with accelerated bone reabsorption after ovariectomy and subjected to anabolic treatments.

THE MICROSTRUCTRUAL RESPONSE OF PORCINE ANTERIOR CRUCIATE LIGAMENT TO COMPRESSIVE KNEE-JOINT LOADING WITH RESTRICTED VERSUS FREE TIBIAL ROTATION

[1]**Lei Zhao**, [2]David Ackland, [2]Peter Lee, [1]Neil Broom and [1]Ashvin Thambyah

INTRODUCTION

Internal tibial rotation is a known risk factor which contributes to anterior cruciate ligament (ACL) injury. Previous in-vitro studies on whole porcine knees, subject to compressive loading, have shown that the potential for ACL injury can be decreased by simply restricting tibial rotation (RTR) [1]. Recently too we have shown that distinct microstructural variations in the ACL exists as a function of its double bundle anatomy [2, 3]. Given these insights, we aim to now determine how the unique double bundle structure of the ACL, responds to the above joint loading restriction.

METHODS

Eight porcine knees, obtained from a local abattoir, were processed

Samples were loaded in compression and in 22˚ flexion to apply an anterior tibial translation [1]. Following the loading protocols shown here, the samples were divided into two equal sized groups and chemically fixed with 10% formalin for 24 hours. Chemical fixation was done under load: for the first group, predetermined loads from step two were applied with free tibial rotation (FTR), and for the second group, predetermined loads from step two were applied with RTR. Ligament-to-bone blocks were harvested after fixation and fully decalcified using 10% formic acid and further examined using differential interference contrast (DIC) microscopy. The level of collagen crimping was carefully imaged and quantified across the ACL, differentiating the anterior-medial and posterior-lateral regions. The extent of crimping, with the ligament fixed under load, was used to correlate with the extent of loading experienced in the particular region of the ligament.

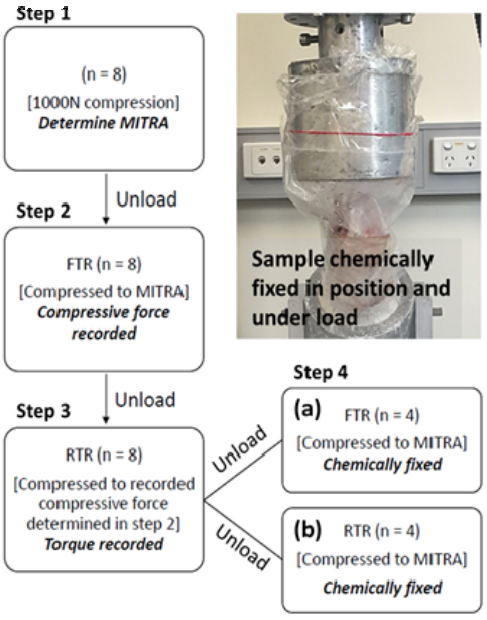

Figure 1: Methods flow chart. Photo showing formalin fixation of sample in position and under load. MITRA: Maximum Internal Tibial Rotation Angle; FTR: Free Tibial Rotation; RTR: Restricted Tibial Rotation.

RESULTS AND DISCUSSION

At the macro-scale level, the anteromedial (AM) bundle was relatively slack in FTR samples when comparing to samples from the RTR group. Also in the FTR group, the posterolateral (PL) bundle of the ACL was slightly impinged by the lateral femoral head. At the micro-scale level, differing crimp patterns were found in the ACL between the FTR and RTR groups. In the ACL of both FTR and RTR groups, there was minimal crimping in the medial region, and substantial crimping in the lateral region, suggesting high and minimal level of tensile load respectively. In the central region (a less distinguishable lateral aspect of the AM bundle and medial aspect of the PL bundle), less crimp was visible in the RTR group than in the FTR group.

CONCLUSIONS

The results suggest that reduced risk of ACL injury from restricting tibial rotation may be due to an offloading from the central portion of fibres in the ACL. This study provides additional insight into the complex injury mechanism of the ACL, and how this ligament may potentially be protected.

ACKNOWLEDGEMENTS

The authors are grateful to funding from the Faculty Research Development Fund from University of Auckland, and the Wishbone Trust NZ for this work.

RESIDUAL FORCE ENHANCEMENT CONTRACTION MODALITIES FOR TRAINING *IN VIVO* HUMAN SKELETAL MUSCLE: A SYSTEMATIC REVIEW

[1] **Neil Chapman**, [1]John Whitting, [1]Suzanne Broadbent, [1]Zachary Crowley-McHattan and [1]Rudi Meir

INTRODUCTION

Conventional early stage hamstring rehabilitation avoids using eccentric muscle contractions. This is despite the ability of this muscle group to lengthen in the deceleration phase of ambulation being functionally essential. Residual force enhancement (RFE), defined as the phenomenon of increased force production following active lengthening (eccentric contraction) of skeletal muscle, has been shown to reduce muscle activation levels and, thereby reduce energy cost compared with purely isometric contractions[1]. Despite these and other potential benefits, there is a paucity of research investigating this contraction modality, particularly in the realm of injury rehabilitation. It is proposed that potential benefits of RFE contraction modalities in acute and sub-acute injury rehabilitation may include i) optimised alignment of collagen fibres during the remodeling phase of recovery; ii) increased fascicle length of skeletal muscle; and iii) earlier implementation of an eccentric component to rehabilitation protocols, resulting in faster recovery times. Prior to investigating such hypotheses, however, it is essential to thoroughly and systematically examine existing evidence. This systematic review aims to summarise and critically analyse the evidence of voluntarily activated muscle contractions involving RFE. The results of the systematic review will inform future experiments of RFE modalities in injured and healthy hamstring muscles.

METHODS

The systematic review adhered to the PRISMA statement. Inclusion and exclusion criteria were specified. Keywords were identified, and articles satisfying the eligibility criteria were identified through an extensive search of CINAHL, Ebsco, EMBASE, MEDLINE, and Scopus. A list of 22 pertinent manuscripts that included experimental and quasi-experimental studies was created according to specific inclusion/exclusion criteria. These manuscripts were critically reviewed for quality according to the Downs and Black scale[2] and descriptive information about the RFE parameters employed in the research was elucidated and categorised.

RESULTS AND DISCUSSION

Cumulatively, 354 healthy subjects were included in the reviewed studies. Methodological quality scores ranged from 11 to 19 (mean ± SD, 17.0 ± 2.27) on a 28-point scale and were rated from poor to excellent as indicated by the data in figure 1. As expected, due to the experimental nature of the pool of studies investigated, several methodological areas were noted as being absent from all articles, including; concealment of allocation, and blinding of participants and researchers. Importantly, RFE was observed in all muscles tested. Voluntary contraction intensities ranged from 10% to greater than 95% maximum voluntary contraction (MVC). The magnitude of RFE appears to be dependent on contraction or activation intensity, particularly during the pre-stretch. Ranges of motion varied from 15° to 60° in experiments assessing a variety of joints. Greater magnitude of RFE was achieved with smaller stretch amplitude, and with faster stretch velocities ranging from 9°/s to 360°/s. Interestingly, the magnitude of RFE in this body of research was observed to be greatest primarily on the descending limb of the muscle force-length curve when muscles are at longer lengths.

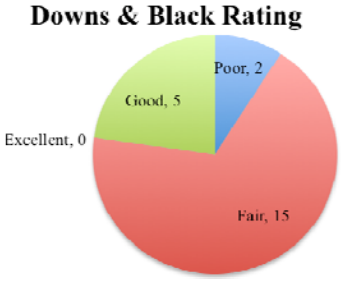

Figure 1: Categorical rating of 22 articles against Downs and Black scores. “Excellent” (24-28 points), “Good” (19-23 points), “Fair” (14-18 points), “Poor” (<14 points)[3].

CONCLUSIONS

This systematic review indicates a growing body of evidence supporting the efficacy of RFE contraction modalities in *in vivo* skeletal muscle. However, the quality of the evidence was largely determined to be “fair”, suggesting that more robust studies are needed. RFE is consistently present in a wide range of contraction intensities, stretch magnitudes, amplitudes, and velocities. This collection of results suggests that RFE modalities may be useful in skeletal muscle rehabilitation protocols, where one could employ highly controlled but minimal eccentric contraction phases at relatively small percentages of MVC and with lower muscle activation requirements than purely isometric contractions. However, the potential efficacy of rehabilitation specific RFE protocols in healthy and injured hamstring muscles is yet to be investigated. Evidence from the current review, therefore, will support the design of a protocol for eliciting RFE responses and activation reductions in healthy and injured skeletal muscle.

THE EFFECT OF SOCCER TRAINING HISTORY AND LOAD CARRIAGE ON JOINT MECHANICS

INTRODUCTION

Female recruits are afflicted by overuse injuries during basic training [1]. The injury rate of tibia stress fracture, one of the most common overuse injuries, is much higher in females than their male counterparts [2]. Load carriage is a major component in basic training. The repetitive elevated ground impact forces during walking with load carriage may contribute to the increased risk of tibia stress fracture. However, the injury mechanism of tibia stress fracture is still far from being understood. It is unclear how lower-extremity joints and bones respond to load carriage and whether a past history of multiaxial loading through soccer could enhance the function of lower-extremity bones and joints to sustain load carriage. The purpose of the study was to examine the effect of soccer history and incremented load carriage on lower-extremity joint mechanics.

METHODS

20 female recreational soccer players (20±1 yr) and 20 mass and height matched sedentary healthy women (21±1 yr) participated in the study. Walking tasks with load carriage of 0kg, 10kg, 20kg, and 30kg were performed on a force instrumented treadmill (AMTI) at 1.67m/s. A VICON motion capture system was used to record kinematics (200Hz) and AMTI force plates were used to record ground reaction forces (2000Hz).

Lower-extremity joint mechanics were computed for each walking task. Two way repeated measures ANOVAs were conducted to examine the effects of soccer history and incremented load carriage on joint mechanics. Significance level was at 0.05.

RESULTS AND DISCUSSION

It was found that incremented load carriage resulted in increases in most joint moments and power (Table 1). The healthy controls showed greater peak hip and knee power than those of the soccer players.

As the amount of load carriage increases, lower-extremity joint mechanics are altered accordingly, signified by increases in joint moment and power. In this study, compared to recreational soccer players, healthy controls revealed greater hip and knee power production during incremented load carriage. These results indicate that the healthy controls face bigger physical challenges during load carriage than soccer players. The greater increases in knee and hip power production suggest that the healthy controls experienced more energy expenditure, which would lead to higher metabolic cost. Thus, the healthy controls may encounter physical fatigue (which may contribute to altered gait mechanics) earlier than the soccer players during load carriage. Furthermore, attenuated increases in joint moments in soccer players may be protective from stress fracture and other musculoskeletal injuries, although this remains to be experimentally demonstrated. Future studies should examine the associations between joint mechanics, power and injury risk as well as determine if multiaxial loading is protective of tibia stress fracture.

CONCLUSIONS

Load carriage introduces significant physical demands on young females signified by increases in lower-extremity joint moment and power. Recreational soccer players demonstrated less alteration in joint mechanics such as smaller knee and hip power than those of the healthy controls. It appears that a history of multiaxial loading may better prepare military recruits for load carriage, which is an essential part of basic training.

TRAINING LOAD MONITORING IN SOCCER: CAN A MASS-SPRING-DAMPER MODEL REPRODUCE GROUND REACTION FORCES DURING DYNAMIC TASKS?

INTRODUCTION

Contemporary body-worn micro sensors using global positioning systems (GPS) and accelerometers are used to quantify the metabolic loading of players [1] to ensure an appropriate training stimulus. Research using these sensors has focused on understanding the physiological loading of the body but little on the mechanical stresses, such as ground reaction forces (GRF), which represent the whole-body external loads. Previous work [2, 3] has shown that a simple two mass-spring-damper model can replicate GRF for running at constant speeds but this model has not been tested in tasks typically performed during soccer. The aim of this study was to determine whether a two mass-spring-damper model can reproduce GRF curves and loading characteristics during accelerations, decelerations and sprinting.

METHODS

A two mass-spring-damper model (Figure 1), based on eight model parameters, was used to replicate GRF. 15 team sports athletes performed a wide variety of soccer specific running tasks including accelerations, decelerations, sprints and steady running at different speeds (2 m/s – 8 m/s), while GRF data were collected at 3000 Hz with a force platform. For each individual step an optimal combination of position, velocity and mass ratio of the two masses, stiffness of both springs, and damping coefficient of the damper, were determined by numerical optimization. Modelled GRF was calculated from this set of parameters. The best combination of model parameters was based on the lowest values for mean square error (MSE) and gradient error of the modelled GRF curve.

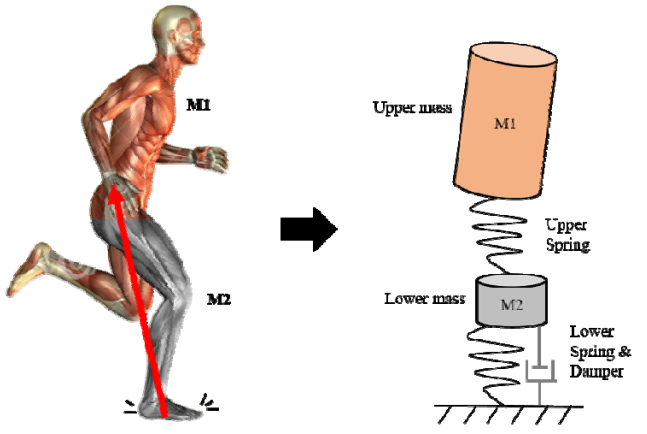

Figure 1: Ground reaction forces were replicated with a two mass-spring-damper model.

To validate the accuracy of replicated GRF profiles, an average curve error together with the impulse were calculated. The average curve error was defined as the MSE of the modelled GRF relative to the measured data. If an impact peak was modelled, the impact peak and loading rate were also examined. GRF loading characteristics errors were defined as the percentage difference between the measured and modelled data.

RESULTS AND DISCUSSION

MSE of the modelled GRF was low (< 1.5 N/kg) for accelerations and steady running, and moderate (1.5-3 N/kg) for decelerations (Table 1). In addition, impulse errors were very low (< 1%) for all tasks. However, errors were found to be moderate to high (5-15%) for impact peaks and very high (>15 %) for loading rates across tasks.

Table 1: MSE and GRF loading characteristics errors for different tasks. Impact peaks and loading rates were modelled for 18%, 99% and 36% of the acceleration, deceleration and steady running trials respectively (grey shaded).

Loading rate (%)				
24.30	ons			
19.94	ons			
17.27	ning			
19.36				

These results show that a two mass-spring-damper model can accurately reproduce the overall loading (i.e. impulse) of various running tasks, but not the subtle GRF loading characteristics. Model parameter combinations of GRF curves appeared to be independent of task. Further research should focus on whether adjusting individual parameter search criteria can improve impact peak and loading rate, without negatively affecting whole curve error and impulse.

CONCLUSIONS

This study shows that a simple two mass-spring-damper model can accurately reproduce overall GRF loading for soccer specific running tasks. These tasks account for the majority of mechanical stresses players experience and predicting GRF for these tasks in the field could help in quantifying mechanical loads of training. If information from body-worn sensors (e.g. accelerations of the upper trunk) can be used as input for the two mass-spring-damper model, this approach might open the door to predicting whole-body loading in the field.

NO CHANGE IN HAMSTRING INJURY RISK DURING SOCCER TASKS FOLLOWING SELF-PACED EXERCISE

[1,2] **Suzi Edwards**, [2] Megan McFarland and [3] Nicholas O'Dwyer
[1] University of Newcastle
[2] Charles Sturt University
[3] University of Sydney
Corresponding author email: suzi.edwards@newcastle.edu.au

INTRODUCTION

Recurrent hamstring strain injuries (HSI) are prevalent among soccer players [1], being the most common severe injury affecting players [2]. Injury is commonly sustained during running, kicking and explosive movements, including change-of-direction (cut) tasks [3]. HSI has not previously been associated with lower limb dominance [4] despite the fact that these high-risk movements repetitively expose the dominant (favoured) kicking limb to greater loading compared to the non-dominant limb, and the presence of bilateral asymmetries of technique and related muscular imbalances associated with injury.

Another factor that has often been identified as a causative factor for HSI [5] is fatigue. Fatigue is frequently encountered environmental constraint in soccer, impacting on performance by reducing an individual's capacity for sustained physical effort. Therefore, this is study aimed to determine whether healthy athletes alter movement mechanics in response to fatigue and if so, to identify whether such altered mechanics are protective against injury. Comparison of the dominant and non-dominant limbs was also carried out.

METHODS

Twelve male amateur soccer players performed 10 consecutive trials of soccer-specific cut task while dribbling a soccer ball for both lower limbs, prior to and following the completion of a 30-minute self-paced treadmill running protocol. For each trial, three-dimensional ground reaction forces (Kistler force platforms; 1000 Hz) and kinematic (Qualisys Oqus 300+ motion analysis system; 250 Hz) data were recorded. Repeated measures factorial analyses of variance were used to identify any significant changes in movement technique across fatigue conditions and between dominant and non-dominant limbs.

RESULTS AND DISCUSSION

A significant main effect of fatigue (grand means: pre-fatigue: 4.3°, post-fatigue: 4.7°) was observed averaged across all angles, events and non-dominant and dominant cut tasks ($F_{1,11}$=5.74, p=0.04). Nevertheless, *post hoc* tests did not identify any significant pre- versus post-fatigue differences for any individual angle during any event in either non-dominant or dominant cut tasks (Figure 1). Hence, this difference appears to be of no functional significance. This findings suggest that participants largely maintained the same level of performance and injury risk whilst executing the dominant and non-dominant soccer-specific tasks prior to and following the completion of submaximal self-paced exercise.

No main effect of cut task dominance was present ($F_{1,11}$=1.63, p=0.23) but there was a significant dominance x angles interaction ($F_{14,154}$=3.47, p<0.0001). Unexpectedly, mean ball speed was higher during the dominant cut task when the participants dribbled with their non-dominant foot ($F_{2,22}$=25.9, p<0.0001), is likely the result of heavier touches on the ball and less control rather than superior technical ability. Reduced ball control during the cut task is further indicated by the participants displaying a more neutral stance limb hip position during the stance phase when dribbling with their non-dominant foot, compared to an internally rotated stance limb hip position when dribbling with the dominant foot. This suggests that the ball was positioned further from the body when dribbling with their non-dominant foot.

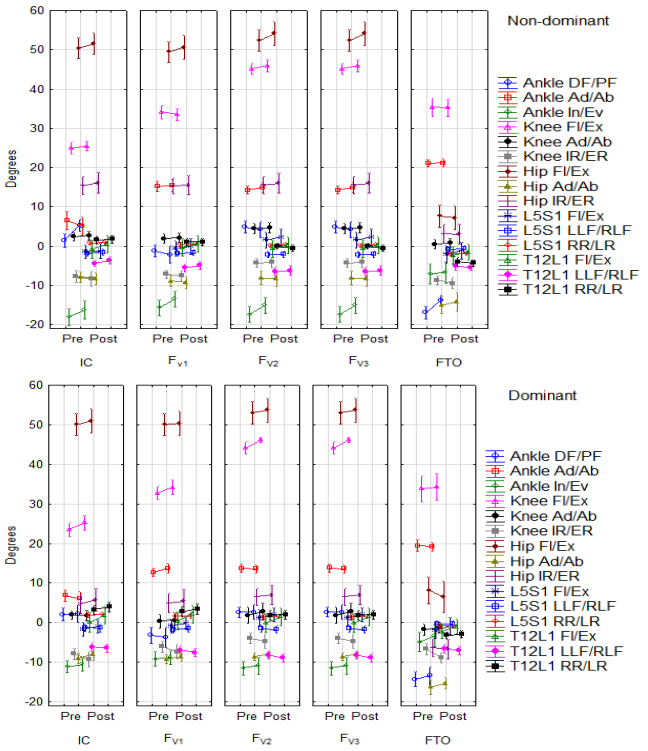

Figure 1: Mean (± SE) values for 15 joint angles in the (A) dominant and (B) non-dominant cut task across fatigue conditions and the five events.

CONCLUSIONS

Minor changes in movement technique during soccer-specific tasks were observed following the completion of self-paced exercise. Changes in task proficiency allowed for maintenance of performance outcomes under fatigue, while no substantial change in injury risk was induced across fatigue conditions.

INTRODUCTION

Enhanced career prospects is one of the key drivers for secondary school students aspiring to study an undergraduate degree at university. However, discussion on graduate destinations for biomechanics students is limited. Enhanced information pertaining to graduate destinations may help guide educational institutions' curriculum design, and improve graduate employability for our future biomechanists.

The aim of this analysis was to describe trends of graduate numbers and destinations for undergraduate biomechanists in the United Kingdom (UK) with respect to the number of graduates, employment, and type of work.

METHODS

Graduate data was obtained through the Destination of Leavers from Higher Education (DLHE) survey which is collected annually in the UK[1]. The survey is sent to all UK higher education graduates and poses questions on employment status, and further study at six months following graduation. We accessed field-specific data through reports compiled by the Higher Education Careers Services Unit (HECSU)[2]. The majority of undergraduate students in the UK study biomechanics as part of a Sport and Exercise Science (SES) programme. Therefore, we compared the graduate destinations of SES graduates (as a proxy of biomechanics graduates) against all graduates annually from 2006-2015.

RESULTS AND DISCUSSION

SES graduates in the UK increased from 5,915 in 2006 to 9,505 in 2015, an increase of 61%. In contrast, graduate numbers across all programmes only increased by 18.7% (263,050 to 312,330). As such, the proportion of all graduates from SES programmes increased from 2.2% to 3.0%.

80% of UK undergraduate leavers completed the DLHE surveys (across all and SES groups). The number of graduates in either full or part-time employment only (i.e. not also studying) increased over the decade despite a recent decline in employment rates for SES graduates in recent years (Figure 1). Notwithstanding this recent fall, unemployment rates were consistently lower for SES graduates. This seeming contradiction was explained by the greater proportion of SES graduates who went on to further study.

The lower unemployment rates are encouraging for SES students, however, the most recent DHLE survey (2015 graduates) showed that proportionally more SES graduates were in part-time employment compared with other graduates whilst proportionally less were in full-time employment (SES: Part: 19.3%, Full: 46.3%; All: Part: 13.1%, Full: 56.5%). SES graduates were also more likely to be working in retail, catering, waiting and bar staff jobs (SES: 16.0%; All: 11.1%) and less likely to be working in professional or managerial roles (SES: 57.4%, All: 70.7%).

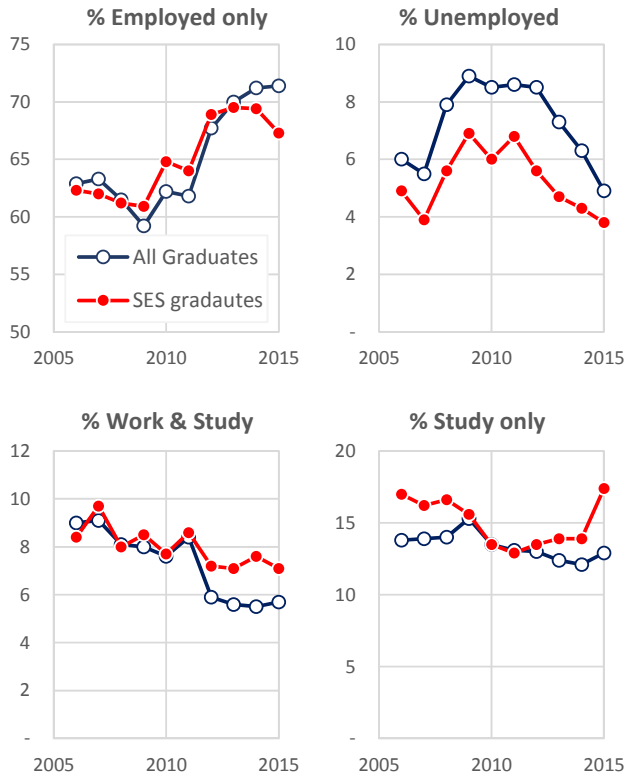

Figure 1: Employment six months after graduating.

CONCLUSIONS

Despite increasing numbers of SES graduates over the past decade, unemployment rates have remained relatively low compared to other graduate disciplines. This low unemployment rate is being helped by a higher proportion of SES students who enroll to further study, or combine both work and study after graduating. SES graduates also find it more difficult to find full time employment in professional positions six months after graduation.

We hope these findings prompt discussion amongst the biomechanics community, given that biomechanics is a core discipline of SES and has an important role to play in shaping the future of SES graduates. Some potential avenues include:

- Aligning curriculum to employer needs.
- Increasing relevant work experience and internships.
- Greater integration of SES professional bodies with established industries (such as the health industry).
- Ensuring relevant post-graduate study opportunities.

A LONG-TERM EFFECT OF ABDOMINAL STRENGTHENING EXERCISE ON REDUCING FEMALE DIASTASIS RECTI ABDOMINIS

[1] **Augusto Gil Pascoal**, [1 2] Natalia Rajkowska and [1,3] Patricia Mota

INTRODUCTION

Diastasis Recti Abdominis (DRA) refers to a musculoskeletal condition in which the horizontal distance between the middle edges of both rectus abdominal muscles, the Inter Recti Distance (IRD), is increased above a certain value. This condition occurs in both genders but is mostly observed during pregnancy and postpartum. Previous studies showed that a single abdominal isometric contraction, during an abdominal crunch exercise, reduces the IRD above the umbilicus in parous [1], postpartum, nulliparous [2] and pregnant women [3]. Results of these studies suggest an immediate effect of the exercise (isometric contraction) on IRD. However, no information exists about the long-term effect of the exercise (musculoskeletal adaptation) and/or the level of exercise intensity. The aim of this study was to compare the IRD in two groups of women, exercise and non-exercise, and between two levels of exercise, "well-fit" (bodybuilders) and "regular-fit".

METHODS

Three groups of women were included in this study: "well-fit" (WF) group [N=10; Age MD(SD) = 29.5 ± 5.1 years; Body Mass Index (BMI) = 19.6 ± 1.0 kg/m^2]; "regular-fit" (RF) group (N=10; Age = 32.7 ± 7.4 years; BMI = 20.6 ± 3.1 kg/m^2); and "non-exercise" (NE) group (N=10; Age = 29.7 ± 3.4 years; BMI = 22.2 ± 1.7kg/m^2). The WF participants were recruited among a population of bodybuilder elite athletes with at least 5 years practice time. The RF group included women who perform global physical exercise, 2-3 times a week, including abdominal strengthening .exercises. Ultrasound images were recorded with a 12 MHz scanner in a supine resting position and a crook lying position (isometric contraction), 2 cm above the umbilicus, and exported in DICOM format for a posterior IRD offline measurement (mm), following previously described procedures [4]. A two-way ANOVA was conducted to examine the effect of group (WF or RT or NE) and muscle activation (rest or isometric contraction) on IRD. Independent t-tests for each group were planned if significant interactions were found between group and muscle contraction. Specific software (SPSS 20) and a significantly level of $p<.05$ was used for statistics.

RESULTS AND DISCUSSION

A significant effect was obtained for factor group, i.e. levels of exercise [F(2,54)=36.95, P=0.00] and for factor level of muscle activation, rest and isometric contraction [F(1,54) =7.31, P=0.00] (Figure 1). No interaction was found between both factors. The NE group had a significantly greater IRD than RF groups [mean difference (MD) (SEM) mm = 5.2 (1.6); 95% Confidence Interval (CI) = 2.1 to 8.3] and WF [MD(SEM) mm = 6.0 (1.6); 95%CI = 2.8 to 9.1] groups. The IRD distance was significantly lower during isometric contraction than at rest [MD(SEM) = 3.5 (1.3); 95%CI = 1.0 to 6.0]. Differences between groups were small (partial Eta square=0.25) as also between levels of abdominal muscle contraction was small (partial Eta square=0.22). Previous studies showed an immediate effect of abdominal contraction on reducing supraumbilical IRD in parous [1], postpartum, nulliparous [2] and pregnancy women [3]. In this study, the results on bodybuilders and RT groups seem to demonstrate a long-term effect of abdominal training (LTAT) reducing supraumbilical IRD.

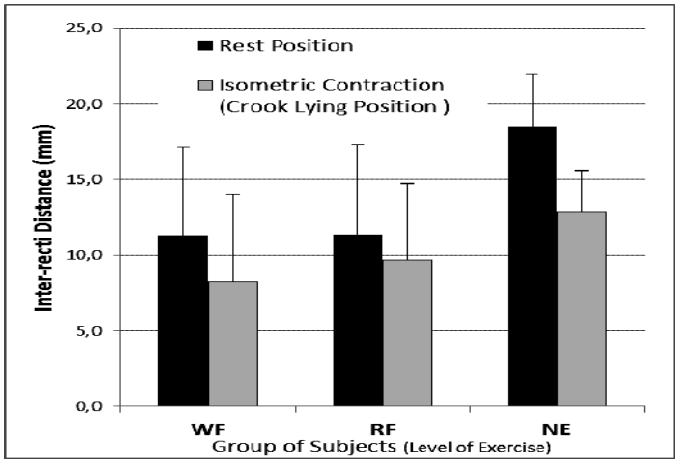

Figure 1: Mean values (SD) for the Inter-Recti Distance across groups (level of exercise) and muscle activation (rest vs isometric contraction).

CONCLUSIONS

Similarly to what other studies found on the immediate effect of abdominal contraction, these results also seem to show that long term strengthening exercises reduce supraumbilical IRD [2,3], a reduction effect of supraumbilical IRD was found associated with the long-term abdominal training. This seems to supports the argument from those who suggest that an antenatal abdominal strengthening exercises program could prevent or reduces postpartum DRA [5]. However further studies are needed to clarify the effectiveness of LTAT on prevention or reduction of postpartum DRA.

RELATIONSHIPS BETWEEN STAIR DESCENT SPEED AND T-SCORE WITH GAIT PARAMETERS IN OLDER WOMEN WITH LOW BONE MINERAL DENSITY

[1] **Ali Dostanpor**, [2] Catherine A Dobson and [3]Natalie Vanicek

INTRODUCTION

Stair descent is more mechanically challenging than level walking and stair ascent [1]. Moreover, stair descent presents a greater risk of falling [2] and often with serious consequences. Therefore understanding how women with low bone mineral density (BMD), and a high propensity to sustaining a fracture following a fall, negotiate stairs is important when devising appropriate exercises to continue using stairs independently, to maintain BMD and also to enhance their physical capacity throughout older age.
The aim of this study was to explore the relationships between gait parameters during stair descent and stair walking speed and T-score in older women with a range of T-scores (healthy level: -1 to +1 SD of the young adult mean, osteopenic level: -1 to -2.5 SD below the mean, and osteoporotic -2.5 SD or less below the mean).

METHODS

45 older women including 13 with healthy BMD levels, 26 osteopenic and 6 osteoporotic [mean (SD): age 67.3 (1.4) years; height 161.4 (4.9) m; mass 63.5 (8.6) kg] were recruited from the Hull and East Yorkshire NHS Trust. 3D kinematic and kinetic data were captured with twelve motion capture cameras (Qualisys, Sweden) and 2 force plates (Kistler, Switzerland) embedded into steps 2 and 3 of a custom-built 5-step staircase. Participants were instructed to descend the staircase at their comfortable pace and without the use of the handrails, unless necessary.
Kinematic and kinetic data were subsequently analysed in Visual 3D™ (C-Motion, USA). All gait data were normalised to the gait cycle starting with toe off. Multiple regression analysis was used to investigate the explained variance (R^2) attributable to speed and femoral neck T-score in gait variables of interest, including temporal-spatial parameters, joint kinematics and powers. $P<0.05$ indicated statistical significance (Stata v14, Texas, USA).

RESULTS AND DISCUSSION

The mean (SD) stair descent speed was 0.80 (0.21) $m \cdot s^{-1}$, which was much faster than age- and gender-matched data from the literature [3]. Speed explained the variance in most temporal-spatial parameters, kinematics and joint powers (R^2=6-49%) ($p \leq 0.001$). Inclusion of T-score to the regression model for kinematic parameters increased the explanatory power of models only by up to 8% for anterior pelvic tilt, hip extension and knee flexion and by 12% for ankle dorsiflexion (Table 1). Although this was a small proportion of the explained variance, it suggested that older women with low BMD may compensate for higher task demands at distal joints (i.e., the ankle) with adaptations occurring more proximally (i.e., at the hip and pelvis). The ankle kinematics demonstrated dorsiflexion at toe off, indicating the ankle plantarflexor muscles did not propel the stance leg into swing.
Negative slope coefficient (B) for both knee (K1) and ankle (A1) power bursts indicated a reduction in speed would result in reduced power absorption at these joints.

Table 1: Magnitude of explained variance (R^2) in temporal-spatial gait parameters explained by gait speed (GS) and gait speed with T-Score (GS & TS). Shaded areas indicate significant findings whereby the point estimate of the regression slope (B) was significantly different from 0 at the following alpha levels; *p < 0.05, **p < 0.01, and ***p ≤ 0.001. K1 and A1 are responsible for power absorption (i.e., eccentric contraction) of the knee extensors and ankle plantarflexors, respectively, at weight acceptance.

Gait Parameter	Mean (SD)	Predictor variable	R^2 %	Predictor variable	SLOPE COEFFICIENT (B)
Anterior Pelvic Tilt (°)	2.83(4.3)	GS	13	GS	-6.848**
		GS & TS	21	TS	-1.865**
Hip Extension (°) (Forward Continuance)	4.44(6.1)	GS	21	GS	-14.717***
		GS & TS	29	TS	-2.164**
Knee Flexion (°) (Leg Pull Through)	107.8(4.5)	GS	14	GS	-9.436**
		GS & TS	21	TS	1.513**
Ankle Dorsiflexion (°) (Controlled Lowering)	37.92(5.5)	GS	2	GS	-3.787
		GS & TS	19	TS	2.976***
K1 (W/Kg)	-1.78(1.2)	GS	21	GS	-2.975***
		GS & TS	24	TS	0.238
A1 (W/Kg)	-5.08(1.7)	GS	13	GS	-3.412**
		GS & TS	13	TS	0.066

CONCLUSIONS

Speed explained most of the variance in the gait parameters during stair descent. However the addition of T-score into the model increased the explained variance for some gait variables, possibly related to deficits at the ankle that were managed by proximal joint compensations. Eccentric muscle strengthening exercises at the ankle and knee, as well as maintaining joint mobility at these joints, are important for safe stair descent in older women. We recommend downhill walking for its eccentric muscle requirements and increased bending moment on the long bones of the lower limbs to maintain BMD in older women.

THE CORRELATION BETWEEN BREAST RANGE OF MOTION AND BRA COMFORT BEFORE AND AFTER RUNNING

[1]**Jordyn Vienneau**, [1,2]Erica Buckeridge, [1]Sandro Nigg and [1]Benno M. Nigg
[1]University of Calgary

INTRODUCTION

Breast movement during locomotion has previously been correlated to bra discomfort [1]. Bra comfort can be determined before an activity (pre comfort) or after an activity (post comfort). However, studies investigating bra comfort during physical activity typically rate comfort after the activity [1,2,3]. Initial bra comfort may be related to an in-store comfort, and provide baseline information regarding the comfort of the bra itself, separate from activity comfort aspects. The quantification of pre-activity comfort is rarely done and, therefore, differences between pre and post comfort are not well understood.

Therefore, the aim of this study was to compare correlations between breast movement and bra comfort 1) before running (PRE), 2) after running (POST), and 3) the change in this comfort score (ΔComfort).

METHODS

Thirty-three females participated in this study (mean ± SD: 23.2 ± 3.7 yrs, 165.7 ± 5.8 cm, 67.2 ± 8.4 kg). Nine bra sizes were included: 32C (n = 4), 32D (n = 3), 32DD (n = 3), 34C (n = 4), 34D (n = 4), 34DD (n = 6), 36C (n = 4), 36D (n = 4), and 36DD (n = 1).

Participants performed running trials (treadmill, 10 km/h) in three compression and four encapsulation bras. 3D range of motion (ROM) of the right nipple, and subjective bra comfort data using a 15 cm visual analog scale were collected. Bra comfort was determined PRE and POST running, and from these results a change in comfort (ΔComfort) score was calculated, where a positive value indicates an increase in comfort after running and a negative value indicates a decrease in comfort after running.

Pearson's correlation coefficients (R) were calculated between comfort (PRE, POST and ΔComfort) and 3D ROM of the right nipple across the seven bras for each participant individually. The R values were averaged across all participants. An R value of greater than 0.7 was considered a strong correlation. The number of participants who showed strong correlations were noted.

RESULTS AND DISCUSSION

On average, PRE comfort showed a weak positive correlation to ROM, with a higher PRE comfort in cases with a greater ROM (Table 1). ΔComfort showed stronger negative correlations to ROM than POST comfort, indicating higher comfort was associated with less breast movement. Additionally, when using ΔComfort, strong correlations were observed in more participants in both the medio-lateral and vertical directions then PRE or POST comforts.

Table 1: Mean Pearson's R values between PRE, POST and ΔComfort across all participants and the direction of the range of motion (ROM). The number of participants in each correlation with |R| > 0.7 is indicated. ML = medio-lateral, AP = anterior-posterior, V = vertical.

	PRE		**POST**		**ΔComfort**	
	Mean R	**# |R| > 0.7**	**Mean R**	**# |R| > 0.7**	**Mean R**	**# |R| > 0.7**
ROM ML	0.15	4	-0.25	2	-0.40	10
ROM AP	0.10	4	-0.16	8	-0.27	8
ROM V	0.27	10	-0.18	9	-0.47	13

The results illustrate that the assessment of comfort after activity differs from an "in store" comfort assessment when purchasing sports bras. Material factors such as bra rigidity and tightness may be perceived as uncomfortable before activity, whereas these attributes may be interpreted as supportive, and therefore comfortable, during and after activity.

A new variable, ΔComfort, was defined to quantify comfort. ΔComfort showed stronger correlations with breast range of motion than POST comfort, suggesting that the initial perception of comfort before activity is relevant information when understanding the relationship between breast movement during activity and comfort.

CONCLUSIONS

The key finding to this study was that the change in comfort, ΔComfort, was a better predictor of breast movement in running than POST running comfort alone. The ΔComfort variable incorporates both a baseline and a dynamic bra comfort, suggesting that bra comfort is a complex and multidimensional variable.

AN AUTOMATED BIOMECHANICS BASED CLINICAL PIPELINE FOR IMPROVING TREATMENT OF BREAST CANCER

[1] **Thiranja P Babarenda Gamage**, [1]Duane T Malcolm, [1,2]Poul M F Nielsen, [1,2]Martyn P Nash

INTRODUCTION

Breast cancer is the leading cause of cancer-related death in females, affecting 1 in every 10 women worldwide. Clinical imaging modalities (e.g. MRI) used for diagnosing the disease are acquired with the patient positioned differently to that assumed during the actual treatment procedures. Since such procedures are not performed under image guidance, localisation of tumours is challenging. This represents a significant challenge for clinicians, with many studies in the literature reporting incomplete excision of tumours in 20 % to 40 % of the patients who underwent breast conserving therapy, the most common procedure used for treating early-stage invasive breast cancers [1]. The biomechanics for breast imaging group at the Auckland Bioengineering Institute aims to create automated clinical pipelines that make use of biomechanical models to help clinicians address these challenges. In this study, we present our latest developments of a novel pipeline to predict the supine shape of the breast from prone MR images to help clinicians pinpoint the location of tumours during breast cancer treatment procedures.

METHODS

The main steps of the model-based prone to supine image processing pipeline are illustrated in Figure 1 and involved: 1) using novel machine learning algorithms to automatically segment the breast and its and internal tissues from diagnostic prone breast MR images [2]; 2) automatically creating personalised biomechanical models of the torso from the segmented image data using a combination of nonlinear geometric fitting and statistical shape analysis techniques [3]; 3) using large deformation mechanics and finite element modelling to simulate the shape changes that occur when the breast is repositioned from the prone to the supine position [4]; and 4) development of a web-based graphical user interface (GUI) to help clinicians easily visualise the motion of the breast tissues from the prone to supine position. The pipeline was developed using high resolution prone and supine MRI images (with 1 mm^3 isotropic voxels) acquired from 114 volunteers at the Centre for Advanced MRI at the University of Auckland, and more than 100 clinical prone MR images from patients diagnosed with breast cancer at Auckland City Hospital. The accuracy of the model simulation was assessed using the volunteer images by comparing the model predicted supine shape and the supine MRI using non-rigid registration techniques [4].

RESULTS AND DISCUSSION

Initial results from the registration analysis on a volunteer indicated modelling errors of (7.1 ± 2.4) mm for prone to supine displacement magnitudes of (61.7 ± 16.5) mm in a model that accounted for the mechanics of the pectoral muscle, breast tissue, and skin. This analysis highlighted the importance of including skin in the models. The lack of a mechanism to account for the motion of the shoulder and arm during prone to supine repositioning was identified as a potential source of error that needs to be addressed in future studies. The registration analysis is currently being automated and applied to all of our images of volunteers.

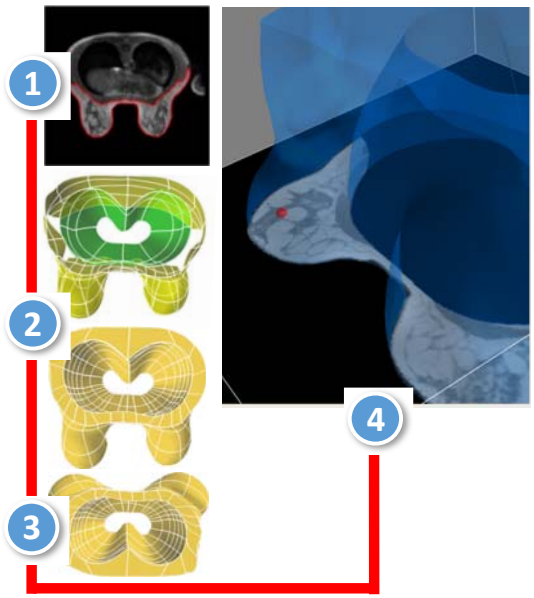

Figure 1: The main steps of the prone to supine modelling pipeline, which include: 1) automatic segmentation of prone MR images; 2) 3D model generation; 3) simulating the supine position using large deformation mechanics; and 4) visualisation of results in a webGUI.

CONCLUSIONS

We have developed a novel automated pipeline that incorporates state-of-the-art breast modelling techniques to predict the supine shape of the breast from prone MR images. Our current research is focused on implementing the pipeline for clinical trials at Auckland City Hospital. We envisage that the clinical adoption of this pipeline has the potential to improve outcomes for breast cancer patients.

INTRODUCTION

Unipolar and bipolar prostheses are two types of radial head prosthesis currently available but none sharply reproduce the anatomical shape of the native radial head. Long-term results of these prostheses are poorly documented, although bipolar prostheses are deemed more congruent, at the cost of lower stability.

The purpose of this study was to compare three different types of radial head prostheses in terms of joint contact areas changes in comparison to the native situation. The hypothesis tested was that the joint contacts are lowered after unipolar arthroplasty.

METHODS

Seven upper limbs of fresh frozen cadavers have been used. An unipolar radial head prosthesis, a classic bipolar prosthesis and a Judet bipolar prosthesis were compared with each other and with the native joint. Physiologic

tension was applied to the tendons of the biceps, triceps and brachial muscles; partial anterolateral capsulectomy was performed with preservation of the lateral collateral ligament complex. Polysiloxane was injected around the loaded radio-capitellar joint to obtain a cast on which the joint contact area was measured. Measurements were performed at three angles of elbow flexion (30°, 60° and 90°) successively in pronation, supination and neutral forearm positions.

RESULTS AND DISCUSSION

In a native elbow, joint contact areas were greater in supination. Elbow flexion had no effect on native and prosthetic joint contact areas, which were significantly ($p<0.05$) decreased after radial head arthroplasty (from 11% to 53%). There was no significant joint contact area difference between the three prostheses (Figure 1). However, bipolar prostheses showed lateral subluxation in neutral forearm rotation resulting in a significant decrease of joint contact areas. Joint contact areas and elbow stability influences radial head arthoplasty longevity. The decrease in joint contact areas after monopolar prosthesis [1] and the lateral instability of the Judet prosthesis with increased elbow valgus laxity in neutral forearm position has already been reported [2].

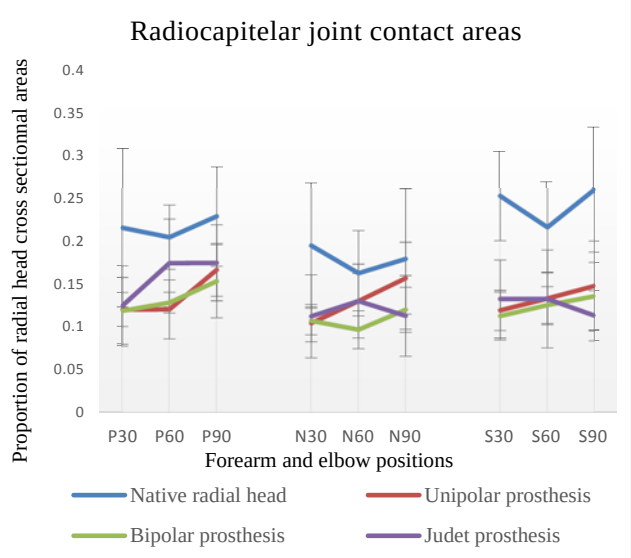

Figure 1: Normalized joint contact areas as proportion of native radial head cross sectional areas (with SD) in native joint and after three radial head arthrolasties.

CONCLUSIONS

The present study showed a great decrease of joint contact areas after all tested radial head arthroplasties. Furthermore, this study shows that Judet prosthesis instability is associated with a joint contact decrease and that the same phenomenon can be observed with a classic bipolar prosthesis.

INTRODUCTION

In orthopaedic tumor surgery, modular endoprosthetic implants have meanwhile become frequently applied to reconstruct the proximal femur. Problems related to these implants are often the significant weight and the non-optimal attachment sites for the soft tissues. The aim of the given feasibility study was to address these shortcomings, thereby developing long-term durable and biomechanically-optimised implant of a proximal femoral replacement.

METHODS

Based on lightweight construction concepts from vehicle construction, a topology optimization was performed with an existing modular implant basic body (Fig. 1). Additive manufacturing process laser beam melting (metallic 3D printing) was applied to produce an implant applying TiAl6V4 as material. The individual modules were coupled by a specially-designed polygon interface. To disconnect the interfaces, a joining instrument was used which applied a force at two pre-defined points, thereby allowing for and elastic deforms of the internal contour of the interface. This allowed for reversible joining of the modular components. In order to fix the muscles anatomically correctly, textile attachment points were made of multifilament polyester, embedded by embroidery. These were firmly bonded to the implant by a polyethylene extrusion of the neck module. The shaping of the plastic was made possible by the creation of an injection moulding tool. In order to determine the fatigue strength of the implant according to ISO 7206, a test was carried out in a certified laboratory. Furthermore, the prototype was trialled in a human body donor, thereby examining dimensions and handling under a surgery-like scenario.

RESULTS AND DISCUSSION

A functional model of a modular implant was successfully manufactured. On basis of topology optimization, the new implant featured a mass reduction of 400 g, compared to commercially-available proximal femoral sets, which was assembled from the MML system (AQ Implants GmbH, Germany). The greatest weight saving potential was reached for in the trochanter module (weight reduction 55%), thereby maintaining similar mechanical stability. The load-bearing structures consisted of TiAl6V4, whereas the shell of the neck module was made of polyethylene. The reversible coupling was implemented by a polygonal interface. Force closure was reached by switching off the external force effect and thus the deformation of the round bore hole into an elliptical geometry, which resulted in a "jamming" of the spigot. According to the ISO 7206 the fatigue strength of the implant was determined. The test implantation in the body donor revealed that the implant can be placed under realistic conditions. The suture fixation of the muscles to the textile attachment points was significantly simplified.

Figure 1: left: Representation of the lightweight construction of the distal femoral replacement as a CAD model, right: Manufactured lightweight implant with textile structures for soft tissue attachment.

CONCLUSIONS

The technological feasibility of a novel biomechanically-optimized implant could be demonstrated successfully. The innovations shall contribute that the implant reflects the original biological situation as realistically as possible. By means of the embroidery technique, textile structures can be produced which, in terms of their properties such as bursting pressure, pore size and thickness, basically correspond to the textile-technological requirements profile in the sense of the soft tissue attachment. The embroidered structures for soft tissue attachment can be injection moulded with plastic without loss of strength. Further tests need to investigate if the modular attachment points of the implant are susceptible to corrosion. Furthermore, it should be evaluated whether the modular components of the proximal femoral replacement can also be applied for the design of a femoral total prosthesis.

KINEMATIC ANALYSIS OF INNOVATIVE KNEE IMPLANTS IN VIVO DURING WALKING BY MEANS OF VIDEOFLUOROSCOPY

Pascal Schütz, Barbara Postolka, William R. Taylor and Renate List
Institute for Biomechanics, ETH Zurich, Switzerland
Corresponding author email: rlist@ethz.ch

INTRODUCTION

In total knee arthroplasty (TKA), reproduction of healthy tibio-femoral kinematics is considered to be beneficial for avoiding overload to the surrounding soft tissue structures. During flexion, the medial condyle is thought to translate no more than ±1.5mm, whereas the lateral condyle translates posteriorly about 15mm through a combination of rolling and gliding [1]. Recent TKAs have therefore aimed to mimic healthy joint kinematics to provide medial stability as well as rotational freedom. Early literature suggests success in this respect for static lunge activities, as well as dynamic step-up/down [2]. However, it is still unknown how these designs perform in vivo throughout both loaded and unloaded phases of complete cycles of dynamic gait activities. Therefore, the objective of this study was to compare the in vivo kinematics of two recent and two conventional fixed bearing TKA designs throughout complete gait activities using videofluoroscopy.

METHODS

23 subjects with a good clinical outcome (69±10y, BMI 26±3kg/m^2) and a unilateral innovative TKA design (Attune CR, DePuySynthes, n=5 and Sphere, Medacta, n=6) or a conventional design (Sigma CR, DePuySynthes, n=6 and Primary PS, Medacta, n=6) were assessed at least one year postop during five complete cycles of free level walking and stair descent (0.18m steps) using a moving fluoroscope (25Hz, 1ms shutter time). 2D/3D registration of the 2D fluoroscopic images was performed using CAD models of the implant components, and relative rotations between the femoral and tibial components were determined [3]. Tibio-femoral A-P translations were described using the nearest points of the femoral condyles relative to the tibial baseplate and normalized to a medium implant size.

RESULTS AND DISCUSSION

The Sphere design showed the least range of medial condyle A-P translation with only a small variation between subjects (4.9±0.9mm) and a large subject-specific translation in the lateral condyle (10.3±4.3mm) over the full cycle of level gait. In contrast, all other three designs showed about equal ranges of A-P translation for the medial (Attune: 6.7±1.0mm, Sigma: 6.6±1.0mm, Primary: 11.4±2.7mm) and lateral (Attune: 6.5±1.9mm, Sigma: 5.49±1.0mm, Primary: 11.4±2.7mm) condyles. During the loaded stance phase, the two newer designs showed medial ranges of A-P translations close to the values found for healthy knees (Sphere: 3.1±0.2mm, Attune: 3.7±0.7mm). While the Attune showed similar ranges for the medial and lateral condyles, the Sphere showed a larger lateral translation (Attune: 4.3±1.2mm, Sphere: 6.1±2.57mm). The unloaded swing phase showed larger ranges of A-P translation for all designs (Figure 1). Although some designs allowed less constrained motion pattern for the lateral condyle, reflected by large interindividual differences, only a few subjects exhibited a posterior translation with increasing flexion. Similar results were found for stair descent.

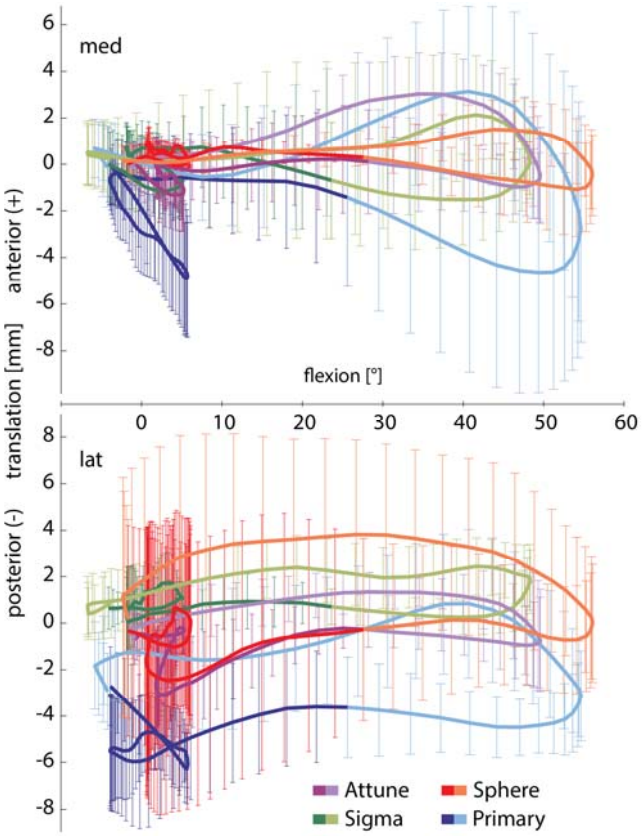

Figure 1: A-P translation-flexion coupling for the medial and lateral condyle of level gait. Dark: stance phase, light: swing phase. Mean and standard deviation over all subjects.

CONCLUSIONS

Innovative TKA designs are able to control the A-P translation in an attempt to mimic healthy kinematics. Improved knowledge of healthy tibio-femoral kinematics during complete cycles of dynamic activities of daily living, as well as their modulating factors, are thus required as a foundation for guiding implant design features. However, the results indicate that such design features could be helpful for targeting patient-specific deficits.

ACKNOWLEDGEMENTS

This study was funded by Medacta and DePuySynthes. subjects were recruited by Balgrist University Hospital, Winterthur Cantonal Hospital, Charité Berlin, Klinikum rechts der Isar München and Leuggern Hospital.

INTRODUCTION

Stiff-knee gait is a common gait pattern in children with cerebral palsy (CP), characterized by diminished and delayed peak knee flexion in swing [1]. Causes of stiff-knee gait are not well understood due to several factors contributing to it. However, over-activity of rectus femoris (RF) muscle is considered a primary cause [1, 2]. Biarticular muscle movement reduces energy consumption during walking because energy is transferred from one joint to the other [3]. As a result, inappropriate activity of RF, which produces insufficient knee flexion during swing, can lead to energy-inefficient compensatory movements [4]. Surgical treatments as RF transfer aims at altering the function of this muscle to improve the overall behavior of gait [2, 4].

It is in this context that we studied if RF transfer improved the muscle energy efficiency in subjects with stiff-knee gait analyzing musculoskeletal simulations in pre- and post-surgical conditions.

METHODS

The study included a group of 5 ambulatory patients with CP. The selection criteria were: GMFCS I and II, able to walk without orthoses or other assistance, diagnosis of symmetric spastic diplegia, stiff-knee gait, pre- and post-surgical gait analysis and surgical transfer of the RF to the sartorius to treat stiff-knee gait.

A musculoskeletal model, available in OpenSim, with 23 degrees of freedom and 92 musculotendon actuators to represent 76 muscles in the lower extremities and torso was used [5]. To simulate the transfer of the RF to the sartorius, the RF insertion was relocated to the effective insertion of the sartorius in the model. The simulated RF transfer closely approximates moment arms of transferred muscles measured [4, 6]. The computed muscle control algorithm [7] was used to estimate the muscle forces (F_i) from the kinematics and to adjust the model. Constraints on muscle excitations were included to have simulated muscle activity consistent with the EMG data of rectus femoris, vastus, gastrocnemius, hamstring and tibialis anterior. In addition, the estimations proposed by Umberger [8] was used to compute the individual muscle metabolic rate ($\dot{E}_i$) throughout the gait cycle. Muscle energy efficiency was quantified for each muscle for all gait cycle, as:

$$MEE_j = \frac{1}{N}\sum_{i=1}^{N}\left(\frac{\dot{E}_i}{F_i}\right)_j ,$$

were MEE_j is the muscle energy efficiency of muscle j and i is the total number of simulation steps during the whole gait cycle.

RESULTS AND DISCUSSION

The results shows (Figure 1) that muscle energy efficiency of RF improved after a RF transfer surgery, increasing the muscle forces developed with decrement of the muscle energy expenditure. Also, results show that the treatment had no effect in the overall behavior of other muscle groups.

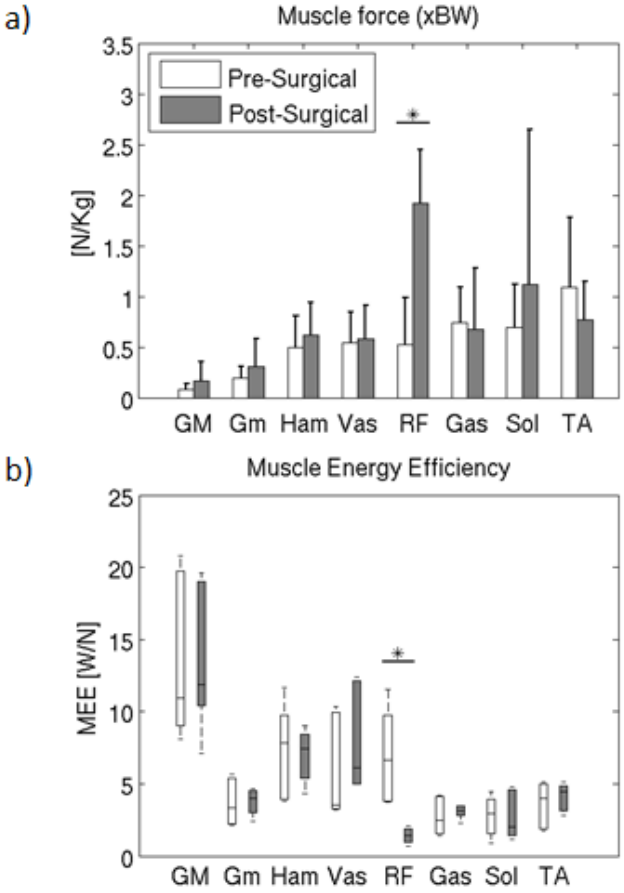

Figure 1: Mean behavior of muscle force (a) and muscle energy efficiency (b) throughout the gait cycle. A (*) indicates a significant difference ($p < 0.05$) in the Mann-Whitney U-test comparing pre- and post-surgery gait.

CONCLUSIONS

This study found that Rectus Femoris transfer surgery improved the muscle energy efficiency of RF which may improve the overall energetic behavior of subjects.

DEVELOPING A MINIMALLY INVASIVE DEVICE FOR BRAIN SURGERY

INTRODUCTION

Stroke is the leading cause of disability and death to human being. Among all, hemorrhagic stroke has a 30-day mortality rate of 25%~50%, which is three times higher than that of the other type of stroke [1], and the severity depends on where it takes place and how the condition is. Unfortunately, deep cerebral hemorrhage is the most common one. As hemorrhage occurs deep inside the brain, it is hard to evacuate without hurting the adjacent brain tissue, and that is why there is still no appropriate method for treatment. Therefore, we developed a stereotactic-assisted device aiming at evacuating the hemorrhage with a smaller damage to brain comparing to currently available endoscopic surgery processes.

METHODS

Device design:

We developed a new stereotactic-assisted device that consisted of fixing and pointing mechanisms used to guide the surgical mechanism to the blood clot (Figure 1, right). In order to firmly attach the device on patient's head in a non-invasive way, we designed a fixing mechanism with components that used the ear canals and the nasion as landmarks (Figure 1, left). Therefore, the fixing mechanism could establish a reference coordinate system through a program developed to register it to different imaging and spatial coordinate systems. We also employed a gear mechanism in the fixing system, thereby allowing the operator to fix the stereotactic-assisted device on the patient's head in only two steps.

In addition, we devised a pointing mechanism based on a spherical coordinate system with five degrees of freedom, to guide the surgical mechanism to the target position. This enabled the operator to finish adjusting the device to the target in only five steps comparing to six steps in current standard of care.

We, lastly, developed a surgical device. The special design enables the operator to evacuate a wide range of blood clot when fixed on the pointing mechanism.

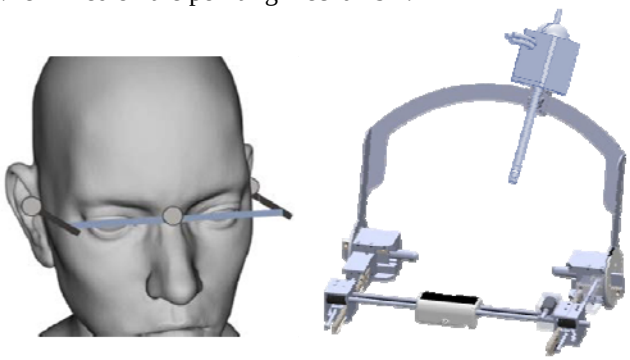

Figure 1: The points to fix the stereotactic-assisted device on patient's head, including ear canals and nasion (left) and the diagram of the whole device (right)

(Patent pending)

Testing experiments:

We divided the experiments into two parts, first is to verify the effectiveness of the pointing mechanisms. We set up the experiments with prosthetic heads and target points placed near the basal nucleus and the hypothalamus. After the experiments, we evaluated the deviation between the pointer and the target, the positions of which were determined using a coordinate-measuring machine.

In the second part, referring to Hossain's thesis [2], we made the brain model and the blood-like gel, according to its shape and physical properties, in order to simulate the real situation of hemorrhagic stroke as a surgery platform. Then we applied our device to the model to evaluate the feasibility and the functionality of the device. Lastly, we repeated the test with the endoscopic surgery process and compared the results with our device. After each test, we recorded the evacuation rate of the blood clot. And we also calculated the total volume of brain affected during the surgery by pouring the colored paint into the inserting point, representing the harm of the surgery to the brain.

RESULTS AND DISCUSSION

The results of the first part show that the deviation between the pointer and the target was 1.493 ± 0.482 mm, with a repeatability of 0.431 ± 0.169 mm.

For the second part, for now we have preliminarily tested our device by suctioning ketchup in jelly. From the test, our device was able to evacuate a wide range of ketchup when fixed on the pointing mechanism.

CONCLUSIONS

In conclusion, we have developed a minimally invasive device which is able to guide the surgical mechanism to the point of the blood clot with high accuracy. In addition, the special designs of the surgical mechanism enable the device to evacuate a wide range of blood clot without moving the entire surgical device, and we considered it can reduce the harm to the brain together with a high evacuation rate of blood clot.

DINOSAUR LOCOMOTOR BIOMECHANICS INFERRED FROM CANCELLOUS BONE ARCHITECTURE

INTRODUCTION

Cancellous bone is highly sensitive to its prevailing mechanical environment, and can adapt its architecture to suit this environment. The paradigm that relates cancellous bone architectural fabric (directionality) to its mechanical environment is the 'trajectorial theory'. This theory has received strong support from experimental and theoretical studies alike: continuum-level fabric directions show strong correspondence with continuum-level principal stress trajectories generated from physiological loading. It stands to reason that this concept will also work in reverse. Given a whole-bone geometry and cancellous bone architecture, if one constructs a continuum-level model of the bone and seeks to determine the loading regime(s) in which stresses align with observed cancellous bone architecture, the resulting loading regime(s) should be physiologically realistic. When framed in the context of a whole limb, this should result in a physiologically realistic posture, and thus provide unique insight into locomotor biomechanics in extinct species, such as theropod (carnivorous) dinosaurs.

METHODS

The three-dimensional architecture of cancellous bone in the femur, tibiotarsus and fibula of various extinct theropods was studied via computed tomographic scanning and qualitative-quantitative image analysis. This determined the primary fabric direction for each region of bone. Cancellous bone architecture was also studied in modern birds, the direct descendants of theropod dinosaurs.

The efficacy of the 'reverse approach' was first verified by developing integrated musculoskeletal and finite element models of a chicken hindlimb. These models were used to determine, in an iterative fashion, the hindlimb posture where principal stresses best lined up with observed cancellous bone architecture: where the angular deviation between stress vectors and fabric directions was least. The same approach was then applied to two species of extinct theropods, *Daspletosaurus torosus* (mass ≈ 2.7 tonnes) and *Troodon formosus* (mass ≈ 45 kg). The reconstruction of muscles in the extinct species was based on analysis of muscle scarring patterns on the bones and comparison to modern relatives (birds and crocodilians).

RESULTS AND DISCUSSION

The 'solution posture' identified for the chicken was quite comparable to that used at around mid-stance during avian terrestrial locomotion (Fig. 1A), with a femur that was 35° below the horizontal. Predicted femoral bone loading was also consistent with previously reported *in vivo* strain gauge data for birds, with torsion as the dominant loading regime. This suggests that the reverse approach can indeed help infer posture and bone-loading mechanics in extinct theropods.

The solution posture identified for *Daspletosaurus* (Fig. 1B) supports previous interpretations of habitual posture in other large species (e.g., *Tyrannosaurus*), in that the femur was held subvertically (70° below horizontal). In the solution posture for *Troodon*, the femur was more horizontally oriented, but not to the degree seen in modern birds (55° below horizontal; Fig. 1C). This befits its phylogenetic position, as a derived but not quite avian theropod. In *Daspletosaurus*, the femur was loaded largely by mediolateral bending, yet in *Troodon* there was a substantial torsional component (in addition to bending), intermediate between the condition in *Daspletosaurus* and the chicken.

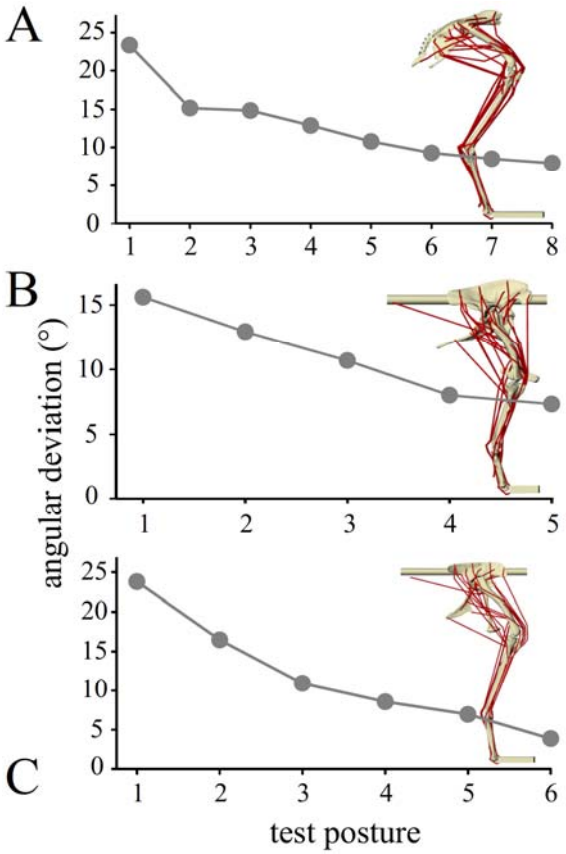

Figure 1: Convergence of principal stress vectors and fabric directions in the femoral head for each species, with musculoskeletal models in their identified 'solution postures'. A, chicken. B, *Daspletosaurus*. C, *Troodon*.

CONCLUSIONS

The reverse application of the trajectorial theory has provided new insight into locomotor biomechanics in extinct theropods. The results of this study suggest that the evolution of locomotion in theropods was gradual through time, with changes in femoral orientation and bone loading regimes occurring in a step-wise fashion. Owing to the generality of the reverse approach, it could also provide insight on locomotion and its evolution in other groups of extinct vertebrates, such as stem-tetrapods or therapsids.

EXTINCT DINOSAURS AND MODERN BIRDS EXHIBIT WALKING, GROUNDED RUNNING AND RUNNING GAITS

INTRODUCTION

Much interest surrounds how extinct, carnivorous theropod dinosaurs (animals like *Tyrannosaurus* and *Velociraptor*) walked or ran. The most direct evidence of locomotion in extinct dinosaurs is fossilized sequences of footprints (trackways); these record the actual movement and placement of feet, revealing unique insight into theropod locomotor kinematics. Only two kinds of obligate, striding bipeds are alive today, ground-dwelling birds and humans, birds being the direct descendants of carnivorous dinosaurs. However, humans employ a discontinuous gait pattern, where walking and running are distinct and discrete; whereas birds use a more continuous gait pattern, where walking merges into running via an intermediate 'grounded running' pattern, that does not have an aerial phase. These differences are reflected in many kinematic parameters previously measured: these parameters change continuously with increasing speed in birds, but in humans they typically show an abrupt, discontinuous change at the walk-run transition. Thus, whether a given extinct theropod exhibited a continuous or discontinuous locomotor behaviour, this should be detectable in kinematic measurements made from its tracks. To investigate this prediction, the present study examined how step width – the mediolateral distance between successive footfalls – changes with speed.

METHODS

Kinematic measurements were made from humans (3 subjects) and 11 species of ground-dwelling bird (from 45 g quail to 80 kg ostriches), moving across a range of speeds from slow walking to fast running. Measurements of step width were made from a unique set of theropod trackways from Virginia, USA, dated at approximately 211 million years old. These trackways show the theropod trackmaker making significant changes in speed throughout the length of the trackways; eight trackways in total were analysed. The similarity in size and morphology of all the footprints suggests that a single species is probably recorded in the trackways, and that the trackmakers were all of similar size. As speed is unable to be measured for extinct theropods, stride length was used as a proxy for speed; stride length was also used as a proxy in the bird dataset. Relative to the estimated hip height of the theropod trackmakers, it is clear that some of these animals went up to a fast run (relative stride lengths > 3.5).

RESULTS AND DISCUSSION

In general, step width decreased with speed in all three groups; at fast running speeds step width could become negative (feet crossing the midline). Paralleling the results for other, previously studied kinematic parameters, step width in humans exhibited a large and sudden decrease with speed, at the walk-run transition (Fig. 1A). Five species of bird showed a decrease in step width with speed, and this decrease was continuous in nature (Fig. 1B; paralleling previous studies' results). No pattern was detected for the other six species of bird, but this could be explained as a result of body proportions: these species were shorter and squatter for their mass. In the theropod trackways analysed, step width decreased with speed, and this decrease was continuous in nature; no evidence for a discrete gait transition was apparent (Fig. 1C). These results suggest that the theropod trackmakers did not have discrete gaits, but rather had a continuous locomotor repertoire as in modern birds, possibly including grounded running.

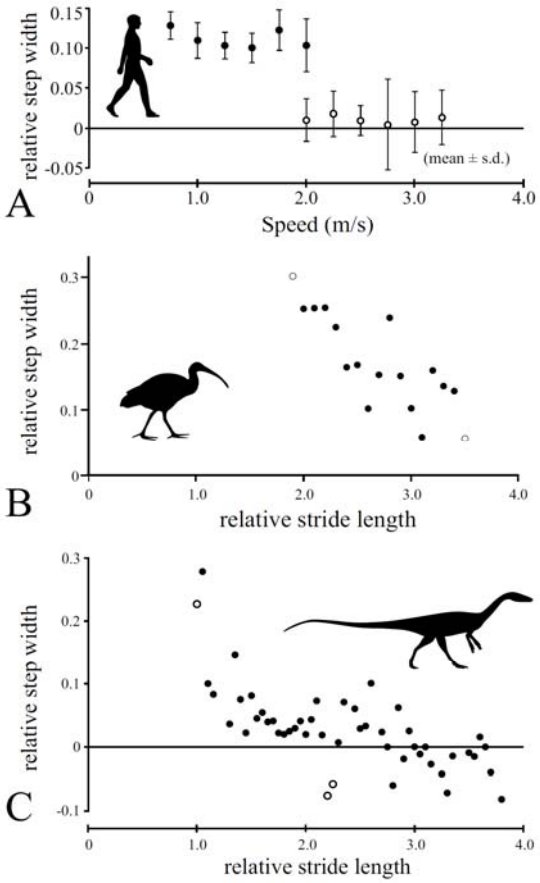

Figure 1: Step width patterns observed for A, humans (exemplar subject), B, birds (exemplar species: *Threskiornis molucca*), and C, extinct theropods.

CONCLUSIONS

The unique locomotor repertoire of modern birds has great antiquity, having begun to be assembled more than 50 million years before the first birds appeared. Additionally, as grounded running could confer a number of benefits for a predator (e.g., greater stability, lower bone and muscle stresses, improved stability of the head, enhancing visual acuity), these benefits may have helped facilitate the evolution of such behaviour in the first place.

HIERARCHIC CONTROL OF FLAPPING FLIGHT OF A BUTTERFLY

[1] **Kei Senda**, [1] Naoto Yokoyama, [1] Yuto Inoue, [2] Norio Hirai, [3] Makoto Iima, and [4] Noriyasu Ando

INTRODUCTION

Butterflies can maintain desired flapping flights against environmental uncertainties and variations, e.g. gust, weight gain or loss, etc., using their adaptation-capability. Such an adaptive function is considered to emerge from the interaction of the nervous system, body, and environment. We call the adaptive motor function the motion intelligence. There are many unknown points about control of flight for stabilization or maneuver, e.g. how the butterfly moves, how the control is realized, etc. The objective of this study is to understand the flight controls of a flapping butterfly.

METHODS, RESULTS AND DISCUSSION

This study investigates these issues by the biological analysis through experimental observations of living butterflies and by the systems engineering or synthetic approach [1-4].

An experimental system with a low-speed wind tunnel is constructed to measure various flapping flight motions of actual butterflies, *Parantica sita niphonica*, quantitatively. A dynamical model is constructed by using a panel method for aerodynamics. A periodic trajectory of flapping flight is searched based on the model. Using the constructed numerical simulator and the obtained periodic trajectory, it is shown that the free-vortices in the wakes provide a type of stabilization effect [1, 2]. This feedback stabilization effect by interaction of the body and environment can be considered as a low-level control, i.e. a kind of preflex [5]. We call this low-level control as the implicit control. An animal is considered to have a hierarchic control structure. But, it is impossible to make stable flight by the feed-forward with implicit control, in case of the actual butterfly, *P. sita*. In fact, a free flying butterfly repeating a same flapping is unstable, and it falls down after several flapping periods [1, 2].

A feedback control system is discussed to realize a stable flight as a high-level control, which is called an explicit control, in addition to the implicit control. At first, two kinds of explicit controllers are designed based on the optimal regulator (LQ) theory. The entire control system is then the hierarchical control with the implicit and explicit control. Secondly, steady flights are realized in the simulator, in which the controllers are implemented to the original non-linear system. Stability of the steady flight is analyzed. Thirdly, the latency, that is the time delay to react from external stimulus, exists. A controller considering the latency as the time delay is designed. The above controllers for no time delay become unstable. However, a redesigned controller considering the time delay realizes a stable flight. Finally, maneuvers of butterflies are realized in the simulator for a ramp input. Controls of the actual butterfly, *P. sita*., and the simulator are discussed by comparing flapping trajectory changes between the experimental observations and the numerical simulations. The numerical simulations are qualitatively similar to the data from an actual butterfly. Accordingly, this study suggests the hierarchical control with the implicit and explicit control.

To discuss propriety of the control, electromyograms (EMGs) of flight muscles of the butterfly, *P. sita*, are measured. Three-dimensional images of thoracic muscles (Figure 1) are obtained by a micro-XCT. Skeletal structure of the thorax was also investigated to know points of attachment of muscles using the binocular. Major indirect flight muscles including dorsal longitudinal muscles and dorso-ventral muscles of this species are identified. At the forewing base, small sclerites, e.g., basalare, subalare, and pleural wing process, are observed. Relating direct flight muscles, e.g. basalar muscles and subalar muscles, are attached below the forewings via basalare and subalare, respectively. EMGs of these indirect and direct muscles are obtained. The EMGs show that *P. sita* basically uses indirect muscles for upstroke and downstroke and uses direct muscles to control forward and rearward inclination of forewings.

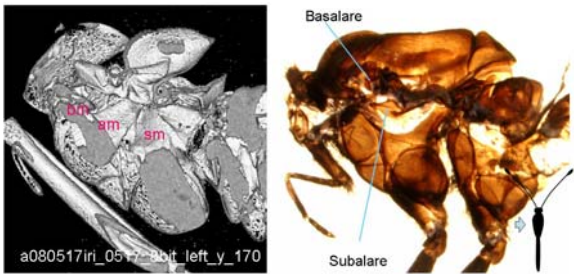

Figure 1: Micro-XCT image and exoskeletal thoracic structure of *Parantica sita niphonica*.

CONCLUSIONS

This study has shown that the designed hierarchical controller is qualitatively similar to the actual butterfly, *P. sita*. This study has discussed the propriety of the controller using the EMGs of the indirect and direct muscles.

INTRODUCTION

The first step to a realistic musculoskeletal model (SIMM, MusculoGraphics, Inc) of a horse, is an accurate representation of the joint constraints. The aim of this cadaver study is to determine the necessary number of degrees of freedom (DOF) in every joint of the horse forelimb (Figure 1). Hypotheses of the DOF's are made based on surface joint morphology and tested with empirical data. The ROM is measured to determine the angular constraints. Calculation of the orientation and translation of the instantaneous axis of rotation (IAR) over the entire ROM determines the stability of the IAR. The outcome of this study will determine the minimal number of DOF's to build a musculoskeletal model of the equine forelimb.

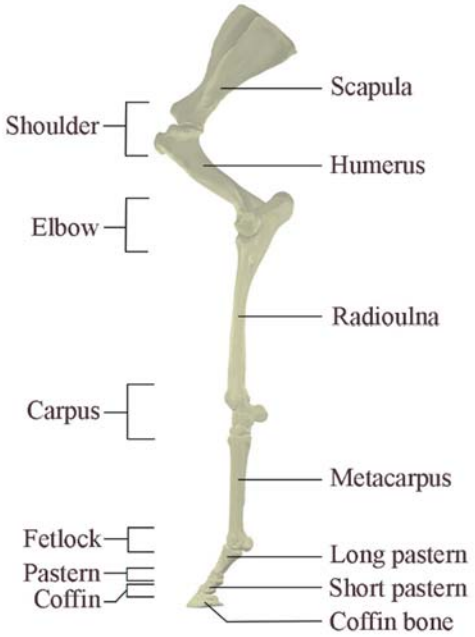

Figure 1: Skeletal forelimb of a horse.

METHODS

Four intact horse cadaver forelimbs were used to determine the ROM and IAR of the shoulder, elbow, carpus, fetlock and pastern+coffin. Standardized cuts were made at the midlevel of each forelimb segment to eliminate the influence of muscle groups. Integrity of the joint capsules was not compromised. Bone pins, fixed with reflective marker triades, were drilled into the scapula, humerus, radioulna, metacarpus, long pastern and trough the hoof into the coffin bone. During the dynamic trials, the different joints were manually moved independently in all three anatomical rotational DOF's: flexion-extension (FE), abduction-adduction (AA) and internal-external rotation (IE). The three dimensional coordinates of the marker triades were recorded using an infra-red six camera system (VICON). After dissection, anatomical markers were placed at standardized locations. Via singular value decomposition, the anatomical marker coordinates were transformed to the dynamic trial data. Right handed local coordinate systems were defined for all forelimb bones using the transformed anatomical marker coordinates. Kinematics were calculated using a customized MATLAB script based on the software package KineMat [1]. The IAR was calculated using the finite helical axis method, their orientation and translation were used to describe the rotational axis over which the distal segment rotated relative to the proximal segment. The IAR was not calculated for DOF with a ROM below 15˚ [2].

RESULTS AND DISCUSSION

Based on the joint surface morphology, the shoulder is classified as an elliptical ball and socket joint, which allows motion into three rotational DOF's. This is also reflected in the measured ROM (FE: 46˚ ±6, AA: 24˚ ±17, IE: 54˚ ±9). The IAR did show a change in orientation throughout the ROM. The elbow and the fetlock are both classified as hinge joints, allowing motion into the FE plane (Elbow 89˚ ±16, Fetlock 103˚ ±7). Within this plane, both joints did not display changes in the orientation of the IAR. The results do show small ROM angles within the other DOF's (IE and AA <15˚). The DOF of the carpus is difficult to classify based on joint surface morphology because it consists of multiple rows of small bones. With the used method the individual effect of the different layers on the ROM and IAR was not taken into account. The carpus shows a clear ROM in the FE plane (FE: 162˚ ±20, IE and AA <15˚) and displays a translation of the IAR within FE. The results of the combined pastern and coffin joint show a ROM in all directions (FE: 59˚ ±14, AA: 32˚ ±12, IE: 25˚ ±9). Individual ROM of pastern and coffin could be lower because the motion of both joints was measured at the same time. The pastern and coffin joints are both classified as saddle joints, allowing motion into 2 DOF's, however the joint surfaces are relative flat which could explain the measured 3 DOF's.

CONCLUSION

If angles below 15˚ are not taken into account, the hypothesised DOF's based on the joint surface morphology agreed with the measured DOF's. Measurable IAR translation and orientation should be taken into account when creating a musculoskeletal model of the horse.

STRIDE LENGTH AS A SPEED INDICATOR IN FAST QUADRUPEDS

[1] **Hasti Hayati**, [1]David Eager, [1]Terry Brown and [1]Ardian Jusufi
[1]University of Technology, Sydney

INTRODUCTION

Studies of animal locomotion have shown that longer stride and higher stride frequency results in an increase of speed [1]. In other words, animals taking a longer stride coupled with higher stride frequency can travel faster. Speed also is in direct proportion to the average ground reaction forces (GRF) exerted by limbs on the ground.

Greyhounds are one of the fastest quadrupeds with the estimated top speeds of 65 km/h. Usherwood et al. 2005 [2] estimated and compared the GRFs in racing greyhounds running in both bend and straight sections of a racing track by calculating the footfall timing of each legs during a complete stride. It was concluded that as there was no significant difference in footfall timing between straight and bend sections, greyhounds do not reduce their speed while turning [2]. Moreover it was also estimated that the greyhound experiences 65% increase in their limb forces when negotiating the turn [2].

Here we measure the stride length of greyhounds running in a straight section and compare with those going around a bend. The paw print of a greyhound running in a semicircular racing track is surveyed. This study sought to determine whether there is a significant difference of stride length. Results suggest that greyhounds exhibit greater stride length when running in the straight section than when going around the bend which may indicate speed alteration in turning.

METHODS

To compare the stride lengths of a greyhound in straight and bend section in a simulated racing condition a paw print analysis was conducted. Trials were conducted at Wentworth Park racing track, Sydney, NSW. Each run started on a straight section (Home Straight) followed by a turn of 52m radius and the second straight (Back Straight). The distance in each race covered was 280m in length within approximately 26s.

The video footage of the entire race showed that the very first paw to contact the ground was the right fore-leg. The stride length is also defined as the distance from the initial contact point of one paw to the next initial contact point of the same paw.

Figure 1 shows a schematic view of Wentworth Park track. To compare the stride lengths of the straight and bend sections, ten strides were chosen from the Back Straight (highlighted blue) and ten strides from the apex of the Northern Turn (highlighted green). To ascertain whether there is a significant difference between the stride lengths of these sections, a one-way Analysis of Variance (ANOVA) was performed using MATLAB R16. The significance was set at $P<0{\cdot}05$.

RESULTS AND DISCUSSION

The mean stride lengths in Back Straight (M=5.53m, SD=0.03) and Northern turn (M=5.02m, SD=0.08) was calculated. The result of ANOVA test showed a significant difference between the stride lengths in straight and bend section [F (1, 18) =20.7, P=0.0002]

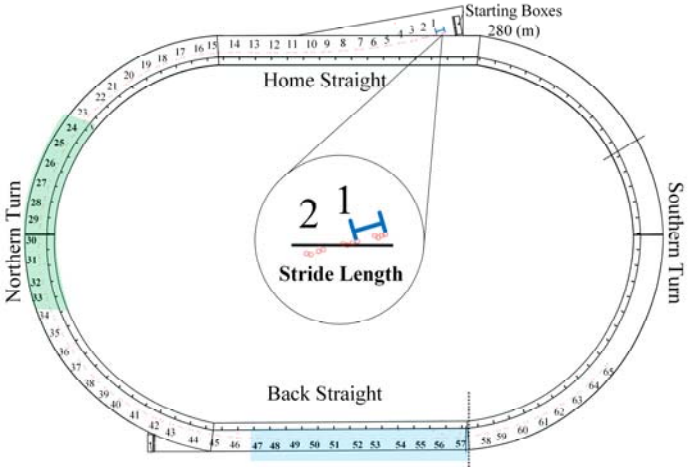

Figure 1: Schematic view of Wentworth Park race track and paw prints of greyhound running at the track. The blue and green highlighted areas shows ten strides at Back Straight and ten strides at Northern Turn, respectively.

The result of a post ANOVA analysis (t-test: Paired Two Samples for Means) showed that stride lengths at straight section are significantly greater than those of turn section [t (9) =4.1, P=0.001]. This may suggest the speed changes during the bend section. However more experimental results are needed to validate the accuracy of the results.

CONCLUSIONS

In this study, the stride lengths of a greyhound running in straight and bend sections of a racing track were measured and compared. The results showed that the stride lengths in a straight section were significantly greater than those in a bend section. These results may indicate that the greyhound does not maintain its speed when negotiating a bend.

INTENSITY-DEPENDENT ACTIVITY OF HAMSTRING MUSCLE REGIONS DURING ISOMETRIC KNEE FLEXION AND HIP EXTENSION CONTRACTIONS

András Hegyi, Taija Finni and Neil Cronin
University of Jyväskylä
Corresponding author email: andras.a.hegyi@jyu.fi

INTRODUCTION

Bi-articular components of hamstring muscles cross both the knee and hip joints, and thus contribute to knee flexion and hip extension. To control the independent rotation of these joints, complex within-muscle coordination may be required. Although task-dependent intramuscular coordination has been found in cat biceps femoris, semimembranosus [1] and semitendinosus [2], few studies have examined region-specific (i.e. proximal vs. distal) activity of the hamstring muscles in humans.

Therefore, the aim of this study was to examine whether recruitment of muscle regions within the biceps femoris and semitendinosus is dependent on the intensity level, and whether the relative contributions of muscle regions differ between knee flexion and hip extension contractions.

METHODS

Fifteen young males (age = 25 ± 4 yrs) participated in this study. 15-channel high-density electromyography (HD-EMG) arrays with 10 mm inter-electrode distance were attached over the semitendinosus and biceps femoris long head muscles to collect EMG data along each muscle.

After preparation and warm-up, isometric knee flexion and hip extension contractions were performed in a dynamometer. First, maximal voluntary contractions of knee flexion and hip extension, and combined knee flexion and hip extension were performed, from which the highest activity for each channel was used to normalize EMG data. Submaximal knee flexion and hip extension trials were then performed. 25, 50 and 75% of MVICs were reached and maintained for 2-3 seconds. These were performed in a random order, and two contractions were recorded at each intensity for better reliability. Visual force-time curve feedback was provided during contractions.

Root mean square EMG activity for every contraction was calculated for all channels and normalized to the highest MVIC activity of the corresponding channel. Channels in the proximal and distal regions of the muscles were then averaged. Proximal-distal activity ratio (PD ratio) was calculated as proximal activity divided by distal activity multiplied by 100. Differences in PD ratio between joints and intensity levels for each muscle were tested with repeated measures ANOVA. The significance level was set at $P < 0.05$.

RESULTS AND DISCUSSION

Figure 1 shows PD ratio at different intensities of knee flexion and hip extension contractions.

Regarding BF, PD ratio was higher in hip extension than in knee flexion in general, i.e. relative recruitment of the proximal region was higher. However, in ST knee flexion showed higher relative proximal activity than hip extension. It is important to mention that in absolute terms, distal activity was higher than proximal activity in almost every contraction type and intensity level in each muscle.

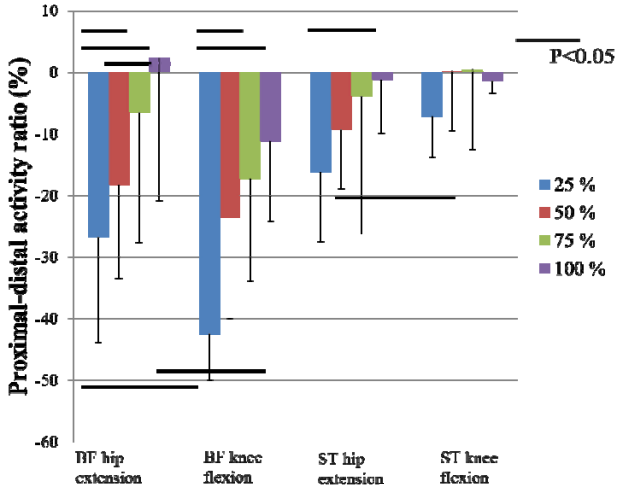

Figure 1: Proximal-distal activity ratio of biceps femoris and semitendinosus in knee flexion and hip extension contractions. Zero (0) represents equal recruitment of proximal and distal regions.

With increasing intensity, PD ratio increased in both muscles in hip extension and in BF during knee flexion. ST showed more homogeneous muscle recruitment than BF. These results show that human hamstring muscles are activated in a task- and intensity-specific way, similar to the rectus femoris [3], which may rely on the multi-branch innervation pattern of these muscles [4] and may indicate small territories of motor units within the examined hamstring muscles.

CONCLUSIONS

Complex within-muscle coordination in hamstrings provides further insights into hamstring muscle function. Its possible relevance to high hamstring injury rates needs to be examined in the future. Our study also suggests that HD-EMG may provide a more comprehensive overview of hamstring muscle function compared to bipolar EMG due to the task- and intensity-specific contribution of different muscle regions.

ILIOCAPSULARIS: TECHNICAL APPLICATION OF FINE-WIRE ELECTROMYOGRAPHY, AND DIRECTION SPECIFIC ACTION DURING MAXIMUM VOLUNTARY ISOMETRIC CONTRACTIONS.

INTRODUCTION

The Iliocapsularis muscle of the anterior hip is thought to play an important role in hip function. Iliocapsularis originates on the inferior border of the anterior-inferior iliac spine, although most fibres arise from an elongated attachment to the anterior capsule; inserting distally to the lesser trochanter [1, 3, 4]. It provides the most substantial muscular attachment to the anterior hip capsule [2] and is hypothesized to have a dynamic role to reduce capsular impingement [3] and in augmenting joint stability [1, 2]. Current understanding of Iliocapsularis' function is based on limited cadaveric and radiographic studies, with no reported real time investigation of muscle activity with electromyography (EMG). Located deep over the hip joint intramuscular fine-wire EMG is required to evaluate its activity directly.

The primary aim of this study was to describe a technique for insertion of intramuscular EMG electrodes into Iliocapsularis and report its activation in different directions of hip maximum voluntary isometric contraction (MVIC).

METHODS

Fifteen healthy volunteers (10 M, mean age (SD) 22 (2) years) who were free from hip pain, were recruited for electrode insertion and to perform MVIC's in nine directions (performed at 0° and 90° of hip flexion).

The insertion procedure was developed based on cadaveric observation, imaging [3] and anatomical studies [2, 4]. An insertion path passing medial to lateral, through sartorius and iliacus was considered as the most appropriate, to avoid the tendon of rectus femoris, and the femoral neurovascular bundle. An intramuscular electrode was then inserted with guidance from real-time ultrasound. The electrode was connected to a Trigno™ Wireless EMG System (Delsys Inc., Boston, USA), and two repetitions of MVIC's in each direction was performed. EMG data was normalised to the highest amplitude across all tasks (%Peak).

RESULTS AND DISCUSSION

Intramuscular electrode placement was tolerated well with no adverse events. One participant inadvertently removed the electrode prior to the EMG recording. The greatest activity from the remaining 14 participants (9 male, 22 (2) years) was recorded during resisted hip flexion at 90° (Median (IQR); 100.0 (1.2) % MVIC) and lowest activity during hip extension, 0° (0.5 (0.3) % MVIC) (Figure. 1). EMG amplitude was variable between participants during hip flexion in neutral (0°), abduction and external rotation (90°) (Figure.1). This data; taken with the attachment of iliocapsularis to the hip joint capsule and its small cross-sectional area, is consistent with a local action on the joint capsule rather than significant contribution to hip torque.

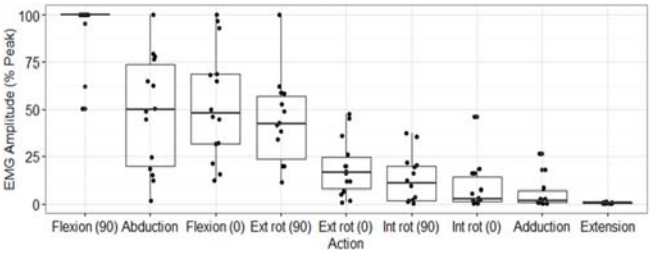

Figure 1: Box (median, interquartile range and range) and scatter plot illustrating amplitude (%Peak) of iliocapsularis EMG across all actions.

The Iliocapsularis muscles proposed role in tensioning the anterior capsule to avoid impingement [3], is supported by high EMG amplitude during positions of possible impingement such as flexion with the hip at 90° flexion. Iliocapsularis' hypothesized action to stabilize the hip anteriorly in hip extension [1, 2] was not supported by findings of relative inactivity in this position, but does not exclude its potential role as an active stabiliser in other positions, dynamic tasks or populations with compromised passive stability.

CONCLUSIONS

This paper provides the first description of insertion of intramuscular EMG electrodes into the iliocapsularis muscle. Confirming the viability of this approach and providing a technical guide for future EMG investigations. Greater EMG amplitude during hip flexion, particularly when flexed to 90°, supports the hypothesis of iliocapsularis having a role on the joint capsule in this position.

THE BILATERAL DEFICIT: A DIFFERENCE IN CONTRALATERAL LIMB TORQUE

[1] **Graham Z MacDonald**, [2]Nicole Mazara, [1]Walter Herzog, and [2]Geoffrey A. Power

INTRODUCTION

The bilateral (BL) deficit is defined by a reduction in force during a BL contraction relative to the sum of left and right unilateral (UL) contractions. Henry and Smith (1961) first observed the BL deficit, concluding that it is likely attributed to a reduction in dominant limb force during BL contractions. Since this initial finding, 70% of studies assessing differences in UL versus BL force production have found a BL deficit when performing upper body isometric maximal voluntary contractions (MVC) [3]. Despite commonly being presented, the underlying mechanisms of the BL deficit remain elusive. This elusiveness is likely the result of the BL deficit being a plastic phenomenon [2,3]. In support of Henry & Smiths (1961) original findings, Oda & Moritani (1994) also found a decrease in dominant arm force and EMG during BL contractions when compared to UL contractions, concluding that UL force differences in contralateral limbs requires further investigation. The purpose of this study was to further investigate whether or not contralateral differences in UL torque are associated with the presence of a BL deficit. We hypothesized that the BL deficit is associated with a difference in contralateral limb torque.

METHODS

14 male subjects (24.8 ± 0.7 yrs, mean ± SE) participated in the study. All subjects were right arm dominant. Subjects performed isometric MVCs of the elbow flexors at 120° of flexion, both UL and BL. Each contraction was repeated twice and MVCs were verified (≥90% activation) using the interpolated twitch technique. Torque was recorded with a Humac Norm dynamometer. Electromyography (EMG) was recorded with surface electrodes on the biceps brachii (agonist) and lateral head of the triceps brachii (antagonist). Both torque and EMG measurements were recorded from 7-7.5 secs into the MVC. EMG root mean square (EMG_{RMS}) was taken over the 500ms window with each subject's biceps and triceps brachii EMG_{RMS} being normalized as a percentage of their UL MVC EMG_{RMS} for both UL and BL contractions. MVC torque recordings were plugged into the BL index (BI) to determine the presence of a BL deficit [2].

$$BI\ (\%) = (100 \times (BL / UL\text{-}Lt + UL\text{-}Rt) - 100$$

RESULTS AND DISCUSSION

A BL deficit was present in 10 out of the 14 subjects. The sum of the UL-Lt + UL-Rt produced significantly greater torque than the BL contraction (113.6 ± 6.1 Nm vs. 104.1 ± 4.5 Nm, $p < 0.01$). In the UL conditions, the dominant UL-Rt produced significantly greater torque than UL-Lt (59.1 ± 3.6 Nm vs. 54.5 ± 2.8 Nm, $p < 0.05$). When comparing UL and BL biceps brachii EMG_{RMS} activity for the left and right arm, the right arm had a 12% decrease in EMG_{RMS} amplitude during the BL condition relative to the UL condition ($p < 0.05$), while the left arm EMG_{RMS} amplitude did not change between conditions. Furthermore, there was no significant differences in triceps brachii EMG_{RMS} amplitude between UL and BL conditions for both the left and right arm, despite the left arm having significantly greater antagonist co-activation compared to the right arm for both UL (55.0 ± 5.9% vs. 37.9 ± 5.3%, $p < 0.001$) and BL (52.9 ± 6.5% vs. 36.2 ± 4.6%, $p < 0.01$) conditions.

With one outlier removed, a Pearson's correlation showed a strong negative correlation between the difference in UL-Lt and UL-Rt torque and the presence of a BL deficit, $r(11) = -0.60$, $p < .05$, with the difference in UL-Lt and UL-Rt torque explaining 36% of the variation in the BL deficit (Figure 1).

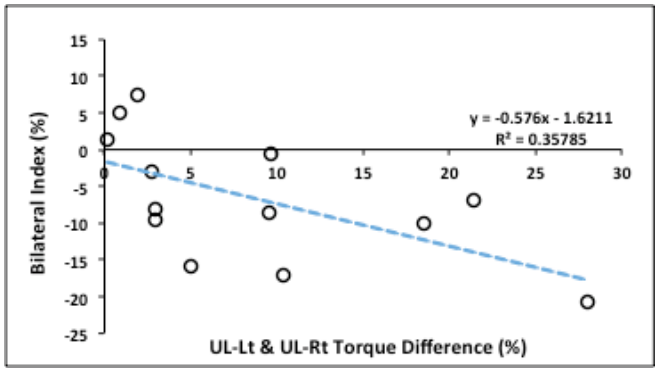

Figure 1: relationship between UL torque differences of contralateral limbs and the presence of a BL deficit.

CONCLUSIONS

Based on the present findings, the dominant right arm displayed a reduction in muscle activation (EMG_{RMS}) and no change in antagonist co-activation during the BL compared to the UL contraction. The presence of a BL deficit is likely the result of a reduction in muscle activation in the dominant arm during BL contractions, leading to a reduction in torque production. A decrease in muscle activation in the dominant arm during a BL contraction likely accommodates for the reduced ability to produce torque in the non-dominant (UL-Lt) arm. This adaptation would allow for symmetrical torque production during BL contractions. This hypothesis is supported by the average difference in UL-Lt and UL-Rt torque (7.8%) and the average BL deficit (8.4%) presenting similar values.

RELIABILITY OF FORCE EVOKED VIA WIDE PULSE HIGH FREQUENCY NEUROMUSCULAR ELECTRICAL STIMULATION

[1]**Nicolas Place**, [1]Bengt Kayser and [1]Daria Neyroud
[1] Institute of Sport Sciences, Faculty of Biology and Medicine, University of Lausanne, Switzerland
Corresponding author email: nicolas.place@unil.ch

INTRODUCTION

Recently, the use of wide pulse, high frequency neuromuscular electrical stimulation (namely WPHF NMES) has been proposed to overcome some of the pitfalls of conventional NMES (for reviews see [1,2]). Despite constant stimulation intensity, responders to WPHF NMES show force increases during the course of a sustained contraction (i.e. "extra force"). This extra force was suggested to originate from a reflexive recruitment of motor units. However, recent works observed high inter-individual and intra-individual variability in the force evoked with WPHF (e.g. [3]). In addition, to date it is unclear whether the amount of extra force or the variability of these evoked force differ between stimulation modalities (nerve trunk *vs.* muscle belly). The purpose of the present study was to evaluate the reliability of force evoked by WPHF NMES delivered over the tibial nerve trunk *vs.* plantar flexor muscle belly.

METHODS

Ten healthy participants (5 women, 5 men; 28 ± 4 years) volunteered to take part to four testing sessions. Each of the session involved ten 20-s WPHF NMES contractions (pulse duration = 1 ms, frequency = 100 Hz, initial target force = 5% maximal voluntary contraction (MVC), as determined with short tetanic train of 1 s) interspaced by 40 s recovery. NMES was delivered on the dominant limb either via tibial nerve stimulation (NERVE 1 and NERVE 2 sessions) or with two surface electrodes fixed over the calf muscle (MUSCLE 1 and MUSCLE 2). In both conditions, sessions 1 and 2 were identical in order to assess test retest reliability of the evoked force. Mean evoked force and force time integral (FTI) of each contraction were quantified. Intraclass correlation coefficients as well as inter-individual and intra-individual coefficients of variation were calculated. Surface electromyography of the *soleus* muscle was recorded to quantify sustained activity after the end of the 20-s stimulation period. The discomfort associated with both stimulation modalities was also quantified using a visual analog scale from 0, corresponding to "no discomfort", to 10, corresponding to "worst possible discomfort". Paired t-tests or repeated measure ANOVAs were performed to compare mean force, FTI or discomfort between conditions (NERVE 1 vs. NERVE 2; MUSCLE 1 vs. MUSCLE 2 and NERVE 1 vs. MUSCLE 1). Data are presented as mean ± SD and the level for statistical significance was set to $p < 0.05$.

RESULTS AND DISCUSSION

For both nerve trunk and muscle belly stimulation, intra-individual test-retest reliability was good (intraclass correlation coefficient > 0.9)

As illustrated in Fig. 1, some participants showed "extra force" during the course of the 20-s contraction, whereas others did not. This resulted in a relatively high inter-individual variability (coefficient of variation between 140 and 180%), with no notable difference between nerve trunk or muscle belly stimulation. Interestingly, mean force or FTI was similar ($p>0.05$) between nerve trunk and muscle belly stimulation, i.e. responders to WPHF NMES evoked at the nerve trunk also responded when muscle belly was stimulated with large electrodes. Sustained EMG activity was found in responders, with no difference between both stimulation conditions, indicating that the extra force was probably of central origin whatever the stimulation site.

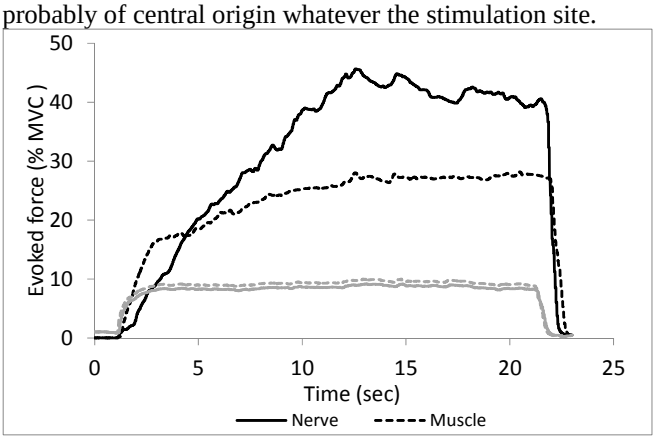

Figure 1: Example of force traces evoked via tibial nerve (continuous line) or over the muscle (dotted line) WPHF NMES for 20 sec. Black lines represent a responder whereas grey lines show traces from a non-responder. MVC = maximal voluntary contraction.

Discomfort was lower for muscle belly as compared to nerve trunk stimulation (respectively 2.3 ± 2.0 vs. 4.6 ± 3.3, $p<0.05$). However, discomfort does not appear to explain differences in extra force production between individuals as no correlation was found between this variable and the magnitude of the evoked force.

CONCLUSIONS

(i) Intra-individual test-retest reliability of forces evoked by WPHF NMES is relatively good, whereas inter-individual variability was large for both nerve trunk and muscle belly stimulation. (ii) Similar force levels are developed in response to WPHF NMES delivered over a nerve trunk and muscle belly. (iii) We advise to individualize stimulation location before any attempt of implementing WPHF NMES in rehabilitation/training programs.

FEMORAL NERVE VS MOTOR POINT STIMULATION FOR THE ASSESSMENT OF QUADRICEPS MUSCLE INHIBITION IN HEALTHY YOUNG WOMEN

INTRODUCTION

Muscle inhibition (MI) is one of the most important manifestations in joint conditions that displays high levels of pain, such as patellofemoral pain syndrome and knee osteoarthritis [1]. MI is evaluated through the interpolated twitch technique (ITT), which consists in the comparison between the supramaximal twitch response obtained at rest and the supramaximal twitch torque superimposed to a maximal voluntary isometric contraction (MVIC).

The femoral nerve (FN) is considered by many the optimal site for the ITT [2,3] due to its superficial location, so that FN stimulation is expected to produce maximal or close to maximal neural activation. However, electrical stimulation at the inguinal area is usually uncomfortable due to its proximity to the genital area, which makes supramaximal FN stimulation very unpleasant.

The motor point (MP) has been proposed as alternative to FN stimulation for the ITT [4]. It is defined as the anatomical region at which the motor axons penetrate the muscle belly and is the skin area over the muscle where the stronger muscle contraction is generated with the smallest current voltage. Due to its location at approximately mid-thigh, and therefore distant from the genital area, the MP seems to be a less uncomfortable area of stimulation as opposed to the FN.

The purpose of this study was to compare the effectiveness of FN versus MP stimulation for the evaluation of quadriceps MI in healthy young women. We also measured current voltage, discomfort level and resting doublet peak torque at different knee joint angles to infer on the optimal stimulation site and knee angle for the evaluation of MI.

METHODS

Sixteen healthy women had their quadriceps MI determined through the ITT. Supramaximal paired stimuli were delivered either to the FN or to the quadriceps MP before and during MVICs of knee extensors at 5 different knee flexion angles (15°,30°,45°,60°,90°) and the corresponding resting and interpolated doublet torques were quantified. Current voltage and discomfort levels were also evaluated.

RESULTS AND DISCUSSION

MI did not differ significantly between the two stimulation modalities. However, smaller resting doublets at 30°, 60° and 90° (Figure 1L), higher discomfort at 15°, 30° and 90°, and higher supramaximal current voltage were observed for MP compared to FN stimulation ($p<0.05$).

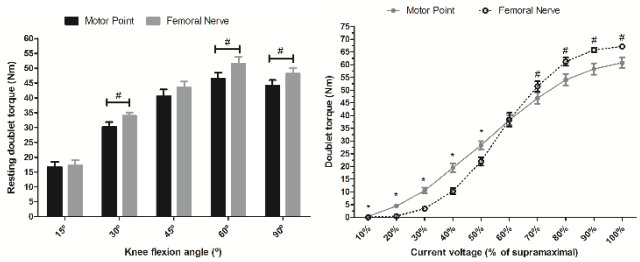

Figure 1: *Left*: Resting doublet torque by stimulation modality and knee flexion angle. # Motor Point < Femoral Nerve ($p<0.05$). *Right*: Doublet recruitment curve by stimulation modality and current level. * Motor Point > Femoral Nerve; # Motor Point < Femoral Nerve ($p<0.05$). Results are presented as mean ± SE.

FN stimulation was better than MP stimulation for the evaluation of quadriceps MI in young healthy women at 15º, 30°, 60º and 90º of flexion due to lower current voltage and discomfort levels. At 45º of flexion, the stimulation sites did not differ for current voltage and discomfort levels. Submaximal levels of NMES produce more force at the MP stimulation, whereas the FN stimulation seems to be more efficient at close to maximal activation levels (Figure 1R).

CONCLUSIONS

The quadriceps MP stimulation is a good alternative to FN stimulation for evaluating quadriceps MI in young healthy women, especially at the 45° knee flexion angle. However, FN stimulation seems to be better tolerated and uses smaller current voltage levels to produce a similar evoked force at 15°, 30°, 60° and 90° of knee flexion. Submaximal levels of NMES produce more force at the MP stimulation, whereas the FN stimulation seems to be more efficient at close to maximal activation levels. MI was influenced by changes in muscle length in both stimulation sites, and therefore it is not possible to generalize results obtained at a single knee joint angle.

THE HETROGENEITY OF THE ELASTIC PROPERTIES OF THE PECTORALIS MAJOR FIBER REGIONS ACROSS POSTURES AND VOLITIONAL CONTRACTIONS

[1]**Joshua M Leonardis** and [1]David B Lipps

[1]School of Kinesiology, University of Michigan, Ann Arbor, United States
Corresponding author email: jleo@umich.com

INTRODUCTION

Irreparable rotator cuff tears require surgical harvesting of either the clavicular or sternocostal fiber region of the pectoralis major to provide structural support to the glenohumeral joint [1]. These surgical decisions are made without considering the biomechanical consequences of choosing one region over the other. Instead, clinicians assume that any function lost after disinsertion of the pectoralis major is compensated by the remaining shoulder musculature [2]. This lack of consideration for the optimal fiber region to harvest is due in large part to the limited knowledge regarding the elastic properties of each region. Assessing the elastic properties of each region can provide insights into the effect that disinsertion of a specific region has glenohumeral dynamics and stability [3]. Our objective was to use ultrasound shear wave elastography to characterize the *in vivo* elastic properties of the clavicular and sternocostal fiber regions of the pectoralis major as a function of shoulder position and torque direction.

METHODS

The right shoulder of ten healthy male subjects (mean (SD) age: 24 (5) yrs., weight: 81 (14) kg, height: 177 (8) cm) was placed in a removable fiberglass cast and attached to a computer-controlled rotary motor instrumented with a six-degree of freedom load cell. Subjects were positioned in a combination of two shoulder abduction angles (60˚ and 90˚) and two external rotation angles (0˚(N) and 90˚(ER)) for a total of four experimental shoulder positions. At each experimental position, participants were asked to produce and maintain isometric shoulder torques equivalent to 0, 15, and 30% of their maximum voluntary contraction in the vertical and horizontal adduction directions. Visual feedback was provided to assist with torque accuracy, and surface electromyography data were collected to confirm that subject's exhibited similar activation patterns across trials.

During each isometric torque task, an Aixplorer ultrasound elastography machine was used to measure the shear wave velocity (SWV) of each region of the pectoralis major. A tissue's SWV along its fiber direction is directly related to its shear elastic modulus [4]. Two images were collected from both regions for each isometric torque task. A four-factor mixed model was used to assess differences in SWV between fiber regions (clavicular, sternocostal), shoulder positions (N60, N90, ER60, ER90), torque directions (horizontal, vertical adduction), and torque levels (0, 15, 30% MVC). Two-way analyses were used to explore any higher-order interactions identified by the four-factor mixed model. All significances are reported at α=0.05.

RESULTS AND DISCUSSION

SWV increased with increasing activation across each fiber region and shoulder position (all $p<0.001$). Within the clavicular region, SWVs were higher at every experimental shoulder position and torque level when torque was produced in the horizontal direction (all $p<0.001$). Within the sternocostal region, horizontal adduction torques resulted in higher SWVs at every experimental position (all $p<0.05$) except N60 ($p > 0.90$).

Resting SWVs were higher in the clavicular region for all four experimental shoulder positions (all $p<0.001$). There were no differences in SWV across regions and torque directions when the shoulder was externally rotated and producing torques greater than passive (Figure 1). The clavicular region exhibited higher SWVs than the sternocostal region when producing a horizontal adduction torque in a neutrally rotated posture (all $p<0.001$). On the contrary, SWVs were higher in the sternocostal region than the clavicular region when producing vertical adduction torque at 30% MVC ($p<0.01$).

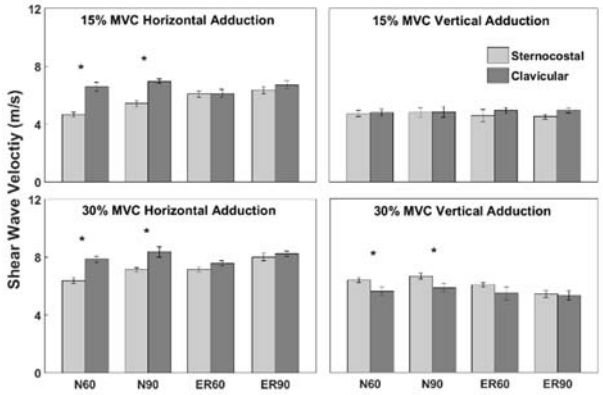

Figure 1: Fiber region differences in active SWVs for each experimental posture (N60, N90, ER60, ER90), contraction level (15% or 30% MVC), and torque direction (horizontal or vertical adduction). Error bars indicate 95% CI * $p<0.05$

Our results indicate that harvesting the clavicular region may affect passive shoulder stiffness to a greater degree than harvesting the sternocostal region, especially at greater abduction and rotation angles [5]. Disinsertion of either region may impact horizontal adduction torque-generation in a similar manner. However, disinsertion of the sternocostal region may result in additional impairments when producing higher-magnitude vertical adduction torques.

CONCLUSIONS

The individual fiber regions of the pectoralis major exhibit distinctly different active and passive elastic properties.

INTRODUCTION

Non-invasive in vivo muscle force production is difficult to measure in humans. Past studies have attempted to isolate force production in a single muscle with invasive force transducers [1,2] and current work is dedicated to the implementation of new, minimally invasive fiber optic technology [3]. Muscle transfer surgeries present themselves as an ideal opportunity to evaluate in vivo force production since the tendon is transected and the muscle exposed.

In this study, in vivo gracilis muscle forces collected during a muscle transfer surgery are compared to an OpenSim model of the muscle. This may be used for patient-specific modelling for transfer surgery optimization in the future.

METHODS

Data collection: Force measurements were taken from two patients (1 female) to evaluate the force-length curve of the human gracilis. While the patient was under anesthesia, the surgeon transected the gracilis tendon and documented the muscle retraction. The tendon was connected to a custom designed muscle lengthening device with an integrated force transducer. Isometric active force measurements were taken at three, 1cm intervals starting with the muscle slack at 0cm. A Viking nerve stimulation system (Natus Medical Inc., Pleasanton, CA) was used to activate the gracilis muscle via the terminal branch of the obturator nerve. Parameters were identified using twitch stimulation to reach maximal compound muscle action potentials (CMAP). The current was subsequently reduced to 50% of the maximum to achieve submaximal tetany where force production of the gracilis muscle was observed (2s, 50Hz). Data were normalized to the maximum force observed in each patient.

Model: In OpenSim, the musculoskeletal model from Rajagopol et al. [4] was used to estimate the force using the musculotendon model from Millard et al. [5]. The muscle was assumed to be slack at 0cm and was evaluated up to 10cm of displacement (Fig 1). This displacement was based on joint angles from a healthy individual's range of motion. The model was normalized by the maximum force calculated and compared to the experimental data.

RESULTS AND DISCUSSION

The in vivo force production data from the two subjects follow the same trend, increasing force with increased gracilis muscle length (Fig 1). No decrease in force was observed. This may be due to two different factors: 1) the muscle was not displaced beyond optimal muscle length or 2) the muscle is beyond muscle length and passive force is adding to the overall muscle force produced. More data points are needed to complete the force-length curve.

The model predicts higher forces than were observed in the subjects and optimal length appears to occur at 4cm of displacement in the model. More work is needed to scale the model in OpenSim to individual patients and observe changes with muscle length. This would allow for direct comparison of absolute force values rather than normalizing relative to peak force.

The current experimental setup makes it difficult to identify the initial muscle length and therefore the corresponding location on the force-length curve. It was assumed that the peak force corresponded to optimal muscle length at 3cm of displacement. With a total of 3cm displacement, the initial muscle length at 1cm may correspond to the observed muscle retraction of 1-2cm when the tendon was transected. Refinement of the experimental setup may provide further insight into properly identifying muscle length during data collection.

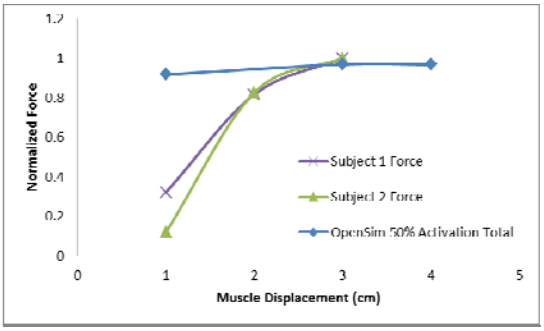

Figure 1: Muscle force calculated in OpenSim with 50% activation compared to experimental data from two subjects (Subject 1 purple 'x'; Subject 2, green triangle).

CONCLUSIONS

This novel data allowed direct measurement of in vivo human muscle force and comparison to a computational model. Experimental data can be used to help improve assumptions made in OpenSim and knowledge of human muscle properties. This may lead to the use of computational modeling to predict muscle properties that can be used to improve orthopedic surgeries.

SHORTENING-INDUCED FORCE DEPRESSION IS MODULATED IN A TIME AND SPEED DEPENDENT MANNER FOLLOWING A STRECH-SHORTENING CYCLE

INTRODUCTION

History-dependent muscle properties refer to the steady-state isometric force following an active shortening or lengthening contraction is smaller (force depression; FD) or greater (residual force enhancement; RFE) compared to a purely isometric contraction at the corresponding muscle length and same level of activation [1]. Despite muscles undergoing stretch-shortening cycles (SSC) on a regular basis, few studies have investigated the effects of FD and RFE in SSC.

It had been shown that stretch preceding shortening does not affect the resulting FD [2] while recent evidence suggests that it might [3]. We hypothesized from the results of these initial studies that stretch might affect force depression in a time-dependent manner, and that the effects of stretch on FD disappear if sufficient time is given between the end of stretching and the end of shortening in SSC.

Therefore, the purpose of this study was to perform SSC where the time between the end of stretch and the end of shortening was manipulated by (i) adding a pause between stretch and shortening or (ii) by performing the shortening contraction at different speeds.

METHODS

Subjects: Sixteen healthy subjects (8 ♂ and 8 ♀; 25±2 years; 170±9 cm; 67±8 kg) participated in protocol 1, and 15 of the 16 subjects participated in protocol 2.

Experimental setup: Thumb adduction forces and carpometacarpal angular displacements were measured using a custom-designed dynamometer, with 0° defined as the highest degree of thumb adduction. The ulnar nerve was electrically stimulated (50 Hz) to evoke 50-60% of the maximum voluntary contraction (MVC) of the adductor pollicis muscle for 7s.

Protocol 1: For FD, the muscle was held isometrically for 1s at 30°, followed by 1s of shortening over a 30° joint excursion. The muscle was then held isometrically at 0° for 5s. Following FD, a purely isometric reference contraction was performed at 0°.

For SSC, the muscle was held isometric for 1s at 0° and stretched to 30°. Following stretching, the muscle was either immediately shortened back to 0° at 30°/s (SSC_0s), held isometric for 0.5s (SSC_05s) then shortened back to 0°, or held isometrically for 1s (SSC_1s) then shortened back to 0°. Following shortening, all SSC were held isometrically at 0° for 4, 3.5, 3s, respectively (protocol 1).

Protocol 2: FD was performed similar to protocol 1. For SSC, the muscle was held isometrically for 1s at 0° and stretched to 30°. Following the stretching, the muscle was shortened immediately to 0° at either 15°/s (SSC_15°/s), 20°/s (SSC_20°/s), 30°/s (SSC_30°/s) or 60°/s (SSC_60°/s) and held isometrically at 0° for 3, 3.5, 4, 4.5s, respectively.

Following SSCs, a 7s isometric reference contraction and a MVC at a thumb adduction angle of 0° was performed.

A one-way ANOVA was used to test for differences between mean steady-state isometric forces following SSC (α=0.05).

RESULTS AND DISCUSSION

The mean electrically evoked isometric contraction force at 0° thumb adduction angle was 52% of the MVC force.

Protocol 1: The steady-state isometric force was significantly depressed (20.6±6.6%) following active shortening (FD) compared to the isometric reference contraction at the corresponding thumb angle. For the SSC, steady-state isometric forces were significantly smaller for SSC_0s and SSC_0.5s compared to the pure FD condition (13.7±7.4% and 15.5±2.9%, respectively), while force depression for SSC_1s (17.6±6.1% force depression) was similar to the pure shortening (FD) contractions (Fig 1).

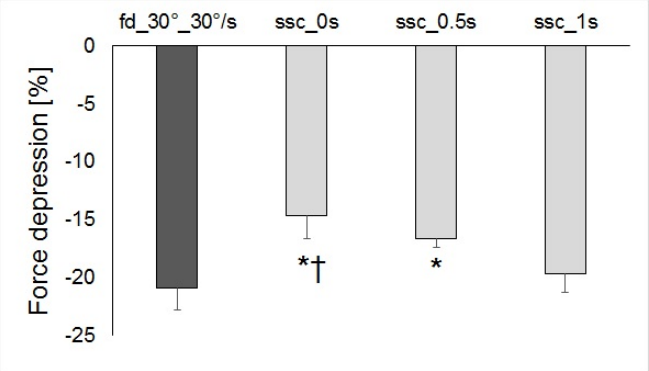

Fig 1 Mean (±) values of force decrease for FD and SSC with 0, 0.5s and 1s interval between stretching and shortening normalized to the reference isometric contraction. (* compared to FD; †compared to SSC_1s).

Protocol 2: The steady-state isometric force was significantly depressed by 20.3±1.4% following active shortening (FD) compared to the isometric reference contraction at the corresponding thumb angle. Force depression in SSC_60°/s and SSC_30°/s was significantly reduced compared to the pure FD condition (13.2±1.3% and 16.8±1.2%, respectively), while FD for SSC_20°/s and SSC_15°/s (19.6±2.1% and 20.3±1.5% were similar to the pure FD condition (results not shown).

CONCLUSIONS

The results of this study confirm our hypothesis that stretch preceding shortening affects FD in a time-dependent manner. This finding provides interesting new information on the potential mechanisms of RFE and FD, as the events occurring during active muscle stretching either inhibit full development of force depression or offset FD in some hitherto unknown manner.

INTRODUCTION

Osteoarthritis is one of the most common ankle diseases and is often treated by arthrodesis or Total Ankle Replacement (TAR). TAR has the advantage over arthrodesis that joint mobility is preserved and adjacent joint arthritis is prevented. However, the failure rate of current TARs is still unacceptably high. It is believed this may be due to non-anatomical geometry of present TAR articulating surfaces. The surface-to-surface motion at the ankle has not been investigated thoroughly in the past. Calhoun et al. [1] studied the interaction between the articulating surfaces at the ankle using pressure sensitive Fuji film by recording peak contact pressure distribution in a number of discrete positions including neutral, dorsiflexion, plantarflexion, inversion, and eversion. However, this study provided only an indirect and discrete description of the articular surface motion. Corazza et al. [2] investigated this interaction using a numerical analysis based on a few digitized points and limiting their study to dorsiflexion/plantarflexion. The present study focuses on the surface-to-surface motion of the natural ankle and subtalar joints using a distance mapping approach. It expands on the above studies by using CT scanned scatter points on the surfaces, including the subtalar joint, and investigating the full three dimensional functional range. This knowledge will provide the necessary foundation and guidance for developing TARs with improved, and more anatomically-based surface geometries to be used in novel TAR designs and possibly leading to reduced failure rates.

METHODS

Seven fresh-frozen cadaveric legs were used in this study. Three fiduciary holes, used for bone tracking, were drilled in each bone and the specimen was then CT scanned (Brilliance CT 16-slice system by Philips Healthcare). Data were post-processed with Analyze Direct© to produce 3D renderings of the articulating bones. Motion was produced in dorsiflexion/ plantarflexion, inversion/eversion, and internal/external rotation through a six-degrees-of-freedom linkage, the Ankle Flexibility Tester [3, 4]. The applied torques, used to produce this motion, were recorded with a torque sensor. The motion produced at the ankle and at the subtalar joints was simultaneously recorded with an optoelectronic stereo-photogrammetric motion data acquisition system (Stryker Knee Navigation System, Stryker). The 3D surface renderings as well as the optoelectronic bone tracking data were exported and used in a 3D CAD software for reverse engineering, Geomagic Control©. The tracked motion data were aligned with the scanned bone CAD models. The surface-to-surface analysis consisted of color-coded distance maps on the articular surface of each bone showing the distance from points on the bone surface to points on the opposed articular surface (Figure 1).

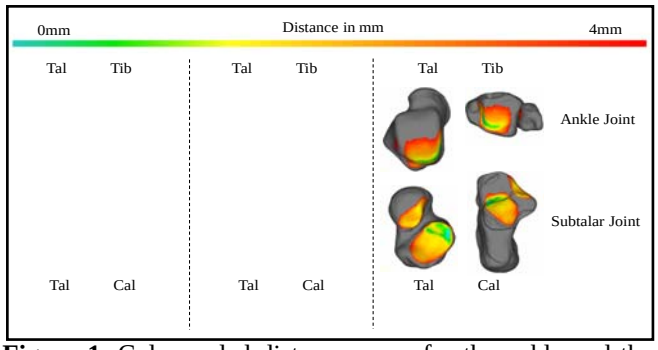

Figure 1: Color-coded distance maps for the ankle and the subtalar joint in dorsiflexion, neutral and plantarflexion.

RESULTS AND DISCUSSION

Dorsi/Plantar-flexion: In dorsiflexion the articulating ankle surfaces come closer on the anterio-lateral side while separating posteriorly. The subtalar articulating surfaces come closer on the posterio-medial side. In plantarflexion the ankle surfaces come closer posterio-medial and separating anteriorly. The surfaces of the subtalar joint come closer on anterio-lateral (Figure 1). This shows the coupling between dorsiflexion to plantar flexion and inversion/ eversion, i.e. pronation/ supination. Similar anterior-posterior shift was found for the ankle joint surface in the previously cited studies [1] and [2].

Inversion/Eversion: In Inversion the ankle articular surfaces come closer medially while separating laterally. The subtalar surfaces show the same effect. The opposite motion can be seen at both joints in eversion.

Internal/External Rotation: In internal rotation the surface-to-surface area between talus and fibula shift to the posterior lateral side. The subtalar joint comes closer on the medial posterior side. In external rotation an opposite shift of the fibula and talus surface to surface area can be seen. The subtalar joint comes closer on the anterior side.

CONCLUSIONS

(1) Distance mapping is a powerful technique to study the articular surface interaction during motion at the ankle and subtalar joints. This study provides a foundation to guide the development of new, anatomically based TARs.

(2) The results show that the articular surfaces of the ankle can't be approximated as two matching cylindrical surface. An improvement to existing TAR surface geometry may lead to improved kinematic behavior leading to improved long term clinical outcome.

THE MORPHOLOGY OF ABDUCTOR HALLUCIS IS RELATED TO BALANCE CONTROL MECHANICS DURING SINGLE-LEG STANDING

[1] **Xianyi Zhang**, [1] Kurt Heinrich Schütte and [1] Benedicte Vanwanseele
[1]Human Movement Biomechanics Research Group, KU Leuven

Corresponding author email: xianyi.zhang@kuleuven.be

INTRODUCTION

Center of pressure (COP) has been used to assess balance. Stabilogram diffusion analysis (SDA) [2] enables COP trajectories to be modeled as fractional Brownian motion, whereby two neuromuscular control systems can be disentangled into two operations: open-loop control operating without sensory feedback, and closed-loop control operating with sensory feedback. Thus, SDA can provide deeper and specific insights into postural control strategies.

Abductor hallucis, as one of the largest intrinsic foot muscles, contributes to stability and balance control [1]. Therefore, investigating the effects of the abductor hallucis' morphology on balance may provide insights into neuromuscular control mechanisms.

METHODS

Twenty-eight recreational runners were recruited in this study. Ethics approval was granted by the Medical Ethics Committee of KU Leuven and written consent was obtained from each participant. All participants were recreational runners who ran at least 15 km per week and were injury-free (lower limb) for the last 6 months prior to testing.

An ultrasound device was used to measure the thickness and cross-sectional area (CSA) of the abductor hallucis (AbH). Participants were required to perform 30 seconds single-leg standing for three trials on a force plate, which was used to record the COP. SDA was performed on COP data. Pearson correlation coefficients were computed to examine the correlation between foot muscle morphology and SDA parameters.

RESULTS AND DISCUSSION

Our results showed that COP movements over short-term intervals exhibited behavior characteristic of open-loop control. In contrast, COP movements over long-intervals exhibited behavior characteristic of a more tightly controlled process (closed-loop control system using sensory feedback). AbH-CSA was negatively correlated with mediolateral critical displacement (Cd_{ML}) while AbH-T was negatively correlated with anteroposterior short-term diffusion coefficients (Ds_{AP}) and critical displacements (Cd_{AP}), as well as with mediolateral critical time (Ct_{ML}). Examples of two participants' COP displacements and the stabilogram diffusion plots are illustrated in Figure 1.

We found that healthy individuals with larger AbH have better anteroposterior short-term dynamic stability (smaller Ds_{AP}), and exhibit more efficient transfers from open-loop to closed loop control in both anteroposterior and mediolateral directions (shorter Cd_{AP} and Cd_{ML}). It has recently been reported that short-term parameters increase significantly after plantar flexor muscle fatigue [3]. Thus, it is plausible to suggest that fatigue and perhaps weakness of the AbH muscle may exacerbate these short-term instabilities and result in poorer open-loop control. In agreement, our critical transition coordinates overall were shorter temporally (Ct_{AP} and Ct_{ML}) while larger spatially (Cd_{AP} and Cd_{ML}) along both axes compared to values previously observed during double-leg stance. Thus, it could be speculated that more efficient use of AbH as a local stabilizer may help minimize balance corrections needed during single-leg stance.

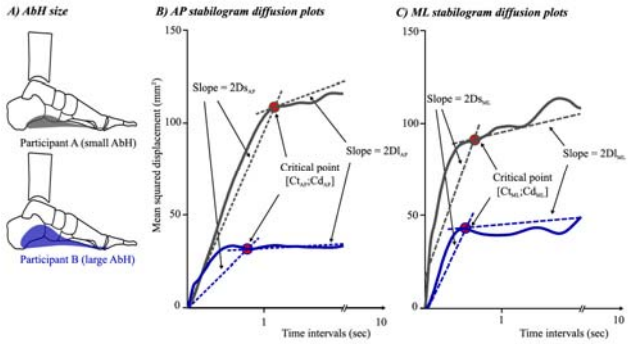

Figure 1: A) Visual comparison of two representative participants with differing AbH muscle size (not to scale). Stabilogram diffusion plots are shown for both **B**) anteroposterior and **C**) mediolateral directions for these two participants. SDA parameters derived from these plots were: short-term and long-term diffusion coefficients Ds_{AP} , Dl_{AP} , Ds_{ML} and Dl_{ML} (dashed lines; derived from the slopes of the lines fitted to the short-term and long-term regions respectively) as well as critical transition points [Ct_{AP}; Cd_{AP}] and [Ct_{ML}; Cd_{ML}] (red circles; indicating time and displacement of the approximated transition from open-loop to closed-loop control).

CONCLUSION

In conclusion, our SDA results indicate that AbH has an influence on balance control mechanisms, with larger AbH contributing to better balance during open-loop control and to a more efficient transition from open-loop control to closed-loop control. It is suggested that strengthening the abductor hallucis may be an efficient way to improve balance.

REAL-TIME IN VITRO MEASUREMENT OF FEMORAL MECHANICS DURING NORMAL ACTIVITY

[1] **Saulo Martelli**, [1]Dhara Amin and [1]Boyin Ding
[1] Medical Device Research Institute, Flinders University, School of Computer Science, Eng. and Mathematics, Australia

INTRODUCTION

The human femur is subjected daily to complex three-dimensional and time-varying loads [1], likely leading to a loading-rate dependent viscoelastic femur response [2]. Nevertheless, in vitro measurements of femoral mechanics are often based on simplified quasi-static loading cases [3], which may not well represent typical daily scenarios. In the present study, we used a six-degree-of-freedom robot and strain gauging technology to measure the in vitro hip force, displacement and cortical strain in human femurs while replicating loading patterns of normal activity at varying loading rates from quasi-static up to real-time.

METHODS

Eight femurs from healthy elderly white women (body height, weight and age at death ranges: 142 − 170 cm, 32 − 136 kg, 56 − 91 years) were obtained from a dedicated body donation program (Science Care, Phoenix, USA). The femoral diaphysis was cut at 180 mm from the proximal femoral head and potted 55 mm deep in aluminum cups using dental cement. Ten rosette strain gauges were attached to the bone surface at the four anatomical aspects (medial, lateral, anterior and posterior) and three anatomical sections (femoral head, neck and metaphysis). Tests were conducted using a custom-built hexapod robot [4] capable of controlling the position of the top plate with a linear measurement error of ± 0.5 μm. Forces and moments at the femoral head center were measured by a six axis load cell (AMTI, Watertown, MA, USA). The specimen was mounted on the base frame using a custom made fixation system while a spherically-shaped nylon pressure socket was mounted on the top plate. Specimens were thawed at room temperature for approximately 20 hours. Bone moisture was maintained throughout the experiment using fabric tissue soaked with phosphate-buffered saline solution. The hip contact force during normal walking, stair ascent, stair descent, stumbling, rising from and sitting on a chair was taken from a public database (http://orthoload.com, [1]). The cycle length was normalized using a cycle length of 1.1 seconds for walking, 1.2 seconds for stair up, down and stumbling and 5 seconds for rising from and sitting on a chair. The average force pattern per activity was calculated and scaled to the 75% of the donor's body weight to ensure no permanent damage was caused to the specimen. The moment at the hip center was set to zero, according to a frictionless ball-and-socket joint assumption for the natural hip. The load was applied to the femoral head through the polyethylene pressure socket by actuating the top plate. One to three pre-conditioning cycles consisting of a sinusoidal cranio-caudal force (amplitude: 300 N, frequency: 0.1 Hz) were used. An adaptive velocity-based load control algorithm was used to apply the hip contact force to the specimen using 50 intermediate frames over each loading cycle. Ten seconds were used to ensure the algorithm convergence at each frame. The position of the top plate was recorded and played back by multiplying the cycle time length by a factor 20 (quasi-static), 5, 2 and 1 (real-time). Strains were recorded at 2 kHz using a modular data logger (National Instrument Corporation, Austin, TX, USA) and a 0.5 V strain gauge excitation to prevent cortex heating. The error across activities in the replication of the hip contact force was calculated. The hip force patterns were synchronized to the real-time simulation. The hip force was normalized by the peak force measured during the quasi-static trial (F_{20x}) to assess changes of femoral stiffness with loading rate. The analysis of cortical strain is in progress.

RESULTS AND DISCUSSION

The protocol successfully replicated the in vitro dynamic three-dimensional hip force experienced by the human femur during normal activity. The error of the hip force time history was 3.3 ± 14.7 N and -0.7 ± 1.6 Nm across activities using the load-control approach while the difference between the quasi-static and the load-control simulation was 9 ± 10 N. The femoral stiffness was activity and loading-rate dependent; the normalized force ranged from 1.1 during stair ascent to 1.35 during walking (Figure 1) where the peak force varied from 556 N (quasi-static) to 749 N (real-time).

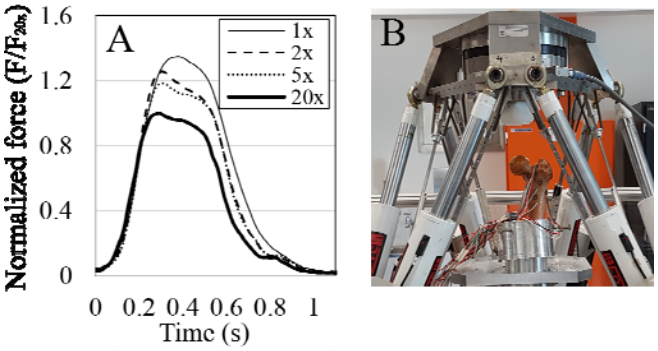

Figure 1: The normalized force at the hip for different loading rates (20x, 5x, 2x, 1x) during walking (A) and one femoral specimen mounted on the testing device (B).

CONCLUSIONS

The stiffness of the human femur during normal activity is loading-rate and activity dependent. The present protocol can be used to study the mechanics of entire bones subjected to complex three-dimensional dynamic loads. In progress, the analysis of cortical strain may elucidate the relationship between femur stiffness and strain rate. This information is important for studying the femur mechanics during normal activity.

THE RANDOMIZED CLASSIFIER: A TOOL IN ASSESSING RELIABILITY OF BIOMECHANICS DATA

[1,3] **Sean T Osis**, [1] Dylan Kobsar, [1] Ryan Leigh, [1,2,3] Reed Ferber
[1] Faculty of Kinesiology, University of Calgary
[2] Faculty of Nursing, University of Calgary
[3] Running Injury Clinic

INTRODUCTION

Advancements in computer and information technology have driven the study of biomechanics towards more sophisticated machine learning techniques, utilizing entire time-series of data. One purpose for applying these techniques is the classification of subgroups, and in clinical cases, this task often requires classification at different time intervals [1]. Given that biomechanical data contains measurement error, it is critical to establish methods to improve data reliability.

One central source of error in kinematic data is deviation in the placement of anatomical markers, and a novel data-driven feedback tool has been developed to reduce this error in practice [2]. However, a challenging component in evaluating the effectiveness of this tool is the assessment of reliability for large feature set, in the absence of a specific classification problem. Therefore, the purpose of this study was to develop and apply a randomized classifier task in order to evaluate the effect of a marker placement feedback tool in improving classification reliability.

METHODS

As part of a larger clinical trial, data were collected on $n = 17$ patients with hip osteoarthritis at two intervals (day 1 and 2), prior to the start of their clinical intervention. Markers were placed by a single examiner over specific anatomical landmarks [2], and a standing trial was collected (pre-feedback). Next, the examiner was presented feedback from a marker placement tool [2], and given the opportunity to modify their placements prior to collecting a second standing trial (post-feedback). Walking data were then collected by an 8-camera optical motion capture system at 200 Hz.

Joint angles were calculated from walking data using both pre- and post-feedback standing trials for day 1 and day 2 [3]. Joint angles were time-normalized, and chained together to form a row vector of 3000 data points for each subject, feedback and day condition. Principal component analysis (PCA) was then applied to reduce the data in each feedback/day condition to a feature set of 16 (n - 1) variables, for input to the random classifier task.

At each iteration of the random classifier task, models were generated by randomly choosing features, and then generating class labels for two arbitrary groups from unsupervised clustering. Class labels were then used to train a support vector machine (SVM) using features from day 1 post-feedback data. Classification accuracy was determined by classifying on day 2 data, and accuracies for pre- and post-feedback data were compared using McNemar's test ($p < 0.05$).

RESULTS AND DISCUSSION

Accounting for training bias, classification accuracy was improved for post-feedback data as compared with pre-feedback data, with 38% of the random models demonstrating an increase in classification accuracy (Figure 1), which was a significant improvement ($chi^2 = 113.72$, $p < 0.0001$, odds ratio = 2.8, odds ratio confidence interval = 2.3-3.4).

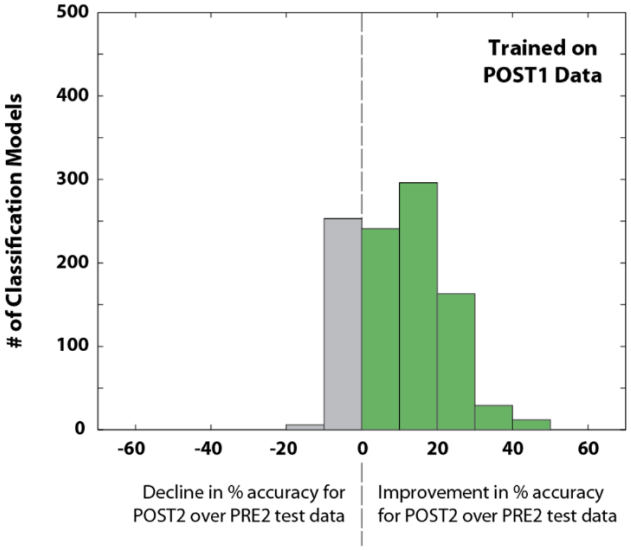

Figure 1: Classification accuracy for random models trained on post-feedback data from day 1 (POST1) and tested on pre-feedback data from day 2 (PRE2) and post-feedback data from day 2 (POST2).

The results of the randomized classifier are supported by an initial analysis of discrete variables for the same study [4], which demonstrated an improvement in the limits of agreement with the use of the feedback tool. The current work extends the benefits of the feedback tool to improve the reliability of classifications based on gait kinematic data.

CONCLUSIONS

The randomized classifier task has demonstrated utility in evaluating reliability of multivariate kinematic data.

THE FUNCTIONAL CHARACTERIZATION OF A KNEE FOCAL CARTILAGE DEFECT COHORT

[1] **Nidal Khatib,** [1]Gemma M Whatling, [2]Christopher Wilson, [1]Deborah J Mason, [1]Cathy A Holt
[1]Cardiff University
[2]Cardiff and Vale Orthopaedic Research Centre
KhatibN@Cardiff.ac.uk

INTRODUCTION

Focal cartilage defects (FCDs) of the knee develop as a result of trauma or repetitive injury or stress, often progressing to full joint osteoarthritis (OA). This progression towards a full joint disease is not well understood, therefore determining early deviations of gait patterns from the norm may reveal information for how OA may develop from this stage. Principle component analysis (PCA) is an effective tool for investigating whole gait waveforms for features of high variation that can be utilized to discriminate pathological knee function from normal function [1]. Here, we use PCA to uncover gait features that discriminate FCD affected knee function from normal.

METHODS

10 asymptomatic healthy volunteers (HV) and 10 patients with ICRS grade III+ focal cartilage defects (FCDs) of the femoral condyle (due for microfracture surgery to treat mild-moderate knee pain) were recruited and consented for motion analysis. A modified Helen Hayes marker set was used with a 9-infrared camera (Qualisys, Sweden) and 4 force-plate (Bertec Corp, US) setup. Biomechanical models were created using Visual 3D (C-motion, Inc.) software, and rotational angles were defined by the orientation of the distal in relation to the proximal segment. A Visual3D 6 degree of freedom model was used for kinematic&kinetic calculations.

Independent T-tests (SSPS Inc.) were carried out to identify differences in age, BMI, speed and cadence between groups. Level gait waveforms were chosen for analysis based on previous literature defining changes in asymptomatic, moderate and severe OA function [2], and in-house studies (MSKBRF research group), which include: knee and hip abd/adduction moments (K/HAMs), knee and hip flexion/extension moments, knee and hip sagittal and frontal ranges of motion (ROMs). Principle Component Analysis (PCA) was performed using Inspect 3D (C-motion) software, and was used to identify a number of principle components (PCs), or 'features' that represent >95% of variation within the gait waveforms. To discriminate groups based on their gait waveform features, group PC scores were tested for significant differences using T-tests (SPSS Inc).

RESULTS AND DISCUSSION

Comparing group means of anthropometric measures showed no differences in BMI or age. Cadence of FCD affected subjects (106 ±6.5) was significantly ($p<0.05$) lower than normal subjects (111.9 ±7.3), which was accompanied by a slower mean speed among affected patients, but with no significant difference.

PCA results (Table 1) revealed significantly higher overall stance knee flexion, and significantly reduced knee range of motion (ROM) in the FCD group, indicating the affected subjects may be adopting a rigid posture to avoid extending the knee during gait. This result was supported with a significantly reduced knee extension moment in late stance phase. The combination of these results suggest subjects may be slowing walking speed, to decrease the extension moment and therefore reducing compressive knee forces, ultimately negating pain, as suggested by previously by Messier et al. [3] in a study investigating osteoarthritic gait.

Gait Parameter	*PC*	*PC feature of FCD group gait waveforms*	*Sig.*
Knee Sagittal Range of Motion	2	Increased knee flexion over stance phase	<0.048
	3	Reduced total range of motion	<0.029
Knee Flexion/Extension Moment	3	Reduced extension moment in late stance	<0.027
Knee Adduction Moment	4	Reduced 1st peak and increased 2nd peak moment	<0.038
Hip Sagittal Range of Motion	2	Reduced range of motion	<0.008

Table 1: Principle component features of gait waveforms that significantly differed ($p<0.05$) between groups.

We found a decrease in the knee adduction moment 1st peak:2nd peak index (Table 1), which is found in moderate and severe OA cases, and is indicative of altered frontal plane dynamic alignment [2]. Contradictory to other studies however, there were no significant differences in overall KAM magnitude or even midstance values as determined in severe OA and moderate OA, respectively. This may be due to more extreme difference in average speed between their [1,2] study groups, as it is shown that speed largely affects KAM magnitude [4]. Interestingly, we found a highly reduced frontal range of hip motion during gait within our FCD affected group, but no significant difference in HAM features as seen in moderate/severe OA [2]. The implications of this on hip function may be due to error, but will be investigated further by looking at hip internal/external rotations to determine possible early gait adaptations that lead to progressive changes in HAMs.

CONCLUSIONS

Our results indicate characteristic patterns of moderate and severe OA, including higher midstance and KAM magnitude, decreased early stance knee flexion moments and decreased HAMs have not been found in FCD subjects, and may arise as a result of gait adaptations developing with progressing joint damage and pain toward OA. Further investigation will be needed to confirm these conclusions.

DIFFERENCES BETWEEN CLINICIAN AND SELF-ADMINISTERED SHOULDER SUSTAINED GLIDE ON SCAPULAR AND SHOULDER MUSCLE ACTIVITY DURING SHOULDER ABDUCTION: A REPEATED-MEASURES STUDY ON ASYMPTOMATIC INDIVIDUALS

Daniel Cury Ribeiro, Gisela Sole, Ramu Venkat, Jonathan Shemmell

Corresponding author email: Daniel.ribeiro@otago.ac.nz

INTRODUCTION

Sustained glides on the shoulder has immediate [1, 2] and short lasting effects [2], improving pain and increasing range of motion in patients with shoulder disorders. Our previous research has shown that clinician-administered sustained postero-lateral glide at the glenohumeral joint reduced muscle activity levels for supraspinatus, infraspinatus, middle and posterior deltoid muscle [3]. It is unknown whether a self-administered version of the glide leads to similar neuromuscular response.

This study compared the effect of sustained clinician-administered shoulder glide with self-administered glide (performed with a belt) on activity levels of scapular and glenohumeral shoulder muscles.

METHODS

This was a laboratory-based, cross-over, repeated measures design. Twenty-two asymptomatic participants completed movements with shoulder glide during active shoulder abduction, performed with a sustained glide under two conditions: (1) manually by a clinician (clinician-administered) and (2) by themselves using a belt (self-administered). Both by a clinician and by themselves. Seven shoulder muscles (upper and lower trapezius, supraspinatus, infraspinatus, posterior deltoid, middle deltoid, and serratus anterior) were monitored using surface electromyography (SEMG) during each of the two conditions. Muscle activity levels were monitored during shoulder abduction movements performed before, during and after clinician- and self-administered sustained glenohumeral glide. Due to lack of information in the literature regarding the post-glide effect on shoulder muscle activity, an arbitrary interval of 5 minutes between the two experimental conditions was used to prevent any carry-over effect. Mixed-effect models for repeated measures were used for within- and between-condition comparisons.

RESULTS AND DISCUSSION

Within-condition comparisons suggested that both interventions lead to reduced activity in most monitored muscles. The upper trapezius was the only muscle for which a main significant effect for condition on activity levels was found [χ^2 (61)=9.9, p=0.007], which indicates that, overall, during the clinician-administered condition, upper trapezius muscle activity was 9.9% MVIC lower than during the self-administered condition. No differences between clinician-administered and self-administered glide at intervention and follow-up were found for the other monitored muscles (Table 1). There was no carry-over effect between clinician- and self-administered glide conditions with a five-minute interval.

Table 1. Between-condition mean differences (95% confidence intervals).

	Self-administered vs Clinician-administered glide
Upper trapezius	
Intervention	-1.7 (-5.9 to 2.5)
Follow-up	-3.1 (-7.4 to 1.1)
Lower trapezius	
Intervention	-0.7 (-5.9 to 4.4)
Follow-up	1.5 (-3.6 to 6.6)
Supraspinatus	
Intervention	3.0 (-0.6 to 6.7)
Follow-up	0.6 (-2.3 to 4.3)
Infraspinatus	
Intervention	-2.9 (-4.9 to -1.0)
Follow-up	-0.2 (-2.2 to 1.8)
Middle Deltoid	
Intervention	-3.5 (-5.8 to -1.1)#
Follow-up	-1.0 (-3.4 to 1.3)
Posterior Deltoid	
Intervention	-0.9 (-1.8 to -0.2)#
Follow-up	-0.3 (-1.1 to 0.5)
Serratus anterior	
Intervention	4.3 (-1.9 to 10.6)
Follow-up	6.2 (-0.1 to 12.5)

#Interaction effect not significant.

CONCLUSIONS

In young, asymptomatic individuals, self- or clinician-administered sustained glide reduced activity levels of most scapular and shoulder muscles monitored in this study, during shoulder abduction. This effect was observed only while the sustained glides were applied to the shoulder. At the immediate follow-up, muscle activity levels were similar to baseline measurements.

GRADE IV INFERIOR GLENOHUMERAL MOBILIZATION DOES NOT IMMEDIATELY ALTER SHOULDER AND SCAPULAR MUSCLE ACTIVITY DURING SHOULDER ABDUCTION: A REPEATED-MEASURES STUDY IN ASYMPTOMATIC INDIVIDUALS

INTRODUCTION

Manual therapy is part of shoulder rehabilitation programme, and joint mobilizations may impact on the mobility of glenohumeral joint and muscle recruitment pattern [1-3]. It is proposed that inferior glenohumeral joint mobilizations: increase the flexibility of non-contractile tissue (i.e. capsule and ligaments); and stimulate mechanoreceptors, reducing the inhibitory stimuli from mechanoreceptors to agonist muscles (in this case the abductor muscles) [2]. The effect of inferior glenohumeral mobilization on scapular and shoulder muscle activity remains unclear.

This study aimed to: (1) the presence of any carry-over effect between interventions; (2) assess the immediate effects of shoulder passive accessory mobilization on shoulder and scapular muscle activity; (3) compare shoulder and scapular muscle activity response between mobilization and control conditions. Due to lack of information about the effects of shoulder accessory mobilization on muscle activity levels, we opted for non-directional experimental hypothesis that shoulder and scapular muscle activity would change following inferior shoulder mobilization.

METHODS

This is a repeated measures, cross-over, pre-post intervention study with sample of convenience. Twenty-two participants, blinded to group allocation, took part in the study. Researchers delivering the intervention and processing the data were not blinded. The intervention consisted of two conditions: shoulder passive accessory mobilization and control. A five-minute interval was set between the two conditions. Participants were requested to perform 10 repetitions of shoulder abduction before (pre) and after (post) each intervention. Surface electromyography (sEMG) was used for recording muscle activity of upper and lower trapezius; anterior, middle and posterior deltoids; supraspinatus; infraspinatus; and serratus anterior. Previous research has shown that sEMG overestimates supraspinatus muscle activity, but in a repeatable manner [4]. Because the present study assessed within-muscle changes, the use of sEMG was considered appropriate for monitoring the supraspinatus muscle.

Repeated measures mixed-model analysis of variance (ANOVA) was used to assess immediate changes in muscle activity levels following inferior shoulder mobilization. Statistical parametric mapping (SPM) was used for comparing muscle activity waveforms between control and mobilization conditions throughout the range of motion.

RESULTS AND DISCUSSION

There was no carry-over effect between interventions. No systematic changes in muscle activity levels were found between: (1) baseline and follow-up for each condition, at the concentric and eccentric phases of shoulder abduction; (2) control and mobilization conditions during the concentric and eccentric phases of shoulder abduction (Table 1). SPM results suggested no differences in muscle activity pattern between conditions.

Table 1. Mean differences (95% confidence interval) in muscle activity change following the intervention between control and mobilization conditions.

Muscle	Concentric phase	Eccentric Phase
Upper trapezius	-4.7 (-17.3 to 26.7)	-9.3 (-25.4 to 6.8)
Lower trapezius	-6.2 (-16.1 to 3.6)	-0.2 (-4.6 to 4.3)
Supraspinatus	-17.7 (-52.1 to 16.6)	-11.3 (-37.6 to 15.0)
Infraspinatus	-1.5 (-5.9 to 2.8)	-1.2 (-4.6 to 2.2)
Anterior deltoid	-17.6 (-52.8 to 17.5)	-9.5 (-24.9 to 5.9)
Middle deltoid	-3.1 (-12.1 to 6.0)	-3.4 (-9.2 to 2.4)
Posterior deltoid	-6.4 (-18.5 to 5.6)	-3.4 (-10.9 to 3.6)
Serratus Anterior	-9.5 (-27.3 to 8.3)	-8.3 (-18.9 to 2.3)

Negative values = higher muscle activity levels observed during the control when compared to mobilization condition.

CONCLUSIONS

Inferior shoulder mobilization did not produce immediate effects on shoulder and scapular muscle activity. It is possible that the dose used was insufficient to generate an immediate neuromuscular response to the mobilization.

INTRODUCTION

The authors have developed the electromyography computed tomography (EMG-CT), which provides the muscle activity distribution within a whole cross section of the forearm on the basis of surface EMG signals around the forearm and an EMG conduction model [1]. The muscle activities in the forearm were investigated during various finger and hand motions by using EMG-CT [2]. In clinical practice, Daniels and Worthingham's muscle testing (D-W muscle testing) [3] is used for evaluating the functions of individual muscles. The external loading is applied to the patient by the hand and the individual muscle activity is evaluated from the resistance of the patient. The present study applies the EMG-CT to the upper arm muscles and aims to investigate the individual muscle activities in the upper arm during the D-W muscle testing for biceps brachii, brachialis, and triceps brachii.

METHODS

Five male subjects (24.0±0.8 years old) participated in the experiments. The surface EMG signals around the upper arm were detected with 40 pairs of bipolar electrodes embedded in a customized EMG-CT band (Harada Electronics, JP2016-131689A). The band was positioned at the distal one-third of the upper arm. An EMG conduction model in the cross section of the upper arm based on the relationship between surface EMG signals and muscle activity [1] was constructed using a circle cross-section with the measured circumferential length. In the model, the muscle region was divided into the muscle elements (1-5 mm) by Voronoi tessellation. The muscle activity of each element (mA dipole/s･mm^2) was calculated by minimizing the sum of the power of the differences between the measured and estimated EMG signals from the model by sequential quadratic programming method [1]. The external loadings were applied to the subject's arm following to D-W muscle testing for the upper arm muscles [3]: elbow extension loading for biceps brachii (Figure 1(a)), forearm pronation loadings for biceps brachii, elbow extension loading for brachialis, and elbow flexion loading for triceps brachii. The subjects were instructed to maintain the initial posture against the external loadings. The loading was applied 5 s three times with 5 s intervals. The averaged muscle activity distribution during loadings was calculated.

RESULTS AND DISCUSSION

Figure 1(b) shows a typical muscle activity distribution in the upper arm during the elbow extension loading. The color scale was normalized with respect to the maximum value in the loading. During the loadings targeted to biceps brachii, high muscle activities were detected in the biceps brachii region. During loading targeted to brachialis, high activity was detected in the brachialis region. The activated regions of biceps brachii and brachialis could be divided significantly. Furthermore, during the loading targeted to triceps brachii, high activity was detected in the triceps brachii region. The individual muscle activity during the tests was clearly detected by EMG-CT, and high activities were not detected in the regions of bone and the other muscles. It suggests the validation of the EMG-CT method and the effectiveness of the tests based on anatomical and experiential knowledge.

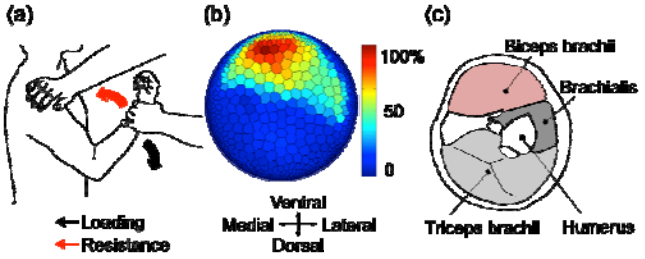

Figure 1: An example of (a) loading directions and (b) muscle activity distributions in Daniels and Worthingham's muscle testing (D-W muscle testing). The elbow extension loading was applied for biceps brachii. The black and red arrows indicate the directions of the external loading and subject's resistance, respectively [3]. Figure (c) shows a typical arrangement of muscles in the upper arm [4].

CONCLUSIONS

Individual muscle activities in the upper arm during Daniels and Worthingham's muscle testing for biceps brachii, brachialis, and triceps brachii were clearly detected by EMG-CT, corresponding to each target muscle region in the cross section.

INTRODUCTION

The glenohumeral (GH) joint is a multi-axial ball and socket synovial joint, which in combination with the acromioclavicular, sternoclavicular, and scapulothoracic joints, facilitates the movements of the upper limb [1].
Shoulder pain is a major worldwide health problem. Rotator cuff pathology is the most common cause of shoulder pain (40%), specifically shoulder impingement syndrome (SIS) [2]. Alterations in normal muscle activation has been suggested as a possible etiological factor for the development and persistence of SIS [3]. Electromyography (EMG) has been used to evaluate muscular activity examining planar shoulder movements (flexion, flexion, abduction, extension, internal and external rotation), however, these are only a small part of the range of motion over which the shoulder functions. There have been studies of muscle activity in more complex situations, but have little to do with the activities of daily living, in which complex movements demand interaction between all segments of the upper limb kinetic chain, with the activity of each segment influencing the response of the next. To perform a full shoulder assessment of its functional state it is not enough to measure the muscle strength and / or range of motion, it is also necessary to incorporate the upper limb as a functional unit under complex situations that are just appreciated during functional movements [4]. The aim of this study is to assess the normal muscles activity (timing) of upper limb region by using surface electromyography (SEMG), during dynamic elevation task based on activity of daily living.

METHODS

20 volunteers were recruited, 10W and 10M, aged 20 to 39 years, without upper limb musculoskeletal disorders. In order to capture the 3D movement, an optic system (Vicon Motion System, Oxford, UK) with reflective set markers (Plug In Gait Vicon Nexus, Oxford, UK) was used for a complete body reconstruction. For surface electromyography records, a 16 electromyography's channels (Delsys Trigno Wireless System, Boston, USA) were used for the acquisition. The recorded SEMG was: Upper Trapezium, Middle Trapezium and Lower Trapezium; Anterior Deltoid, Middle Deltoid and Posterior Deltoid; Serratus Anterior, Biceps Brachii, Triceps Brachii, Flexor Carpi Radialis and Extensor Carpi Radialis Longus. Each subject performed one shoulder reach task using 1 kg jar set above a shelf, built according to upper extremity functional assessment (FIT-HaNSA) protocol. The task started after a sound and visual sign, 500 ms duration, located on the shelf in front of the subject. Task: Take a jar on top shelf (eye level) and leave it on bottom shelf (anterior superior iliac spines level), performed at self-selected comfortable speed. Each subject performed five repetitions of this task. Statistical analysis software (IBM SPSS Statistics 24) was utilized to compute an Intraclass Correlation Coefficient (ICC) to statistically compare the reliability of each repetition and one-way analysis of variance (ANOVA) for the dependent variables of onset muscle.

RESULTS AND DISCUSSION

ICC showed high reliability. Figure 1 shows the results of Post hoc comparison procedure (Tukey) for onset activation of each muscle in relation to Anterior Deltoid. These results suggest changes in the onset of muscle activation during reach functional task. The shortest activation onset time occurred in upper and middle trapezium muscles and elbow flexors and extensor muscles. It is noted that during task, onset muscle activation was anticipatory to the movement for most of the assessed muscles.

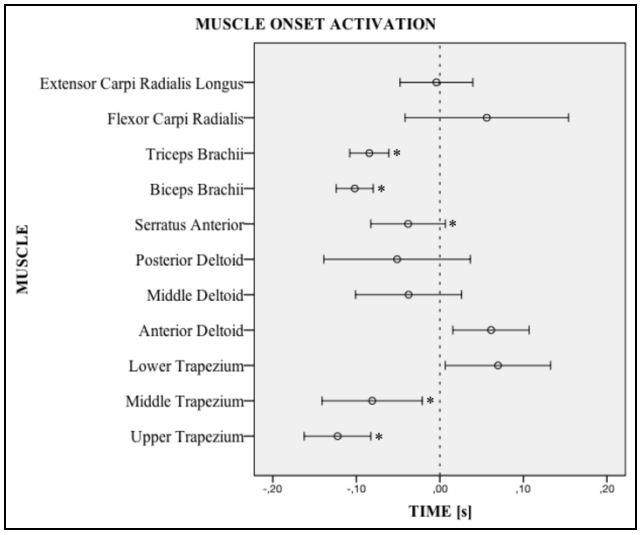

Figure 1: Muscle onset activation (* $P < 0.05$)

CONCLUSION

These results suggest that changes in muscle activation times show the existence of diverse strategies for controlling the movement of each joint involved in performing shoulder elevation tasks. Apparently, the velocity of elevation task performance was not a significant variable for this muscles activation pattern.

INTRODUCTION

Shoulder overload injuries are a major problem in throwing sports [1]. Proprioception and adequate muscular activation are considered important for functional stability of the shoulder, and many prophylactic and rehabilitation exercises are aiming to improve these functions. The objective of the present study was to investigate the reliability of a new test of shoulder stability, defined as reaction to a sudden external perturbation, with the shoulder in a position similar to a throwing position.

METHODS

10 athletes (aged 17-19 yrs) were recruited. Maximal isometric internal rotation strength (MVIC) was measured in a supine position with the shoulder and elbow in 90° abduction and flexion, respectively, using a handheld dynamometer. Subsequently, the subjects were seated upright with the upper arm supported in 90° abduction in the scapula plane, the elbow in 90° flexion and the forearm vertical. From the back side of a firmly attached wrist band, a cable was directed around a pulley to an electromagnet with a load attached. The subject would hold the load slightly above the ground by a slight internal rotation of the shoulder joint to a vertical position of the forearm, and as such be in a position similar to a throwing position. At a random interval 1-3 second after lifting the load off the ground, the load was released and the shoulder would internally rotate. The subject was instructed to, as quickly as possible, to decelerate the internal rotation, thus simulating the situation after ball release in throwing. An accelerometer was attached to the wrist to record the movements. After integration of the acceleration data the time from release to the start of deceleration (reaction time, RT) was determined as the time to peak velocity. The time from the start of the deceleration to end of internal rotation, i.e. the instant of zero velocity was defined as deceleration time (DT). The total stop time (ST) was the sum of RT and DT, and by further integration of the velocity curve the total distance moved was obtained (D), and these parameters comprised both RT and DT as an overall measure of shoulder stability. After 3 practice trials, 5 test trials were performed. The tests were performed with two different loads corresponding to 30 % MVIC (L30) and 50% MVIC (L50) in a randomized order between subjects. The tests were repeated one week after the first test, and Intra-Class Correlation Coefficients (ICC (2,1)) were calculated on the mean of the 5 trials for the different parameters and different loads. Student's T-test were used investigate potential differences between pre- and post-test and load conditions.

RESULTS AND DISCUSSION

All ICCs were moderate but significant and ranged between 0.71 and 0.86, with highest ICCs for DT and D for L50 condition and highest ICCs for RT and ST in L30 conditions (see table 1). Only RT improved significantly indicating that there was a learning effect from pre to post test. Comparing L30 and L50 conditions, RT was on average 5 ms slower for L30 ($p<0.05$) compared to L50, which may be a result of a weaker stimulus to the proprioceptive organs detecting the start of the internal rotation. Thus, RT may serve as a parameter of proprioception in this test, and the slightly higher ICC in the L30 may indicate that a smaller load is more reliable for this parameter.

On the other hand, DT was on average 7 ms faster for L50 ($p<0.05$) and ST was shorter for L50 ($p<0.01$), despite the total distance traveled was 20 % longer ($p<0.001$). The ability to decelerate the internal rotation as fast as possible may depend on strength and rate of force development of the external rotators, which has been found to be important for prevention of shoulder injuries in sports [2]. The heavier, and thus more strength depending, L50 condition induces a higher internal velocity, and the observed shorter ST despite a longer D emphases the influence of fast and strong muscular activation. The slightly higher ICC for DT and D in the L50 condition may indicate that this condition is more reliable as a measure of explosive eccentric activation of the shoulder external rotators.

Parameter	Pre (SD)	Post(SD)	p	ICC	95 % CI	p
L30 RT (ms)	94 (7.5)	89 (6.7)	0.02	0.78	.34-.94	.002
L30 DT (ms)	70 (7.9)*	71 (9.7)	0.66	0.75	.27-.93	.004
L30 ST (ms)	163(10)*	160 (12)	0.11	0.86	.54-.96	<.001
L30 D (mm)	18 (3)*	18 (4)	0.68	0.71	.18-.92	.008
L50 RT(ms)	89 (7.4)	84 (7.9)	0.03	0.71	.19-.92	.007
L50 DT (ms)	63 (5.7)*	64 (3.8)	0.35	0.76	.29-.94	.003
L50 ST (ms)	152(10)*	148 (10)	0.14	0.76	.28-.93	.004
L50 D (mm)	23 (4)*	22 (3)	0.10	0.81	.41-.97	.001

Table 1. Mean values and ICC. * denotes significant differences between. L30 and L50 conditions at pre-test.

CONCLUSIONS

This new approach to testing shoulder stability during conditions more close to functional conditions was proven reliable. However, the RT, which likely depends more on proprioception, improved between tests, which may indicate that the subjects should need more practice trials before testing for this parameter. DT and D, which probably relies more on strength and rate of force development of the shoulder external rotators, were slightly more reliable for L50. Future studies will investigate the validity of this test.

THE STRUCTURAL ROLE OF THE STRATUM CORNEUM ON SKIN WRINKLE FORMATION

[2]University of Cape Town, South Africa
Corresponding author email: g.limbert@soton.ac.uk

INTRODUCTION

In popular culture, skin wrinkles are the hallmark of ageing. This topic is therefore of significant social and scientific interest. Besides the cosmetic aspects, unveiling the underlying mechanical principles that condition the morphologies and patterns of wrinkles are essential in predicting how an aged skin interacts with its environment. Many products that interact with, support or protect human skin actually cause discomfort for the user and even irritation or damage to the skin. Examples include hygiene products such as diapers and incontinence products, electronic wearables that cause skin rashes as well as clinical straps and hoists used to move patients that cause shear-related skin injuries, and, in the most severe cases, medical surfaces that can lead to life-threatening pressure ulcers. Through adhesive and deformation-induced friction skin wrinkles play a central role in contact interactions [1]. During intrinsic and extrinsic ageing, the formation and evolution of wrinkles are conditioned by and alter the physical properties of the skin surface. From the view point of physics, wrinkles are the result of a complex interplay between adaptive material and structural properties as well as boundary and loading conditions [2] the skin is subjected to over a life time.

The objective of this study was to investigate the structural role of the stratum corneum on the topographic characteristics of compression-induced skin wrinkles and explore their sensitivity to changes in relative humidity.

METHODS

Acquisition of the 3D surface topography of a 5 x 5 mm^2 silicone replica of a patch of human arm skin surface was performed using a Xyris 2000 TL laser profilometer (Taicaan Technologies, Southampton, UK). From the 3D grid of points a parametric 3D finite element four-layer skin model was built and developed in a customised computational environment implemented in Mathematica® (Wolfram Research, Inc., Champaign, IL, USA). The stratum corneum viable epidermis, papillary dermis and reticular dermis layers were assumed to be respectively of a 0.02, 0.6, 1 and 1 mm thickness. Materials were assumed to obey a neo-Hookean constitutive law. To simulate the effects of alteration in relative humidity conditions variations of the ground state Young's modulus of the stratum corneum were conducted (0.6, 6, 12, 60, 120, 240 and 360 MPa) [3]. Wrinkle formation was induced by applying a 25% uniform uniaxial compression to one of the skin lateral faces. To handle the highly non-linear behaviour of surface instabilities a finite element path-following procedure based on an arc-length method was devised. Beside stress, strain, strain energy density, various surface metrics were calculated to evaluate the effects of stratum corneum stiffness on its deformed topography (e.g. RMS roughness, average and RMS wave length).

RESULTS AND DISCUSSION

The critical role of the ratio of elasticity between the stratum corneum and the underneath layers was demonstrated. As predicted by theoretical models of idealised multi-layer soft assemblies, as the stratum corneum stiffens (for example as a result of dehydrating conditions) the wave length and amplitude of surface wrinkles increase [1,4] (Figure 1). In these conditions, results also showed that strains in the stratum corneum significantly decreased because of the structural folding rather than stretching/compression of the surface. Period-doubling phenomena were also observed.

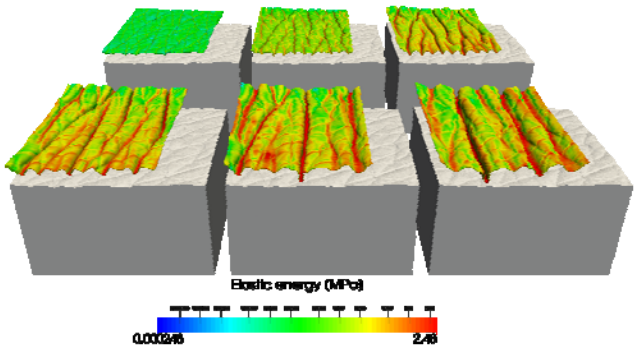

Figure 1: Colour plots of strain energy density of the stratum corneum layer as a function of its elasic modulus after in-plane compression in the *undeformed* and *deformed* configurations. [Young's modulus of stratum corneum: Left to right: top: 0.6, 12 and 60 MPa, bottom: 120, 240 and 360 MPa].

CONCLUSIONS

These results have important implications for the nature of contact interactions of the skin with counter surfaces as environmental conditions (e.g. relative humidity) change. Modifications of surface topography modulate the magnitude and directionality of skin friction [1] which in turns affect the likelihood of critical shear stress injuries.

ACKNOWLEDGEMENTS

The author would like to thank Prof. Ellen Kuhl and Prof. Michel Destrade for many fruitful discussions on the topic of surface instabilities.

INTRODUCTION

Sitting for extended periods of time can compromise the health of gluteal soft tissues and may lead to discomfort or even injury [1]. The high mechanical loads and the associated large soft tissue deformation below bony structures such as the ischial tuberosities are major factors contributing to sitting related discomfort and injury [3, 4]. Access to data describing the deformation history throughout the transition between the extreme loading conditions may help develop a comprehensive understanding of how muscles and fat tissues deform under various sitting loads. To date, such data have only been published in single-subject studies or for loads that are too small compared to those experienced during sitting. Hence, the aim of this study was to quantify, using MRI scanning, the *in-vivo*, quasi-static deformation of gluteal muscle and fat tissues for a diverse sample of seated humans with focus on tissues below the ischial tuberosity.

METHODS

Ten healthy men within a diverse range of stature and body mass were scanned, while sitting in a recumbent posture, using a wide-bore MRI scanner. In each scan, the subject's posture was supported by cushions placed behind the back and under the knees. The angle of the back support surface was 135° to forward horizontal (45° to vertical). The lower-extremity support produced a 60° of knee flexion. The buttock area was supported by a pair of horizontal, flat, rigid boards, one under each buttock. Due to the reclined posture, a head support was provided. A belt was strapped around the subject's knees to prevent body movement during the scans. Each subject was exposed to three loading conditions and a scan was taken for each of these conditions. In the first scan, the subject sat in a weight-bearing posture, with the left and right buttocks deformed by the subject's weight. The second scan was taken after removing a 10-mm wooden block under the subject's left buttock, which left it partially deformed. In the final scan, the non-weight-bearing posture was simulated by removing two additional wooden blocks under the left buttock, leaving all soft tissue layers undeformed. Each subject remained in each posture (after the blocks were removed) for approximately five minutes before the scanning started. A proton density sequence with inter-slice interval of 10 mm in the transverse plane was used for all scans. For each of the loading conditions, the thicknesses of muscle and fat tissues below the ischial tuberosity and the greater trochanter were measured from the MRI data. Tissue deformations from the weight-bearing to non-weight-bearing, and from partial-weight-bearing to non-weight-bearing conditions were calculated as differences between the undeformed and the fully deformed thicknesses, and differences between the partially deformed and fully deformed muscle and fat thicknesses, respectively.

RESULTS

Muscles and subcutaneous fat tissues of all subjects deformed the most below the ischial tuberosity. The mean (± SD) total deformation (from fully deformed to fully undeformed) of muscles and subcutaneous fat tissues below the ischial tuberosity were 17.7 mm (± 4.8 mm) and 4.3 mm (± 5.6 mm) respectively. The Gluteus Maximus muscle deformed the most in the transition from the partially deformed to the undeformed condition. The muscle further deformed while transitioning from the fully deformed to the partially deformed states (Figure 1). Fat tissues below the ischial tuberosity were deformed by a few millimetres while transitioning from the partially deformed to the undeformed state. However, fat thickness below the ischial tuberosity remained almost constant as the buttock transitioned from the fully deformed to the partially deformed states.

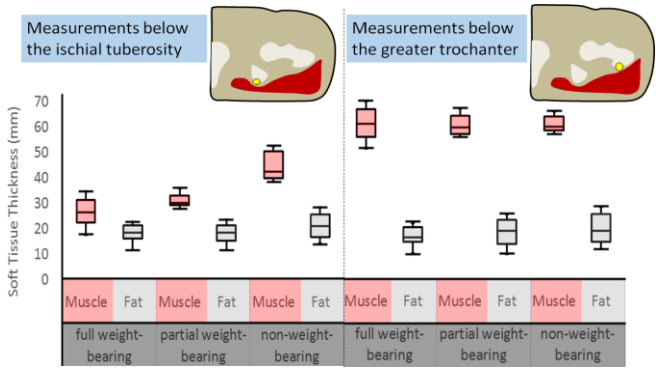

Figure 1: box plots for soft tissue thicknesses below the ischial tuberosity (left) and the greater trochanter (right) for each of the studied loading conditions.

DISCUSSION AND CONCLUSIONS

The study revealed that muscles below the ischial tuberosity deformed during both phases from weight-bearing to non-weight-bearing, while subcutaneous fat tissues deformed only from weight-bearing to partial weight-bearing conditions. This behaviour, observed across the entire cohort, suggests that the muscle strain will be more sensitive to changes in seat support surface and load distribution than strain in subcutaneous fat.

VISCOUS LOAD CHANGES THE CILIARY FORCE AND FLOW ON A TRACHEAL LUMEN

[1]**Takuji Ishikawa**, [1]Kenji Kikuchi, [1]Tomofumi Haga, [1]Keiko Numayama-Tsuruta, [2]Hironori Ueno

INTRODUCTION

Mucous flow in a tracheal lumen is generated by the beat motion of ciliated cells to provide a clearance function by discharging harmful dust particles and viruses. Due to its physiological importance, the cilia-generated flow and the rheological properties of mucus have been investigated intensively [1]. The effects of viscosity on the cilia-generated flow, however, have not been fully clarified. Moreover, no previous study has clarified the pump power generated by cilia, which provides important information with regard to understanding the molecular motor properties of cilia. In order to answer these questions, we measured ciliary motion and ciliary flow under various viscosity conditions in mice in this study [2].

METHODS

Experiments were conducted with the approval by the Animal Ethics Review Board of Tohoku University. Respiratory epithelial tissues were dissected from female wild-type mice that were 6–10 weeks old. The experimental procedure followed our previous study [1].

In order to investigate the effect of viscosity, the sample specimens were suspended in L-15 medium with several concentrations of methylcellulose 400. The rheological properties of methylcellulose solutions were measured using a cone-plate rheometer. It is found that the rheological properties of the methylcellulose solutions were well expressed as a power-law fluid.

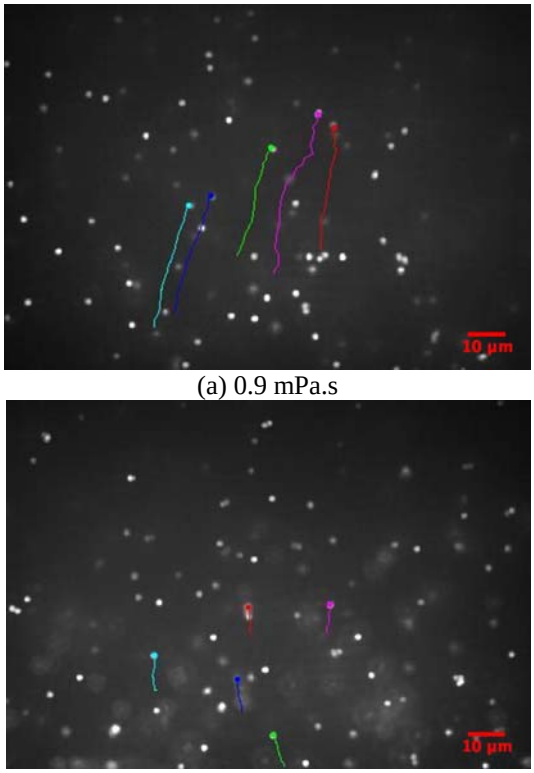
RESULTS AND DISCUSSION

We first measured the area ratio of ciliary cells in the trachea and main bronchus by visualizing the cell shape and cilia using phalloidin staining of f-actin and immune-fluorescent analysis of acetylated-tubulin. Respiratory cilia were distributed sparsely in the airway surface, with no significant difference between the trachea and the main bronchus.

Second, we observed ciliary motion using μPIV and a high-speed camera equipped to a differential interference contrast microscope. As a result, the influence of viscosity on the ciliary beat frequency and the beat amplitude was revealed.

Third, in order to elucidate the effect of the viscosity on cilia-generated flow, we used μPTV and observed the flow by a confocal microscope, and tracked fluorescent particles transported by ciliary motion. Fig. 1 shows trajectories of tracer particles during 1 second with two different apparent viscosities: 0.9 mPa.s and 76.9mPa.s The results illustrated that the velocity of cilia-generated flow decreased as the viscosity was increased in trachea and main bronchus.

Last, measurements of both the ciliary flow and the ciliary motion were conducted to determine the cilia pump power. Our results indicated that the cilia pump during the effective stroke did not drive the ciliary flow efficiently under high viscosity conditions, though the ciliary force increased almost linearly with the viscous load.



(a) 0.9 mPa.s

(b) 76.9 mPa.s.

Figure 1: Trajectories of tracer particles during 1 s with two different apparent viscosities [2]

CONCLUSIONS

We investigated experimentally, using both mouse trachea and bronchi, the effect of viscous load on ciliary motion and cilia-generated flow. The force induced by cilia to the fluid was directly discussed by combining the results of ciliary motion and cilia-generated flow. Our results indicated that the cilia pump during the effective stroke did not drive the ciliary flow efficiently under high viscosity conditions. The finding is necessary to resolve the clearance function.

MODELING APICAL COLUMNAR EPITHELIUM MOVEMENT FROM CIRCUMFERENTIAL FIBERS

[1] **Andrew RB Boyd**, [2]Stephen Moore, [1]John E Sader and [1]Peter VS Lee
[1]University of Melbourne
[2]IBM Research Australia

INTRODUCTION

Columnar epithelial cells are one of the most common cell types in the human body. They are involved in both normal and diseased body activity. Individual epithelial cells combine together to form a continuous sheet called an epithelium. Each epithelium has a contractile cross section located near the top surface of the cells. This cross section produces forces that help to control the movement of the epithelium. The contractile nature of the cross section arises from a ring of sub cellular circumferential contractile fibers that surround the circumference of each cell. The movement of the contractile cross section has been modelled using a number of approaches [1]. These approaches variously describe the movement of the epithelium based on forces produced by sub cellular structures in and around the contractile cross section and geometric constraints such as conservation of area.

Here we investigated whether a contractile cross section model based only on circumferential contractile fibers can reproduce the movement of the columnar epithelium when perturbed by laser ablation of edges. We based our description of contractile fiber movement on work that investigates movement of contractile fibers as an individual system, which provides additional insights into how epithelium contractile fibers move.

METHODS

In our model we described the contractile cross section of the columnar epithelium using a force based vertex modelling approach. In this approach, the contractile cross section is described by a series of edges (representing cell peripheries where contractile fibers are located) and vertices (representing points where three or more cell meet). We then solved the overdamped equations of motion at each vertex [1], where the forces in each equation result from the cell edges connected to each vertex.

We considered that each contractile fiber, and the edge of which it is a part, can undergo both stretching and contraction. We used an experimentally found engineering linear stress strain relationship [2] for stretching, and a linear contraction speed versus load relationship common in individual contractile fiber literature [3] for contraction. When the contractile fiber description was added to each vertex the final equation of motion was:

$$\dot{\boldsymbol{x}}_{i,v} = \sum_{d=1}^{D}\left(\frac{\boldsymbol{F}_{i,d}^{Con}}{\mu} + \left(\frac{AE}{\mu} \frac{\left\| \boldsymbol{L}_d \right\| - L_{\min,d}}{L_{\min,d}} \frac{\boldsymbol{L}_d}{\left\| \boldsymbol{L}_d \right\|} \right)_i \right)$$

where $\boldsymbol{x}$ is vertex location, μ is damping, $\boldsymbol{F}^{Con}$ is contraction force, A is cross section area, E is the modulus, $\boldsymbol{L}_d$ is edge length, $L_{\min,d}$ is edge minimum length, i the two dimensions, d each edge of a vertex and v the vertex number. We matched the model parameters to a primary dataset (from [4]), and then used those same parameters to predict a second dataset (from [5]) as validation. The geometry of each simulation was matched to the experiment.

RESULTS AND DISCUSSION

The model reproduced the experimentally determined qualitative movements of a laser ablated columnar epithelium (Figure 1a), specifically, anisotropic movement reducing with distance from the cut point. Quantitatively the model reproduced the overall sheet movement (Figure 1b) and the final movement of the severed edge (Figure 1c). The model, however, predicted that movement of the severed edge happened much faster than in experiments. The validation dataset had the same trends and quantitative matches (data not shown); though the final cut join movement could not be compared as it was not shown in the validation dataset. Taken together these results indicate that a contractile fiber based model can reproduce the majority of epithelium movements upon laser ablation.

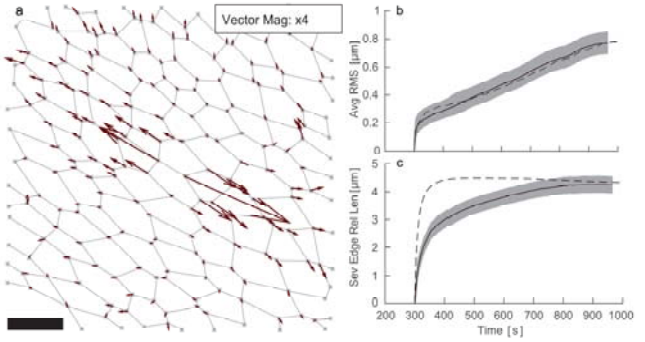

Figure 1: Simulation prediction of primary dataset. **a)** Vertex movement from just before severing to 350 seconds. Scale Bar: 5 microns. **b & c)** Average root mean squared and severed edge movement of sheet respectively. Solid line and grey are experimental movement (mean and three standard deviations). Dashed line is model prediction.

CONCLUSIONS

In this work we showed that a contractile cross section model based solely on circumferential contractile fibers can reproduce the majority of columnar epithelium movement upon laser ablation.

MECHANICAL PROPERTIES OF SYNTHETIC POLYMERIC NANOFIBROUS WITH PROTEIN NANOCOATINGS

[1,2]**Daniel Hadraba**, [1]Frantisek Lopot, [2]Marketa Bacakova, [2]Julia Pajorova and [2]Lucie Bacakova

INTRODUCTION

Plain or protein-coated synthetic materials are promising for the fabrication of advanced tissue engineered constructs. These materials are often based on engineered nano structures from different resources which are produced and post-processed for a broad spectrum of applications; skin, bones, or vessels scaffolds. To better understand the function of the components in the multi-hierarchical nano structure and the relationship with the growing cells, it is necessary to observe the materials at different scale levels. This brings several challenges as the nano structures are below the resolution limit of conventional visualization methods which are used with mechanical testing protocols, and also the mechanical protocols are often transferred from the fields of industrial material testing. Therefore, it is necessary to update or invent imaging and mechanical testing protocols which offer precise material identification for cell *in vitro* tissue engineering experiments. In this study, the electrospun polylactide (PLA) and polyactide-co-glycolide nanofibrous (PLGA) membranes were coated with fibrin or collagen I, and then with fibronectin attached to the surface of these proteins. Finally the membranes were tested for their mechanical properties and spatial organization.

METHODS

The nanofibrous membranes in the Cell Crown inserts (n = 6 for each group of scaffolds) were placed into the manufactured holder and secured against a tilt. Then the holder was fastened in the standard microscope stage (Leica DM2500, Leica, Germany) and the microscope condenser was replaced with a manufactured tooling that carried the low level force sensor Kistler 9203 (Kistler, Switzerland) with a spherical cup probe (Figure 1.1). Due to the construction of the DM2500 microscope, the force sensor can move independently on the stage in respect to the focal plane. First, the membranes were focused and imaged by the confocal microscope (objective 4x, image resolution 1024x1024, pixel size 1.8 μm) to verify their structural integrity. Second, the camera started capturing the calibrated images (image resolution 1920x1440, pixel size 0.05 mm) of the membrane at 10 Hz repetition rate and the force sensor recorded the force changes at 100 Hz repetition rate. Finally, the force sensor with the probe moved towards the sample at the speed of 0.2 mm/s until the force value returned to zero. The deformation u_z of the nanofibrous membranes was evaluated in Matlab 2015a (Mathworks, USA) by image segmentation (thresholding and edge detection using Sobel filter). The stress in the membrane σ_t is based on static equilibrium and calculated from the force data F_z and deformation u_z as

$$\sigma_{t(u_z \geq a)} = \frac{F_z}{2\pi R d \tan^{-1}\left(\frac{R}{u_z}\right)}$$

or

$$\sigma_{t(u_z > u)} = \frac{F_z}{2\pi R d \tan^{-1}\left(\frac{R-r}{u_z-f}\right)}$$

for

$$a = \frac{f}{r}R.$$

RESULTS AND DISCUSSION

The puncture testing revealed a faster mechanical response of PLA membranes. At about 1 mm deformation, the direction changed dramatically and the PLA response is linear until rupture. On the other hand, the PLGA membranes reacted to loading gradually and reached significantly lower ultimate strength then PLA groups (Mann–Whitney U test, p = 0.032). After the collagen modification, the membranes seemed to become brittle. The fibrin modification caused an upward trend in ultimate strength. However, there was not a significant difference at the ultimate strength when comparing all the modifications (Kruskal-Wallis test, p = 0.177).

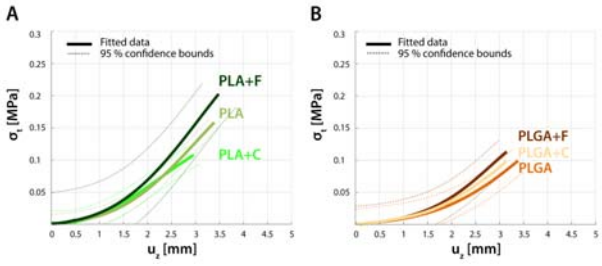

Figure 1: The puncture mechanical testing. The membranes mechanical response was plotted for each modification of PLA and PLGA as a polynomial fit for the mean values (thick colored line) and as the confidence bounds (thin dashed line).

CONCLUSIONS

The protein nanocoatings developed for this study on nanofibrous PLGA and PLA membranes has a major influence on the behavior of skin cells as well as on the mechanical behavior. For this reason, the new instrument was developed to measure the mechanical behavior of the nanofibrous material or the material with the cell culture. Thanks to this approach, it was revealed taht the collagen-coating did not improve mechanical properties compared to fibrin-coating that showed an increase in the membrane stiffness. Thus the fibrin-coating could better resist contractile forces from fibroblasts than the collagen gel.

INTRODUCTION

Muscle contractures are a common complication of stroke injury, characterized by an increase in muscle stiffness and a restriction of joint range of motion (ROM) [1]. Since contractures are interfering with motor recovery [2], muscle stiffness measurements are relevant to support treatment plans fighting against contractures. However, it remains unknown whether contractures are homogenous among a muscle group or if specific locations are more affected. This could be particularly important to propose targeted treatments on predominantly affected locations. Therefore, the purpose of the present study was use a previously validated protocol [3] to measure the shear modulus (i.e., index of stiffness) distribution of plantar flexor muscles using shear wave elastography (SWE) in stroke survivors and matched-controls.

METHODS

13 stroke survivors (8 men/5 women; age: 54.3±12.6 years; height: 170.0±6.5 cm; weight: 69.8±10.4 kg) and matched controls were recruited. Participants were lying supine with the knee full extended. Slow passive ankle dorsiflexions were performed from 40° of plantarflexion up to 80% maximal dorsiflexion ROM. The shear modulus was randomly measured using SWE [3] for the *gastrocnemius medialis* (GM x 3 probe locations), *gastrocnemius lateralis* (GL x 3), *soleus* (SOL x 2), *flexor digitorum longus* (FDL x 1), *flexor hallucis longus* (FHL x 1), *peroneus longus* (PL x 1) and main dorsi flexors *tibialis anterior* (TA x 1), and *extensor digitorum longus* (EDL x 1). The same experiment was performed with the knee flexed, but only the results obtained knee extended are presented in this abstract.

Due to skewed and non-normal distribution of data, Mann-Whitney U tests were conducted to compare the shear modulus values between stroke survivors and matched controls: i) at the same ankle angle, corresponding to the maximal common ankle angle in dorsiflexion between each of pair of participants; ii) at 80% of the maximal ROM for each subject. Effect sizes were estimated using the General Mann-Whitney measure (θ) corresponding to the degree of discriminatory between two populations [4]. θ=0.5 gives a perfect concordance (i.e. equal distribution of the populations), and θ=0 or θ=1 no overlapping between the two populations.

RESULTS AND DISCUSSION

The analysis performed at the same ankle angle between pairs of participants (i.e. 22.6° in dorsiflexion) showed that the shear modulus values were consistently greater for stroke survivors than controls whatever the probe location on *gastrocnemii* muscles (all p-values<0.014, Figure 1). Differences also appeared for SOL muscle (SOLpro, p=0.009), FDL (p=0.006) and TA (p=0.031). Excepted for the TA, large effect sizes were found with θ consistently lower than 0.25.

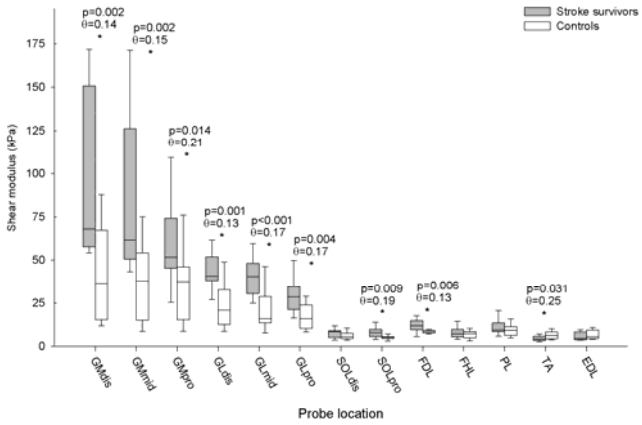

Figure 1: Shear modulus values for stroke survivors and controls, at the maximal common ankle angle.

The analysis performed 80% of the maximal ROM in dorsiflexion (i.e. 16° and 28° for stroke survivors and controls, respectively) showed no significant differences in shear modulus (p>0.05) between both populations for all locations, excepted for TA (p=0.021, θ=0.23). This finding suggest that the increase in muscle shear modulus at a given angle is mainly due to retractions (i.e. decrease in slack length). A further analysis on slack angle [3] will be performed to discuss this point in more depth.

CONCLUSIONS

The first results obtained knee extended suggest that the *gastrocnemii* are predominantly affected, and that SWE is a promising tool to analyze muscle stiffness distribution for stroke survivors.

EMG NORMALIZATION TECHNIQUE FOR UNDERSTANDING LOWER EXTREMITY MUSCLE FATIGUE INTERACTION WITH JOINT KINEMATICS IN RECREATIONAL ENDURANCE RUNNERS

[1] **Muhammad Jafar Ali**, [1]Hoon Kay Hiang, [1]Seet Gim Lee Gerald, [2]Govindasamay Balasekaran
[1] School of Mechanical and Aerospace Engineering, Nanyang Technological University, Singapore
[2] Physical Education and Sports Science, Human Bioenergetics Laboratory, National Institute of Education, Singapore

INTRODUCTION

Technique related to time-frequency domain analysis of EMG signal is critical to understand muscle fatigue and the neuromuscular control strategies of the lower extremity muscles. As lower extremity involves biarticular muscles like hamstring, quadriceps, gastrocnemius and shank muscles, using the maximal voluntary contraction (MVC) technique to normalized the activation level of biarticular muscle during running gait cycle is a matter of concern due to the existing activation differences in force-length relationship of the working muscles [1] under dynamic contractions and their relative support contribution at different joint angle during running. It has also been said that finding the MVC level required complex approach as accompanying joint do support the particular muscle during dynamic contraction [2] whereas such support is restricted under static contraction which may change the activation dynamics either way. Considering such complex issue, this paper proposed a methodology to record the neuromuscular activity of the lower extremity muscles (RF, VL, BF, ST, GM, GL, TA) at the 4th minute of run during submaximal critical speed run to exhaustion for endurance recreational runners and to use that as a reference to normalize and understand muscle fatigue and its modalities in the lower extremity running mechanics.

METHODS

Total of 17 non-injured male recreational runners (age 22.94±1.48 year, BMI 22.16±1.92, VO_{2max} 57.63±5.46 $ml.kg^{-1}.min^{-1}$) gave written informed consent. Total 2 testing sessions were conducted with a recovery period of 5-7 days in-between. Session 1 was used to determine the endurance pace, using anaerobic threshold of lactate 4.0 mmol. l^{-1}. Session 2 was administrated to simulate endurance running and to collect EMG data using Trigno wireless EMG system for rectus femoris (RF), vastus lateralis (VL), bicep femoris (BF), semitendinosus (ST), gastro medial (GM), gastro lateral (GL) and tibialis anterior (TA) muscles whereas for lower extremity kinematic data (hip angle, knee angle, ankle angle, foot pronation), video data were recorded. Both data were recorded for 20 seconds after every two minute of run till volition exhaustion.

Video data was digitized and joint angles were determined using 'Kinovea' software whereas EMG data was processed in 'EMGWorks'. EMG signal was processed using 2nd order butterworth filter (35-500Hz cut-off frequency) for consecutive 5 running gait cycles after dc-offset removal. Cyclic analysis was carried using step detection algorithm to determine neuromuscular activation profile of each muscle during running gait (using 30 msec avg. window). Time dependent median frequency (TDMdPF) was determined to study fatigue dynamics of the lower extremity muscles. Following eq (1) represents the calculation for fatigue index (Fi), using first recording ($TdMDPF_{1^{st}\ stage}$) as the reference to calculate muscle fatigue index with fatigue progression (shift in TDMdPF known as $TDMdPF_i$).

$$\text{Fatigue\_Index} = \left((TDMdPF_i / TDMdPF_{1^{st}\ stage}) - 1 \right) * 100 \quad \text{.. Eq (1)}$$

RESULTS AND DISCUSSION

Neuromuscular activation differences were observed in term of activation level and median frequency shift with fatigue progression. These alterations in neuromuscular activity were basically because of force fatigability relation of the working muscle, physiological status and sense of effort of the working muscles to determine level of impairment [3]. Finding of lower extremity muscles activation reported that the average trend of iEMG for the selected group of muscles (GL, TA) was observed to decrease, RF, ST and GM almost remain stable, VL and BF was observed to increase and ST did not report any change for the generalized data. Considering the 'Fi' of the quadriceps and hamstring group of muscles, hip angle reported a positive significant correlation with RF (r=0.316, p=0.005) and VL (r=0.188, p=0.025) whereas knee angle was not found to have a significant correlation. For the calf and shank, difference in iEMG of GM and GL muscles at midstance and propulsion phase of running gait cycle were observed. Such relative difference in GM and GL during heel off at externally rotated and internally rotated feet position were also reported by Riemann et al. [4] and it can be concluded that altering foot position during heel-off will prompt varying degrees of GM and GL activation, as reported in this study. Results reported significant correlation between pronation and fatigue status of GL (r=-0.169, p=0.05) and non-significant with GM (r=0.114, p=0.214) muscles. Ankle angle was also found to have a negative correlation with TA (r=-0.365, p=0.0001) which shows that reduce TA activity due to fatigue will increase the ankle angle at midstance and hence may reduce the impact energy absorption during landing at ankle joint due to reduced tibialis activity.

CONCLUSIONS

The results of present study suggest that studying neuromuscular fatigue behavior in lower extremity during endurance running through proposed data analysis technique result in better understanding of neuromuscular changes with fatigue progression and explain its interaction with joint mechanics. However, more studies are needed to support the observed findings in order to establish the proposed data analysis technique widely acceptable.

BETWEEN SESSION SHIFT IN JOINT ANGLE TRAJECTORY USING OPTICAL MOTION CAPTURE

[1]Ulster University
[2]The R&A
Corresponding author email: kristianjones@randa.org

INTRODUCTION

The accurate and consistent measurement of kinematics is of primary importance to the sports biomechanics community. The wide spread use of marker based motion capture systems has made the ability to collect and process large amounts of movement data more prolific than ever. However, marker occlusion, marker placement, soft tissue movement and other errors can all affect the quantification of kinematics obtained using motion capture. Thus, our ability to detect real and meaningful changes in kinematics can be limited by the effects of these motion capture errors.

Of interest to this research were the errors in kinematics introduced by the removal and re-application of motion capture markers in essentially the same location, for instance between multiple testing sessions. In these situations, shifts in joint angle trajectories between sessions of up to 10° have been observed [1]. Furthermore, the minimal detectable change in healthy gait kinematics measured on two separate occasions has been reported as between 3-5° depending on the joint [2]. The current study used different artificial conditions to determine the effect of removing and reapplying motion capture markers on the resultant kinematics.

METHODS

Testing used a golf robot as a convenient mechanical system with well-defined joints. Fixtures were fitted to the surface of the golf robot which provided different surfaces on which to attach 12mm spherical retro-reflective markers. A four-camera motion capture system (Oqus 3+, Qualisys, Gothenburg, Sweden), measuring at a capture frequency of 500Hz, was used to capture the movements of the markers. The conditions tested were: markers adhered directly to the surface of the robot, markers adhered to a fixture attached the surface of the robot using screws and cable ties and markers adhered to gelatin molded onto the fixture. Thus, each condition added a level of compliance to the rigid links of the underlying system.

For each condition, the test procedure was as follows; First markers were applied to the system and a static trial of 1 second was collected. Movement trials were then taken to determine the location of functional joint centres for the kinematic model [3]. A reference movement was then recorded. The process of static trial and functional joint trials was then repeated 6 times with all the markers left in place and 6 times with a subset of markers removed and replaced in between trials. The subset of markers which remained in in place were not used in the joint centre calculations or in the kinematic model. Instead they allowed the joint coordinate systems calculated from the removed markers to be tracked during the reference movement, despite markers being replaced between the two trials.

Marker trajectories were labelled and exported into Visual 3D (C-Motion, Germantown, MD) and a kinematic model constructed for each trial using the replaced markers. The joint coordinate systems from these models were tracked with the static markers and applied to the reference movement. This way only the differences in kinematics caused by the removal and re-application of markers was observed. Joint angles, the positions of all replaced markers and the positions and orientations of the local coordinate systems based these markers were calculated in the appropriate static coordinate system and data exported to Matlab (R2015b, Mathworks, Natick, MA).

RESULTS AND DISCUSSION

In all conditions, the standard deviation of marker position was below 1.5 mm depending on the marker location. Under the first condition, where the markers were adhered directly to the surface of the robot, the functional joints approach proved successful at minimising the difference between trials where the markers were replaced. However, in conditions where there was compliance added to the system, both with the fixture and the gelatin, offsets in joint angle of up to 10° between trials was observed.

CONCLUSIONS

These results suggest that, in situations where markers are removed and re-applied, shifts in joint angle data can occur due to slight differences in marker location combined with the underlying compliance of the system being studied. These shifts can occur even when the kinematic model uses functional joint centres calculated from movement trials. In situations where markers have been removed or replaced between sessions, it may be more appropriate to study the difference in shape between curves, as opposed to the distance between curves or absolute joint angle.

INTRODUCTION

Drilling is one of the commonly used surgical procedures involved in most of the orthopaedic surgeries. Controlling the force to prevent drill-bit breakthrough, excessive heat generation and mechanical damage are of great importance in orthopeadic surgery. In this work, ten freshly harvested adult cadaveric human femurs were used for the experiments. Three levels of spindle-speed (500, 1000, and 1500 rpm) and feed-rate (40, 60, and 80 mm/min) with 3mm diameter drill-bit were considered for the experiments. Multiple linear regression model with 5% significance level ($p < 0.05$) was developed to estimate the cutting force. A CT image based reconstruction which could store and retrieve the cutting force data depending upon the anatomical locations was developed. The proposed method could accurately estimate the cutting force from the CT data sets and can give idea to surgeon before real-time surgery.

METHODS

Ten adult cadaveric human femurs free from fracture and disease were collected in the 58 to 70 age group. SIEMEN SENSATION® CT scanner was used to scan the femurs and the data sets of the femurs were saved in the protocol for further analysis. The proximal head and condyle portions of each femur were removed and only the shaft portions of the femurs were considered for experiments. Two parameters (speed (s) and feed (f)), each at three levels were considered. The cutting forces developed at the drilling sites were recorded with a six-component KISTLER® dynamometer. The cutting force generated for the 9 sets of parameters (40 mm/min and 500 rpm, 40 mm/min and 1000 rpm,……., 80 mm/min and 500 rpm, and 80 mm/min and 1000 rpm) were investigated in the radial direction of the proximal-diaphysis, mid-diaphysis and distal-diaphysis regions to account the variations of apparent density (ρ_a) considered from grey to black. Totally 135 (9-sets of parameters X 3-anatomical regions X 5-drills) holes were drilled and the corresponding forces were recorded. Pearson linear coefficient estimated between cutting force and spindle-speed (r = 0.87) and feed-rate (r = 0.83) show strong positive correlations. But, it shows a moderate positive correlation between cutting force and apparent density (r = 0.72). By employing multiple regression analysis on force versus speed, feed, and apparent density, a linear correlation model was established. Then the cutting force required to drill the cortical bone in the radial direction can be expressed as follows:

$$F_c(\mathrm{N}) = \left(0.33 f - 0.016 s + 15.60 \rho_a\right) \quad (1)$$

To validate the protocol developed in this work, 72 years old male was considered and the CT data sets of the right femur obtained were loaded in MATLAB ®. After calibration [1], the relation between CT number in Hounsfield unit (HU) and cortical bone apparent density in g/cm^3 was established [2]. Then the mean CT number was computed for 135sites randomly. By using the equation (1), the cutting force required to drill the cortical bone was estimated for each site and the typical femur was reconstructed with 3 mm X 3 mm X 3 mm voxle. Then the geometric model was developed and constructed with force data. In this work, the voxel size was decided based upon the drill-bit diameter (3 mm) and depth of hole drilled (3mm) in respect of the drill-bit axis.

RESULTS AND DISCUSSION

It was observed that the increase in cutting force was increased linearly, when feed-rate, spindle-speed and apparent density increased (Figure 1). Because of the distribution of high apparent density in the mid-diaphysis region of the femur, the magnitude of cutting force required to drill was more compared to proximal and distal diaphysis regions. Moreover, the influence of spindle-speed on cutting force was more followed by feed-rate and apparent density.

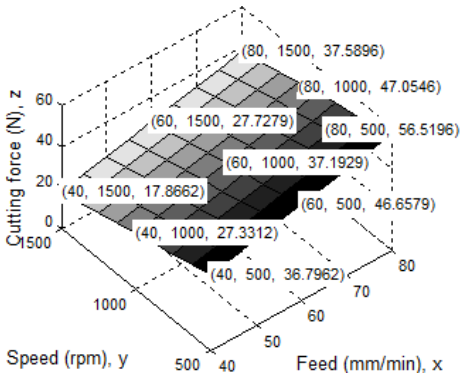

Figure 1: Force versus speed, feed and apparent density.

CONCLUSIONS

Owing to the orientations of large number of pores in the longitudinal direction, force required to drill in that direction was less followed by radial and circumferential directions. Also, chance to get drill-bit breakthrough, osteonecrosis and damage to bone were more in the mid-diaphysis region. Thus the regression model developed in this work can give idea to surgeons about the required cutting force before performing real-time surgical operations in the radial direction for a fixation of plate specific to a bone site.

NORMAL WIDTH OF THE LINEA ALBA IN PREGNANT AND POSTPARTUM PRIMIPAROUS WOMEN

[1,2] **Patrícia Mota**, [1]Augusto Gil Pascoal, [1]Ana Isabel Carita and [3]Kari Bø

INTRODUCTION

Diastasis recti abdominis (DRA) refers to a musculoskeletal condition in which the horizontal distance between the middle edges of both rectus abdominal muscles, the Inter Recti Distance (IRD), is increased above a certain value. The IRD is equivalent to the width of the linea alba, widens during pregnancy, and at 6 months postpartum many women have not recovered[1]. There are normative values on the width of the linea alba for nulliparous women [2]:up to a width of 15 mm at the xiphoid, up to 22 mm at 3 cm above the umbilicus and up to 16 mm at 2 cm below the umbilicus. However, to date there are few studies about the normal width of the IRD in pregnant and postpartum women. Normative reference values for the IRD in primiparous women are important to identify deviation from normal and evaluate response to treatment.

The purpose of this study was to evaluate the width of the linea alba, i.e. the IRD, measured at three reference points in order to establish normative data for IRD in pregnant and postpartum (6 months) primiparous women.

METHODS

This was a cross-sectional observational study. Ultrasound images were recorded in 84 primiparous women with a 12 MHz scanner (GE Logic-*e*) in a lying supine rest position, at three locations on the linea alba: one below the umbilicus; 2 cm below (BL2) and two above the umbilicus; 2cm (AB2) and 5 cm (AB5). The measurements were made in the third trimester of pregnancy (>37 gestational weeks), and at 6 months postpartum. The 20th and 80th percentiles were calculated to define the normal width of the IRD. Specific software (SPSS 20) and a significantly level of $p<.05$ was used for statistics.

RESULTS AND DISCUSSION

The mean age of the 84 participants was 32.1 years (range 25-37) and 81% of the women had undergone university education. They gave birth at mean gestational week 38.8 (range 37-41). 61.9% had vaginal delivery and 38.1% had cesarean sections, and the mean birth weight was 3130 grams (range 2300 to 4000).

At gestational week 37 the mean IRD was 64.6 mm (SD 19.0) and ranged from 22.1 mm to 126.0 mm at rest on measurement 2 cm below the umbilicus, with a prevalence of DRA of 100%.

The results revealed a broad range of values at the three reference points measured (Table 1). There was no significant correlation of age or body height with the widths of the linea alba. There was no correlation between body weight and body mass index with the widths of the linea measured at the 3 reference points during pregnancy. There was a weak, positive correlation between body weight and body mass index with the widths of the linea at AB5 at 6 months postpartum ($r = 0.3$). The linea alba was widest at AB2 reference point in pregnancy and postpartum (86 mm and 28 mm respectively). During pregnancy, the width AB2 was significantly greater than that at AB5 ($P < 0.001$). At 6 months postpartum the width at AB2 was significantly wider than at BL2 and AB5 ($P < 0.001$). The 20th, 50th, and 80th percentiles are listed in Table 1. The 20th and 80th percentiles were calculated to define the normal width of the linea alba. These values indicate that the linea alba width can be considered ‘‘normal’’ during pregnancy from 49 to 79 mm at BL2, from 54 to 86 mm at BL2 and from 44 to 79 mm at AB5. At 6 month postpartum, the linea alba width can be considered ‘‘normal’’ from 9 to 21 mm at BL2, from 17 to 28 mm at AB2 and from 12 to 24 mm at AB5.

Table 1: The 20th and 80th percentiles calculated to define the normal width of the Linea Alba (in mm) at three reference points (AB2, AB5, BL2) in pregnant and postpartum women (n=84).

		Percentiles		
		20%	50%	80%
Pregnancy	AB5	44	59	79
	AB2	54	64	86
	BL2	49	63	79
Postpartum	AB5	12	17	24
	AB2	17	22	28
	BL2	9	14	21

AB2 and AB5: 2cm and 5cm above umbilicus
BL2: 2cm below umbilicus

CONCLUSIONS

The IRD varies along the linea alba. The normative values for the width of the IRD should be defined at different reference locations on the linea alba. In primiparous women, the IRD may be considered “normal” up to values wider than for nulliparous women.

In clinical practice physiotherapists need to identify the different normative values for the IRD, depending on different conditions (e.g. parity), so that deviations from normal are accurately accessed. Further studies with larger sample sizes are warranted.

INTRODUCTION

Incidence of congenital hearing loss is as high as one in 800, and congenital hearing loss brings about serious language disorder. Currently, congenital hearing loss is usually detected in neonatal period. However, the inner ear is developed and is completely formed from 22 weeks gestational age (GA) to 28. If fetal hearing screening is therefore possible, early recognition of congenital hearing loss and development of early treatment might be possible. In this study, we measured piezoelectric vibrator-stimulated potential (PVSP) on the surface of the maternal abdomen in order to examine hearing ability of fetuses.

METHODS

Bone conduction is more effective sound transmission way for fetuses than air conduction [1]. We therefore developed a sound stimuli system via bone conduction equipped with a piezoelectric vibrator. This system consists of a function generator (WF1944, NF Corporation), a piezo driver (As-904, NF Corporation), and a piezoelectric vibrator (AE1414D16F, NEC Tokin). The relationship between the input voltage applied to the piezoelectric vibrator and the sound pressure generated in the uterus was evaluated using a physical model made by a sponge plate and a plastic case [2] and a finite-element model of the uterus. The vibrator was placed on the surface of the maternal abdominal wall just above the fetal temporal bone. Intrauterine environmental sound is composed of lower frequencies than 500 Hz, and the intensity is increased from 20 dB to 50 dB as the frequency becomes lower [3]. Therefore, tone burst sound stimuli (2 kHz, 70 dB) were delivered through the piezoelectric vibrator. The duration of sound stimuli was 2 ms, and the stimuli were applied every 100 ms intervals. The data of potential waves were averaged over 1000 times using a Neuropack EMG/EP measuring system (Nihon Kohden). Two recording electrodes were placed on the surface of the abdominal wall above the fetal head, and the reference electrode was placed on the femur which is considered to be not affected by brain waves of the fetus (Fig. 1 (a)). The PVSP responses were measured in 13 healthy pregnant women in the period of 33 to 38 weeks GA. To enhance reproducibility of the PVSP responses, each subject was measured three times.

Correlation factors were calculated between the three PVSP curves and the similarities of these curves were evaluated to detect auditory evoked response from the PVSP. The correlation coefficients of combinations of two of the three potential curves were calculated in each short time segment. Then, if the three correlation coefficients were positive and the average of these correlation coefficients exceeded 0.4 at a certain moment, the PVSP were considered as auditory evoked response.

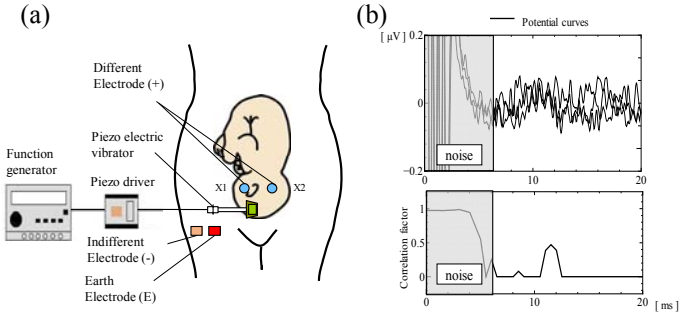

Figure 1: (a) Measurement system of piezoelectric vibrator-stimulated potential. (b) Example of measured potential curves and time variation of the average of the correlation coefficients in 38 weeks gestational age.

RESULTS AND DISCUSSION

Auditory evoked responses were detected 17 out of 19 subjects, and the detection rate was 89.5%. Figure 1 (b) shows an example of the measurement result at 38 weeks GA. The upper figure shows three original waves and the lower figure shows the time variation of the average of the three correlation coefficients. The auditory evoked response appeared with a latency of 10 to 12 ms. Moreover, focusing on 35-37 weeks GA, the average of the latencies in 35-36 weeks GA fetuses are longer than that in 37 weeks. This tendency is similar to the characteristic of auditory evoked response in preterm infants [4].

CONCLUSIONS

In order to examine hearing ability in fetuses, PVSPs were measured on the surface of the maternal abdomen. As a result, auditory evoked responses were detected 17 out of 19 subjects. The average of the latencies of the auditory evoked responses to the stimuli in 35 - 36 weeks GA was longer than that in 37 weeks.

DIFFERENCE IN THE DYNAMIC BEHAVIOR OF THE HEARING APPARATUS BETWEEN NEONATES AND ADULTS: THE EFFECTS ON TYMPANOMETRY

INTRODUCTION

Although early diagnosis and treatment of hearing disorders in neonates are highly effective for realization of linguistic competence and intellectual development, the diagnostic accuracy in the initial period of life is low. Tympanometry has generally been used to diagnose middle ear dysfunction. Conventional tympanometry with a probe tone of 226 Hz has been acknowledged as a reliable method for adults and children [1,2]. However, this method has proved to be inaccurate in the diagnosis of infants younger than 7 months of age [3-6]. In the present study, therefore, an attempt was made to evaluate the difference in the dynamic behavior of the hearing apparatus between neonates and adults using a sweep frequency impedance (SFI) meter, which was developed for measuring dynamic characteristics of the middle ear in adults and children in our previous study [7,8]. Based on these data, the effects of the difference in the dynamic behavior of the hearing apparatus between neonates and adults on tympanometry were investigated.

METHODS

The SFI meter (Fig. 1) measures the sound pressure level (SPL) in the ear canal when a sound of the sweeping sinusoidal frequency from 0.1 to 2.0 kHz is presented to such canal under positive and negative pressures. The resonance frequency (RF) and the mobility of the middle ear in terms of changes in SPL (ΔSPL in dB) can be measured. The tests were performed in 10 ears of 9 Japanese neonates and 4 ears of 3 Australian neonates.

To investigate the dynamic characteristics of the neonatal external ear canal, a finite-element model of the neonatal ear canal was developed. Modal analyses were then performed using this model.

A graph obtained by tympanometry, called a tympanogram, expresses acoustic admittance $Y = \{j\omega\Delta V / (P_{REF} \times 10^{SPL/20})\} \times 10^8$ [mmho] as a function of static pressure applied to the ear canal. Since a variable SPL can be measured by using the SFI meter at frequency range from 0.1-2.0 kHz, the acoustic admittance Y with a different probe-tone frequency can be calculated within such range.

RESULTS AND DISCUSSION

The SPL curve for adults greatly varies at a frequency of about 1 kHz [9], reflecting the resonance of the middle ear. Interestingly, however, two variations of the SPL curve, one at around 0.3 kHz and the other at around 1.2 kHz, were observed in healthy neonates. This result suggests that there are two vibrating elements in the neonatal auditory system, possibly including the external and middle ears.

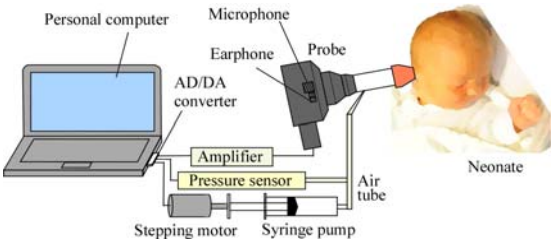

Figure 1: Schema of the SFI meter. This meter consists of a personal computer, an AD/DA converter, a probe, a stepping motor, a syringe pump and a pressure sensor. From the probe, a sweeping sinusoidal sound and static pressure were delivered to the external ear canal in neonates.

Modal analyses of the constructed neonatal ear canal model revealed that there is a resonance at ~0.3 kHz, suggesting that the first variation of the SPL curve found in neonates may be related to the resonance of their external ear canal.

Tympanograms were numerically derived from the SPL curves obtained from healthy neonates, the tympanogram being found to show type A and type M when the test frequency was lower and higher than the resonance frequency of the ear canal wall (~300 Hz), respectively. This result suggests that conventional 226-Hz tympanometry in neonates is possibly affected by the resonance of the ear canal wall.

CONCLUSIONS

There were two variations in the SPL curve at around 0.3 kHz and 1.2 kHz in neonates, which is significantly different from those reported in adults. The first and second variations may possibly be related to the resonance of the external ear canal wall and the middle ear, respectively. The application of conventional 226-Hz tympanometry to neonates results in either a type-A or a type-M tympanogram due to the ear canal wall resonance, leading to inaccurate diagnosis in neonates.

DYNAMIC CHARACTERISTICS OF NEONATAL EAR UP TO 6 kHz USING A FINITE ELEMENT MODELING APPROACH

[1] **Shinji Hamanishi**, [2]Michio Murakoshi and [3]Hiroshi Wada

INTRODUCTION

Single-frequency (220 or 226 Hz) tympanometry is widely used for diagnosis of middle-ear diseases. In infants, however, conventional tympanometry often indicates middle ear abnormality when measuring otherwise normal middle ears (Keefe et al., 1996) [1], suggesting a need to develop measurement techniques for the neonatal population.

We have developed a Sweep Frequency Impedance (SFI) meter which can measure the dynamic behavior of the middle ear by sweeping frequency tones from 100 to 2000 Hz to screen for neonatal middle-ear diseases (Wada et al., 1998; Murakoshi et al., 2013; and Aithal et al., 2014) [2-4]. In addition, computational modeling approach showed that the dynamic characteristics of the neonatal ear using a newly constructed Finite Element (FE) model is consistent with SFI measurements and is thus a viable representative model for the neonatal ear (Hamanishi et al., 2014, 2015) [5-6].

Merchant et al. (2015) [7] recently reported that Power Reflectance (PR) measurements have potential for the diagnosis of inner-ear dysfunction (e.g., superior semicircular canal dehiscence) as well as middle-ear dysfunction by sweeping frequency tones up to 6 kHz.

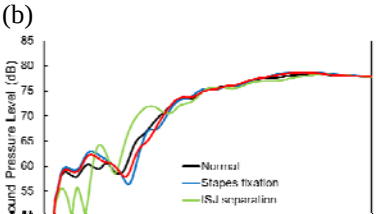
Our working hypothesis is that our SFI measurement for neonates can be applicable up to 6 kHz. As the first step toward improving our understanding of the sensitivity and specificity of SFI measurement for clinical use, we tested this hypothesis by simulating middle-ear admittance (Y_{ME}), PR, and SFI up to 6 kHz using the FE model. We also simulated some middle- and inner-ear dysfunction.

METHODS

Figure 1(a) shows the proposed FE model of the neonatal ear. Many studies have shown that the neonatal tympanic membrane and middle-ear ossicular morphometry are adultlike (Dahm et al., 1993) [8]. Geometries of the ear canal and adult middle ear were therefore constructed based on FE models by Qi et al. (2006) [9] and Cai et al. (2010) [10], respectively. The middle-ear model geometry is based entirely on a 3D reconstruction obtained by microCT imaging.

We solved the acoustic-structure interaction formulations using COMSOL Multiphysics (www.comsol.com). A constant-volume displacement (equivalent to 80 dB SPL at 1.0 kHz in a 2 cc cavity) was applied to the entrance of the ear canal, and Y_{ME} and PR were calculated for model validation. In the SFI simulation, the resonance frequency (RF) and change in canal pressure around RF for the following conditions were calculated at 0 daPa ambient static pressure: (1) normal, (2) immobilized stapes (stapes fixation), (3) no stapes load (ossicular chain separated at the ISJ), and (4) higher- and lower-cochlear impedance.

(a) (b)



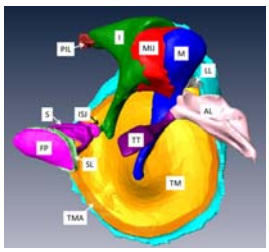


Figure 1: A FE model of the neonatal ear. (a) The middle ear includes the malleus (M), incus (I), stapes (S), malleus–incus joint (MIJ), incus-stapes joint (ISJ), footplate of the stapes (FP), tympanic membrane (TM), tensor-tympani tendon (TT), anterior ligament of the malleus (AL), lateral ligament of the malleus (LL), posterior incus ligament (PIL), stapes annular ligament (SL), and tympanic membrane annular ligament (TMA). (b) Frequency characteristics of sound pressure level (SPL) at the entrance of the ear canal in normal, diseased middle-ear and inner-ear conditions.

RESULTS AND DISCUSSION

Simulated Y_{ME} and PR are consistent with previous measurements by Keefe et al. (1996), even at 6 kHz. SFI simulation showed a significant difference between normal and diseased middle-ear conditions around 1 kHz, which was related to resonance of the middle ear. Changes in cochlear impedance induced sound pressure variation around 1 and 2 kHz in simulated SFI.

CONCLUSIONS

SFI simulation up to 6 kHz using the FE neonatal ear model indicated that a "wideband" SFI meter can possibly be used to screen for inner-ear as well as middle-ear dysfunctions. Further calculations in various inner-ear conditions are needed.

ACKNOWLEDGEMENTS

We are grateful to Sunil Puria, Massachusetts Eye and Ear, for providing the FE model of the middle ear and for information regarding simulation. This work was supported by JSPS KAKENHI Grant Numbers 26350826, 16K11194.

INTRODUCTION

Mechanical stimulation generated by fetal kicking and movement is known to be important for prenatal musculoskeletal development [1], particularly joint shape formation [2]. Significantly, abnormal joint shape leads to increased risk of osteoarthritis in later life [3]. Developmental dysplasia of the hip (DDH) is a common joint shape abnormality [4], with risk factors being associated with restricted fetal movement, such as fetal breech position [5]. Evidence suggests that movements late in gestation are particularly important for normal hip joint development, as even short term breech positioning at this stage is associated with an increased risk of DDH [5]. In this study, we investigate the biomechanics of fetal movements over gestational time by modelling fetal movements *in utero* captured using novel cine-MRI technology.

METHODS

Using in-house custom-designed tracking software [6], joint displacements during fetal kicking were tracked from each cine-MRI scan (Figure 1a). A finite element (FE) model of the reaction force resulting from the displacement of the uterine wall was generated, comprising a probe of fetal cartilage (E=1.1 MPa, ν=0.49), a thick uterine wall (E=586 kPa, ν=0.4), and two components of the thin fetal membrane; the amnion (E=21 MPa, ν=0.4) and the chorion (E=2.3 MPa, ν=0.4) [7-9].

The data obtained from these two steps were applied as boundary conditions for a musculoskeletal model of the fetal leg in OpenSim (Figure 1a) [10]. These data were generated from observed kicks of fetuses at around 20, 25 and 30 gestational weeks (n=6 or 7 per group; 19 in total).

Finally, these forces were applied to geometries of fetal bones generated from post-mortem MRI and CT scans (Figure 1b), allowing characterisation of the mechanical stimulation experienced by fetal limb tissues during kicking, at each gestational age.

RESULTS AND DISCUSSION

It was found that maximum displacement of the uterine wall due to kicking ranged from 6–14 mm over the 10 week period. These conditions resulted in maximum predicted forces of 6.9 N, 7.6 N and 8.8 N generated by the rectus femoris, gluteus medius and biceps femoris muscles, respectively. It was found that the maximum stress and strain stimulation both increased with gestational age, increasing from 0.8 kPa and 0.06% at 20 weeks to 6.1 kPa and 0.3% at 30 weeks (Figure 1b).

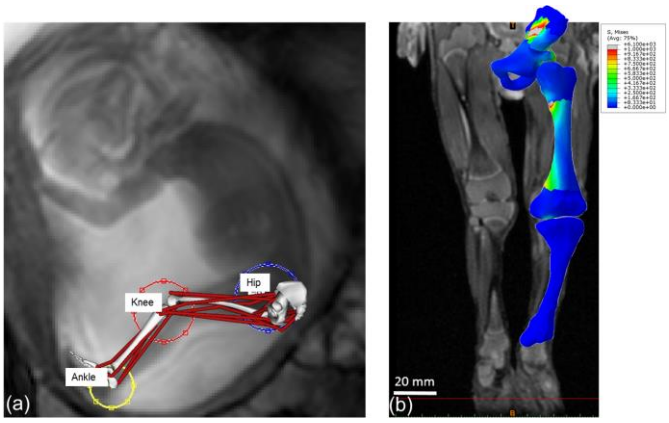

Figure 1: (a) Musculoskeletal model superimposed on a cine-MRI scan of a fetal kick, and (b) the resulting stress stimulation of the lower limb

This study provides a new insight into the biomechanical environment *in utero*, through the use of cine-MRI data of fetal movements. This research represents the first quantification of changes in biomechanical stimulation in the fetal skeleton with gestational age due to movements *in utero*, elucidating a potential upward trend in mechanical stimuli. This increasing trend with gestational age is important, as restricted leg movements late in gestation (such as occur with fetal breech) increase risk of DDH.

CONCLUSIONS

This novel computational pipeline enables us to characterise patterns of stimulation *in utero*, which cannot be achieved experimentally. Further analysis of the observed trends in developmental biomechanics may shed new light on the link between fetal biomechanics and anatomy, and thus inform future preventative or rehabilitation measures for neonatal joint conditions.

A NOVEL 3D-PRINTED PROSTHETIC JOINT REPLACEMENT FOR THE TREATMENT OF END-STAGE JAW OSTEOARTHRITIS: FROM IMPLANT DESIGN TO IMPLANTATION

[1]**David Ackland**, [1]Dale Robinson, [1]Michael Redhead, [1]Adrian Mosklajuk, [1]Peter Lee, [2]George Dimitroulis

INTRODUCTION

Painful disorders involving the temporomandibular joint (TMJ), including osteoarthritis have a prevalence ranging from 16-59%[1]. TMJ replacement surgery is the established treatment for end-stage TMJ osteoarthritis; however, current TMJ prosthetic implant designs face a range of problems including fracture, screw loosening, and mandibular nerve damage. The aim of this study was to develop, test and implant a personalised prosthetic TMJ into a patient with end-stage osteoarthritis of the TMJ. This joint replacement is an improvement on existing 'off-the-shelf' components, since it was designed to conform to the anatomy of the patient's mandible, while avoiding the mandibular nerve. A secondary aim was to use musculoskeletal modelling to assess functional performance of the joint replacement by comparing the modelling results to that of the Biomet Microfixation prosthetic TMJ implanted in the same patient.

METHODS

A female subject (age: 58 yrs, weight: 69 kg) with symptomatic and radiographic osteoarthritis of the left TMJ was recruited. Computed Tomography (CT) images of the patient's skull and jaw were obtained and digitally segmented to reconstruct 3-D surfaces of the skull, mandible, glenoid fossa and articular discs. The major muscles of mastication – the masseter, temporalis (anterior and posterior), lateral and medial pterygoids – were also digitally reconstructed (Fig 1).

Using the muscle architecture data, a rigid-body musculoskeletal model of the patient's jaw and masticatory system was developed in OpenSim. Muscles were represented as Hill-type muscle tendon units with muscle-tendon parameters defined previously [2]. Muscle forces were calculated for a worst-case bi-lateral bite force of 800N positioned at the second molar. The calculated muscle forces were then used as boundary conditions in a finite element model of the patient's jaw, created from the CT dataset.

A personalised prosthetic TMJ system was designed for the patient and implanted into the jaw model via virtual surgery. The muscle forces calculated with the rigid-body model were applied to the finite element model, and implant stresses and strains were computed. The customised implant was then replaced with the Biomet Microfixation TMJ, and the simulations repeated. The customised prosthetic TMJ was 3D-printed in plastic and implanted in a cadaver, and a passive range of motion test performed to assess post-operative joint stability. The customised TMJ was then 3D-printed in Titanium-64 and implanted into the subject at Epworth Healthcare, and jaw function evaluated 3-months post-operatively.

RESULTS AND DISCUSSION

The maximum von Mises stress at the condyle in the personalised and Biomet prosthetic TMJ was 126.9 MPa and 173.1 MPa, respectively. The largest screw stress in the personalised prosthetic TMJ was 318.2 N, which was below the yield strength of the titanium material in which the implant was made (880 MPa). After implantation of the customised prosthetic TMJ into the subject, passive, forceful range of motion tests demonstrated that dislocation of the prosthetic TMJ was not possible. Post-operatively, the customised prosthetic TMJ increased jaw opening distance by 14mm.

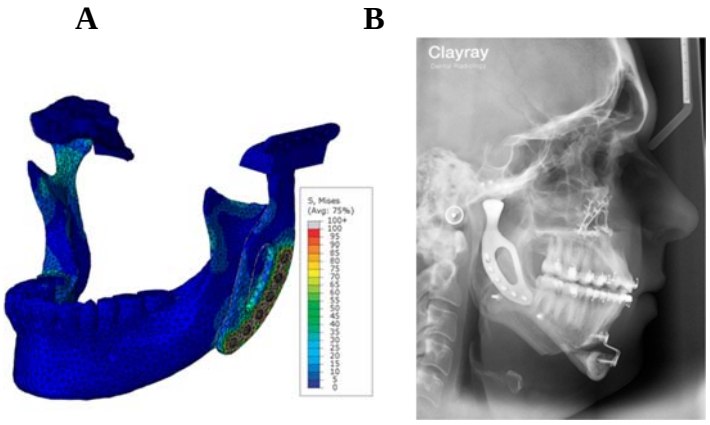

Figure 1: (A) finite element model of TMJ prosthesis (B) post-operative radiograph of prosthesis recipient

CONCLUSIONS

This study describes the development, testing and implantation of a personalised TMJ for a patient with end-stage osteoarthritis of the jaw. Multi-body musculoskeletal modelling indicated that the largest implant stresses were well below the material yield. Cadaveric testing indicated high joint stability and range of motion of the prosthetic TMJ, and a 3-month post-operative review indicated improved jaw opening distance and reduced pain for the recipient. Since the personalised prosthetic TMJ developed conforms to the anatomy of the patient, avoids the mandibular nerve and has fewer fixation screws, it may represent an improved joint replacement system over current off-the-shelf devices.

EVALUATION OF PREDICTED SUBJECT-SPECIFIC TEMPORAMANDIBULAR JOINT KINEMATICS

[1]**Michael S Andersen** and [1]Mark de Zee
[1]Aalborg University
Corresponding author email: msa@m-tech.aau.dk

INTRODUCTION

Treatment of orthodontic disorders, such as malocclusion, is typically planned based on static information such as x-rays and imprints. However, the resulting temporomandibular joint (TMJ) mechanics, i.e. joint forces and kinematics, is typically not systematically evaluated when planning the intervention. While this would be beneficial, there is currently a lack of a validated approach to estimate TMJ kinematics and forces based on clinically obtainable data.

Therefore, the aim of this study was to develop a subject-specific musculoskeletal model of the mandible and evaluate the predicted TMJ joint kinematics against measured kinematics obtained through a gold standard.

METHODS

A subject-specific musculoskeletal model of a male subject (age 40, mass 70 kg) was developed in the AnyBody Modeling System (AMS, AnyBody Technology A/S) with the model geometry obtained from a cone beam computed tomography (CT) (NewTom 5G, QR Verona, Italy) segmented using Mimics (Materialise, Belgium). The model was equipped with 24 Hill-type muscles with the origin and insertion estimated based on the model of de Zee et al. [1].

Two different models of the TMJ were developed: 1) a point-on-plane (POP) model where the most superior point of each condyle was constrained to a plane angled 30° downwards and canted 5° medially relative to the Frankfurt horizontal plane [1]. 2) A model where the movement of the TMJ in the same three degrees of freedom (DOF), that were constrained in the POP model, were resolved by assuming quasi-static force equilibrium between all acting forces in the model at each time step in the analysis. The acting forces were gravity, inertial forces, contacts between mandible and skull, modeled using an elastic foundation contact model, and the TMJ ligament. These movements were resolved by the Force-dependent Kinematics (FDK) solver in AMS [2].

To accurately measure the movement of the mandible relative to the skull, a custom brace was developed based on a dental impression onto which retro-reflective markers were affixed (Figure 1). The trajectories of these markers were tracked by eight infrared high-speed cameras and collected at 100 Hz (Qualysis, Sweden).

While wearing the brace, the subject was instructed to, among others, open and close his mouth consecutively for 10 seconds after which the process was repeated. Subsequently, the first five completed cycles were extracted and used as input to the model to drive the three DOF not controlled by the TMJ models and to validate the three DOF estimated by the model.

RESULTS AND DISCUSSION

The measured and predicted kinematics of the open-close task are depicted in Figure 1.

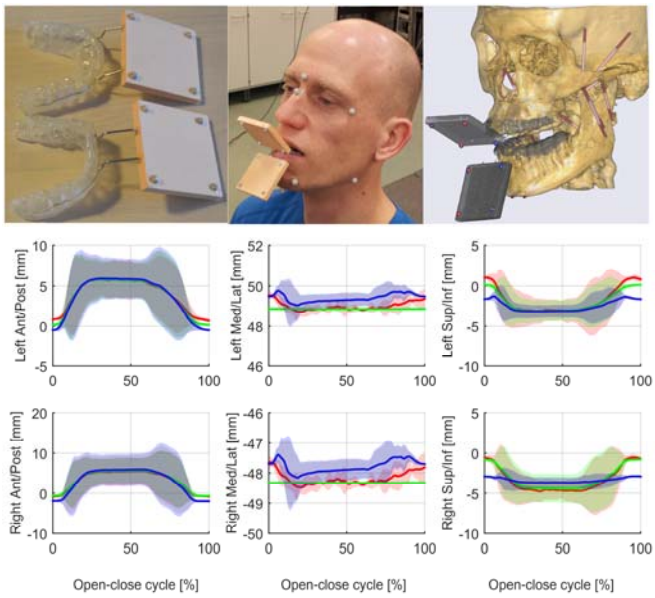

Figure 1: Top row from left to right: the subject-specific brace, the subject wearing the brace during the motion capture session and the musculoskeletal model driven by the measured marker trajectories of the brace. Middle and bottom rows: Predicted left (middle) and right (bottom) joint kinematics during an open-close cycle of the FDK TMJ model (blue), POP TMJ (green) and measured kinematics (red). Shaded areas indicate ±1 standard deviation.

The POP model predicted the movement of TMJ with a Root-Mean-Square (RMS) error of at most 0.47 mm (Sup/Inf direction) and with a Pearson's correlation coefficient above 0.98 for the Ant/Post and Sup/Inf directions. The Med/Lat direction showed poor correlation (0.14). The FDK model showed comparable results although the RMS errors were higher (at most 1.41 mm) and the correlation coefficients slightly lower (0.85 or higher) for the Ant/Post and Sup/Inf directions but higher than the POP model in the med/lat direction (0.30). The improvements in the Med/Lat direction is likely caused by allowing the FDK solver to predict this movement whereas the slightly poorer predictions in the two other directions is likely caused by the simplified representation of the TMJ geometry, where especially the contribution of the TMJ disc was omitted.

CONCLUSIONS

In this study, we presented a subject-specific musculoskeletal mandible model and evaluated the predicted joint kinematics for two different models of the TMJ against measured joint kinematics. The model represents an important step towards enabling evaluation of subject-specific TMJ mechanics that may ultimately be used when planning orthodontic treatments.

DENTAL STRESS ANALYSIS ON BRUXISM PATIENT WITH HARD ACRYLIC SPLINT

[1]Satrio Wicaksono, [1]Yadi Ferdian, [2]Aldilla Miranda, [1]Sandro Mihradi, [1]Tatacipta Dirgantara and [1]**Andi Isra Mahyuddin**

INTRODUCTION

Bruxism is a para-functional habit where teeth keep grinding and clenching when sleeping [1] and could cause temporomandibular disorder (TMD) [2]. There are several available therapies for bruxism, including occlusion intervention and the use of splint [3]. Unfortunately, there is yet a method that could cure bruxism permanently. To reduce the detrimental effects of bruxism, night guard or occlusal splint may be used [4]. One of the most common night guard is hard acrylic splint. This type of night guard may help distribute the load during teeth grinding and clinching.

Finite element method is a numerical tool that has been used in a lot of applications including dental biomechanics especially to help finding the teeth stress distributions. Quite a few researches on bruxism have employed finite element method. Among them, is Sakaguchi et al. [5] that investigated stress due to occlusal loading. Even though many studies have been conducted in this area, detailed analysis on the teeth stress distribution with and without the usage of splint is still needed in order to ensure the effectiveness of splint. In a previous research, stress analysis on the bruxism patient teeth were conducted using a CT scan to expedite the 3D reconstruction time [6]. The current research will use the same method to investigate the effect of using hard acrylic splint on the stress magnitudes of the teeth of bruxism patient. This research will be very useful in assessing the effectiveness of hard acrylic splint on bruxism patient.

METHODS

In order to find the stress distribution of bruxism patient teeth with hard acrylic splint, several steps need to be taken. First, in order to fasten the reconstruction process, CT scan is performed on the hard acrylic splint. The 2D picture from CT scan is then processed using 3D-DOCTOR software in order to get 3D surface model. This surface model is converted to 3D solid model in CATIA and then is joined together with jaws and teeth 3D solid model from the previous research [6] and exported to finite element software (ANSYS). In ANSYS, the final assembly is meshed using tetrahedral element due to the model complex geometry. The interface between teeth, periodontal and alveolar bone is modeled as bonded, meanwhile, the interaction between teeth and hard acrylic splint is defined as contact with no separation. The load magnitudes and directions are varied to simulate three possible bruxism movements, i.e. clenching, lateral grinding and longitudinal grinding. Hence, the stress distribution of the teeth and hard acrylic splint are investigated for each type of bruxism movement.

RESULTS AND DISCUSSION

The finite element result (Figure 1) shows that the maximum principal stress in the case of clenching are 20.2 MPa, 20 MPa and 3.6 MPa, respectively at alveolar bone, teeth and periodontal ligament respectively. In the case of lateral grinding, the maximum principal stresses are 58.8 MPa at alveolar bone, 70.4 MPa at teeth and 16.5 MPa at periodontal ligament. Moreover, for longitudinal grinding, the maximum principal stress at alveolar bone, teeth and periodontal ligament respectively are 44.7 MPa, 48.7 MPa and 9.3 MPa.

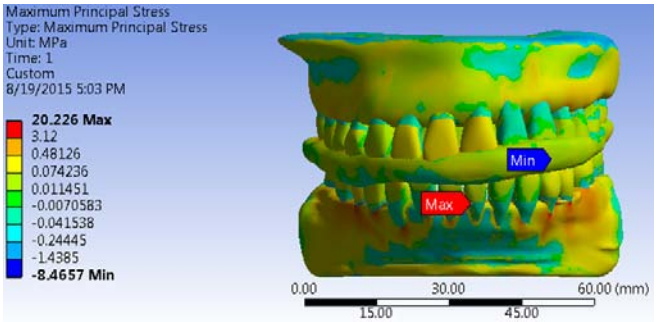

Figure 1: Finite element result (maximum principal stress)

The use of hard acrylic splint, considerably reduce the maximum principal stress at alveolar bone, teeth and periodontal ligament in comparison to the maximum principal stress for the case without hard acrylic splint which was obtained from the previous research [6]. The splint usage reduces the local stress concentration due to contact between maxillary and mandibular teeth and distributes the stress more evenly to all teeth surfaces.

INTRODUCTION

Knowledge of the mandibular kinematics during functional movement is crucial for the management of diseases of the temporomandibular joint (TMJ) and for various dental applications. Several studies[1,2] have attempted to measure mandibular kinematics, including trajectories of the incisors and condyles. While 3D trajectories of the incisors have been measured using apparatuses directly attached to the teeth, accurate condylar trajectories have been difficult to obtain either with external devices or skin markers. Another approach is to calculate the endpoint trajectories from the rigid-body mandibular kinematics[2]. This would require very accurate mandibular kinematics and identification of the endpoints on the mandible, which has not been achieved successfully. The current study aimed to fill the gap by measuring the mandibular kinematics during functional movements using subject-specific CT-models and marker-cluster-based 3D fluoroscopy technique (MCRM)[3], which was used to reconstruct 3D trajectories of the functional endpoints.

METHODS

Ten healthy young adults without missing teeth, dental prostheses, or any neuro-musculoskeletal disease of the TMJ participated with informed written consent as approved by the IRB. For each subject, four radio-opaque crystal markers were attached to each of the mandible and maxilla to form the marker-clusters. The positions of the marker-clusters with respect to the subject-specific bone models were obtained using a customized cone-beam computed tomography (CBCT) (i-CAT, Imaging Sciences International, Hatfield, PA, USA) with a voxel size of 0.4×0.4×0.4 mm^3 and a gray intensity of 12 bits. Each bone was embedded with an anatomical coordinate system. Each subject performed four functional movements in a random order, namely opening-closing, lateral-gliding, protrusion-retraction, and chewing at a self-selected pace, while under the fluoroscopic surveillance using the CBCT system at a sampling rate of 7.5 frames/second, giving 2D fluoroscopic images with an image size of 756×960 pixels and a pixel size of 0.254×0.254 mm.

For each image frame, the marker-clusters were registered to the fluoroscopy image using the MCRM method[4] to obtain 3D poses of the mandible relative to the maxillary, which were then used to calculate the kinematics of the TMJ. The trajectories of the mid-tip of the incisors and the centroid of the condyles were obtained by using the subject-specific bone models and the measured rigid-body kinematic data.

RESULTS AND DISCUSSION

During opening-closing and protrusion-retraction, both symmetrical movements, similar condylar trajectories but significantly different incisor movements were found (Fig. 1). The most anterior positions of the condylar trajectories were 4.7±1.8 mm anterior and 2.9±1.0 mm inferior to the initial position. At that position, the TMJ during opening-closing was 8.8±4.0 degrees greater in flexion than during protrusion-retraction, leading to a significantly posterior and inferior incisor location (posterior displacement: up to 5.4±3.1 mm; inferior: 13.2±5.5 mm; $p < 0.01$). During lateral-gliding, an asymmetric movement, different paths of the two condyles were needed, a feature different from symmetrical movements. Lateral-gliding showed a maximum incisor lateral displacement of 6.0±2.3 mm, 3.3±2.5 mm of which were the results of the rotations of the mandible with 1.3±0.5 degrees of external rotation and 3.0±1.2 degrees of abduction at the TMJ of the working side. These rotation components were accompanied with a posterior displacement of 2.8±0.6 mm and a superior movement of 6.7±1.2 mm of the condyle on the working side relative to the contralateral condyle (Fig. 1).

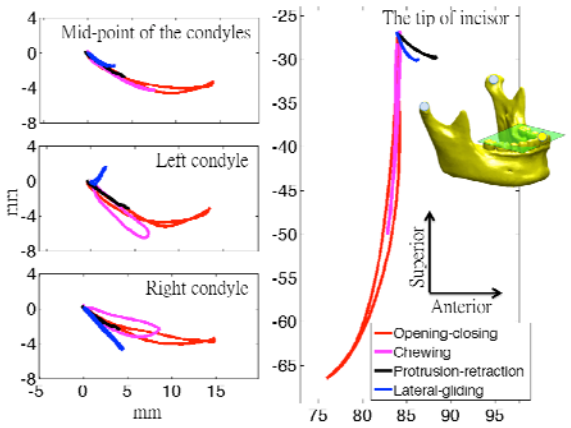

Figure 1: The sagittal view of trajectories of the functional endpoints and the mid-point of the condyles (i.e., rigid body translations).

CONCLUSIONS

Three-dimensional *in vivo* kinematics of the mandible and the trajectories of the incisors and condyles during functional movements were measured on a subject-specific basis for the first time in the literature using integrated CT-based bone models and accurate kinematic data obtained with MCRM. Rotation components were found to play a crucial role in controlling both the vertical and horizontal endpoint trajectories. The current technique and data will be helpful for future studies on mandibular function and relevant clinical applications.

MUSCULOSKELETAL BEHAVIOR OF THE HUMAN TEMPORO-MANDIBULAR JOINT – A MULTIMODAL IN-VIVO STUDY

[1]**Serge Van Sint Jan**, [2]Michèle Gales, [1]Bruno Bonnechère, [3]Thierry Metens, [3]Julie Absil, [1]Victor Sholukha, [1]Patrick Salvia, [1]Stéphane Louryan and [2]Régine Glineur

INTRODUCTION

The human tempo-mandibular joint (TMJ) is one of the most important joints found in the human body due to its key implications in many vital functions such as feeding (opening of the mouth for food insertion and chewing), talking and yawning. TMJ dysfunctions might appear if TMJ musculoskeletal components are impaired, and can lead to a variety of clinical signs (e.g, articular pain, limited mouth opening, unusual movements, tooth erosion, tooth socket distortions, etc) and TMJ disorder prevalence is reported to be between 5% and 12% [1,2].

Despite the importance of the TMJ in our daily life and the relatively high TMJ disorder prevalence, only few extensive quantitative studies can be found in the literature about the TMJ musculoskeletal behavior and methods to collect relevant data. This is peculiar because there is need for methodologies enabling health professional to report patient functional outcomes to provide more effective services to patient or to demonstrate accountability. This paper presents the results of an in-vivo multimodal study that aimed to collect quantitative data on TMJ kinematics, TMJ displacements (rotation vs. translation) during different functions and an analysis of muscle and ligament behavior. Data fusion was applied to obtain musculoskeletal TMJ models.

METHODS

The method is based on previous work of the authors about fusing motion data (MO_data from stereophotogrammetry) with anatomical data (AN_data obtained from MRI medical imaging) [3]. Fusion occurred thanks to the use of virtual and manual palpation of key anatomical landmarks of the subjects and their MRI 3D models, respectively [4,5]. The model obtained from AN_data includes bones model; local frames for motion representation and TMJ-related relevant soft tissue information (all muscles and all ligaments). Further measurements similar to every-day clinical scores were added for comparison. A total of more than 200 biological signals (i.e., kinematics degrees-of-freedom, muscle length, clinical measurements) were included in each subject-specific model. Five subjects were processed. Note that the availability of the subject-specific morphology allowed fitting of the local frames along the TMJ joint

After fusion occurred (in a customized software called lhpFusionBox), the behavior of all available biological signals were visualized in lhpFusionBox and real-time graphs were generated for further analyzed. Helical axis parameters were also obtained, and muscle and ligament moment arms (MA) determined.

RESULTS AND DISCUSSION

A first interesting result was related to the obtained TMJ kinematics. Indeed, for a very long time TMJ literature described the jaw behavior as the succession of firstly a rotation, then secondly a translation of the jaw condyle [6]. In all processed subject, our results contradicts this and shows that the condyles both rotate and translate simultaneously. This contradiction is probably due to the fact our model include perfectly aligned local motion frames leading to more accurate motion representations. Other results shows that the mechanical axis of the jaw (i.e., obtained with from the mean helical axis in this study) is quite complex, leading to also complex MA behavior. More extensive results will be presented during the congress.

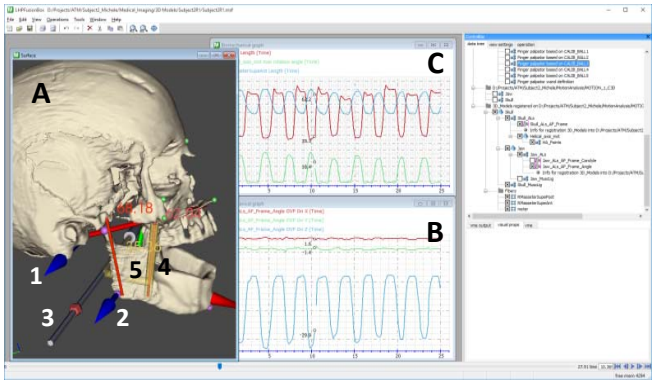

Figure 1: Example of results (displayed in lhpFusionBox). A: snapshot after fusion between AN_data and MO_data. B: motion representation (here OVP convention, other conventions are available as well). C: real time display of musculoskeletal value (indexed in A). 1 and 2: proximal and distal motion frames, respectively. 3: instantaneous helical axis. 4: MRI estimation of one masseter m. fiber. 5: direct moment arm of 4 (shorter distance with 3, visible through the jaw that was made transparent here).

CONCLUSIONS

This novel method seems to be satisfactory and led to collecting numerous biological signals related to in-vivo TMJ behavior. Running research is now prospecting the use of this method in clinical practice for patient follow-up before and after therapy related to TMJ disorders.

THE FIRST WHOLE-BODY BRADYKINESIA DETECTOR FOR PARKINSON'S DISEASE

[1]Roy SH, [2]Shiwani B, [1]Kline JC, [3]Saint-Hilaire MH, [3]Thomas CA, [2]Gennert MA, [1]De Luca G

INTRODUCTION

Sensor-based systems have been used to monitor the motor symptoms of Bradykinesia in Parkinson's disease (PD), but only during scripted activities defined by the Unified Parkinson's Disease Rating Scale (UPDRS), such as repeated finger tapping and opening and closing of the hand[1]. These approaches lack a complete framework to monitor the full complement of motor symptoms associated with whole-body bradykinesia that fluctuate throughout the day[2]. Therefore, we have developed a new approach consisting of a reduced set of body-worn sensors and machine-learning algorithms to autonomously monitor, in real-time, the symptoms of UPDRS-defined Body Bradykinesia during unconstrained activities of daily living.

METHODS

Patients with mild to moderate Parkinson's disease (n=17, Hoehn & Yahr 1-3) participated in experiments designed to monitor motor symptoms during a 3-hour period of unconstrained activities of daily living in a home-like setting. Trigno™ IM wireless sensors (Delsys, Inc. Natick, MA) placed on the distal upper- and lower-limbs of the more symptomatic side of the body were used to record electromyographic (EMG) and inertial measurement (IMU) data. Videos of the subject were recorded and annotated by movement disorder experts to identify activity states and score Body Bradykinesia (Item 3.14 UPDRS).

We designed a unique algorithm architecture to detect Bradykinetic motor symptoms without a-priori knowledge of movement activities being performed. Because the motor symptoms of Body Bradykinesia may manifest differently for different activities, we designed a feedforward neural network to autonomously detect walking and non-walking (Figure 1). We tracked Body Bradykinesia separately for these activities by extracting characteristic features of motor symptoms from the recorded EMG-IMU signals. Features during walking included reduced arm swing, shuffling, reduced cadence, and reduced step length while those during non-walking included paucity of movement, reduced amplitude, reduced speed, and hesitancy of movement. Dynamic Neural Network (DNN) algorithms were designed to classify the presence and severity of Body Bradykinesia based on these features. Clinician annotations of video provided the ground truth for assessing accuracy.

RESULTS AND DISCUSSION

Our algorithms detected walking and non-walking activities with an accuracy of 99.5% and successfully identified Body Bradykinesia with an accuracy of 95.0%.

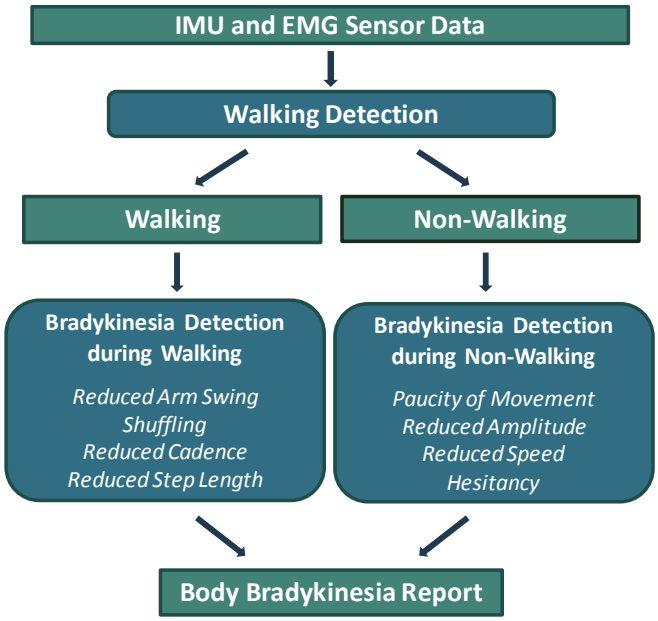

Figure 1: Algorithm approach for tracking Body Bradykinesia during unconstrained activities of daily living.

CONCLUSIONS

These results demonstrate the first successful sensor-based approach for autonomous monitoring of Body Bradykinesia during activities of daily living. By eliminating the need to perform scripted activities, our approach supports the viability of an ambulatory system that could be used in the home or community to monitor fluctuations of Body Bradykinesia. By developing similar algorithms for tracking the full complement of movement disorders associated with PD[3], the take-home system will address the healthcare needs to better manage medication titration, adjust DBS settings, and improve empirical outcomes for clinical trials or early detection.

PEOPLE WITH LARYNGECTOMY CAN COMMUNICATE BY FACIAL EMG RECORDINGS OF MOUTHED SPEECH

[1,2]Meltzner GS, [3]Heaton JT, [4]Deng Y,[1]Roy SH, **[1]Kline JC,** [1]De Luca G
[1] Delsys, Inc. and Altec, Inc, Natick, USA

INTRODUCTION

Each year thousands of individuals require surgical removal of their larynx due to trauma or disease, impairing their ability to vocalize speech. Studies of alternative forms of communication have found that synergistic activation of muscles involved in speech – which largely remain intact after laryngectomy – produce unique combinations of surface electromyographic (sEMG) signals when articulating different phonemes [1]. This is true even when speech is mouthed or spoken in a silent (unvoiced) manner, indicating that the use sEMG signals for speech recognition could be a powerful potential platform to help individuals communicate after laryngectomy. Therefore, we developed a system to record sEMG signals from muscles of the face and neck during silently mouthed speech in patients with laryngectomy and translated patterns of sEMG signals into words using phoneme-based silent speech recognition.

METHODS

Experiments were conducted with n=7 participants with laryngectomy (mean 64 years). Custom-designed miniaturized sEMG sensors were strategically placed on 8 muscles of the face and neck previously identified as those most involved in the articulation of speech (Fig. 1) [1]. A vocabulary of 1000 commonly used English words primarily from the TIMIT data corpus were used to test different combinations of phonemes. Words were presented in token sentences on a computer screen for subjects to silently recite by mouthing the words. A two-stage speech recognition algorithm was designed to process the sEMG signals recorded during silent speech. First, signal segments containing speech data were identified by a finite state-machine Speech Activity Detection (SAD) algorithm and processed with speaker-dependent window lengths and frame rates to compute Mel-frequency cepstral coefficients

{3,5,6,7}	15	30.8	19.7	19.2	**10**	**13.1**	18.1
8 Sensors	10	13.6	13.3	12.8	8.7	8.9	10.2
Mean	15.9	22.3	17.3	22.0	12.6	16.9	16.7
BEST	10.6	19.2	13.8	17.5	10	13.1	14.4

(MFCC) [2]. Hidden Markov Models were used to develop a multi-stage phoneme-based model specific to each subject. The models were trained on 550 sentences and tested on 430 sentences. All words presented in the testing data were unique and did not appear in the training data.

RESULTS AND DISCUSSION

We found that the synergistic activation of speech muscles while mouthing different words produced discriminable combinations of sEMG signals that could be used for speech recognition. From the full 8-sensor set, word error rates were on average 11.1% for all subjects tested. When we tested the best 4-sensor combination from each subject (Table 1 and Figure 1), we found average word-errors rates moderately increased to 14.1%, indicating the potential to simplify the system for in-home use.

CONCLUSIONS

These results provide first-of-its-kind demonstration that unique combinations of sEMG signals obtained from synergistic activation of speech muscles can be used for recognition of silently mouthed speech in patients with laryngectomy. While there is room to improve the accuracy, possibly through increased training data, inclusion of further speaker-dependent parameters or alternative algorithm approaches, the ability to recognize words using phoneme-based patterns of sEMG provides an impactful first-step towards developing a practical body-worn system for alternative communication for persons with laryngectomy.

A NOVEL APPROACH OF COGNITIVE-STIMULATION INDUCES VOLUNTARY MOTOR OUTPUT IN PAITNETS WITH SEVERE STROKE

[1] **Fuminari Kaneko**
[1] Laboratory of Sensory Motor Science and Sports Neuroscience, Sapporo Medical University
Corresponding author email: f-kaneko@sapmed.ac.jp

INTRODUCTION

Kinesthetic illusion is a sensation of being in motion that results from a sensory input, even when one is not moving. In our original method, a kinesthetic illusion was induced by a visual stimulus (KiNvis) projected at the person's own body part, consisting of an image of that body part moving [1]. In our KiNvis induction protocol, an actual body part is replaced by an artificial (virtual) image of the body part within the actual environment, and it may be visualized in the real world or in a head-mounted display. Therefore, KiNvis is different from virtual reality, in which one senses a motion within a virtual world. Instead, an artificial environment is added into the real world as an augmented reality, and only a part of the body image is replaced by an artificial object within the actual environment as a background in order to induce an illusion. Alternatively, this situation can be considered as a mixed reality involving both the real world and the artificial body image projected in a head-mounted display through a camera that records the real world in a real-time.

In the present talk, I will introduce our study exploring the physiological effects of KiNvis, particularly those on motor function in patients with stroke.

SCIENTIFIC BACKGROUND OF KiNvis

Psychological testing

Subjective feelings were assessed using 100-mm visual analog scales with five graduations [2]. To assess the sense of ownership, participants were asked to indicate whether they agreed or disagreed with the sentence: "I felt as if I was looking at my own hand being projected on the screen." To assess the consistency of the feeling of ownership, participants were required to answer the following question: "For each trial, how long did you feel that it was your own hand being projected on the screen for?". Similarly, to assess the strength of the illusion, participants were asked to answer the question: "Did you feel your hand move while watching the video?". The appearance of the sense of ownership and a strong illusory feeling were indicated by the results of the psychological examination.

Physiological testing

We reported that motor evoked potentials (MEPs) obtained by stimulating the primary motor cortex using transcranial magnetic stimulation (TMS) were markedly increased during a kinesthetic illusion [1]. The effect was significantly greater than that obtained by simply observing a moving image, when subjects did not experience any kinesthetic illusion. Analyses using functional magnetic resonance imaging (fMRI) have shown that, during kinesthetic illusion, the bilateral supplementary motor area, contralateral dorsal and ventral premotor areas, superior and inferior parietal lobules, occipitotemporal area (extrastriate body area), bilateral anterior insula, bilateral caudate nucleus, and the putamen show increased activity compared to when a moving image is simply observed. While no increase in the activity of the primary motor cortex and somatosensory area was detected, many other areas showing activation were the same as those activated during actual motion. Another study indicated that KiNvis increases the effects of transcranial direct current stimulation (tDCS) on the enhancement of excitability in the corticospinal tract. Furthermore, we recently observed that KiNvis combined with electrical stimulation of the peripheral nerve sustained the enhancement of excitability in the corticospinal tract for one hour. The data showing the physiological effect of KiNvis suggest that this technique could be applied as an intervention to improve motor function in patients with neurological disorders.

EFFECT OF KiNvis ON MOTOR FUNCTION IN PATIENTS WITH STROKE

We have recently initiated a clinical trial, and here, we present several acute and chronic effects of our novel approach to motor recovery after stroke. Patient 1 was a 51-year-old man with damage to a wide area of the left putamen caused by a hemorrhagic stroke that had occurred 11 years earlier. He had not received therapy for the involved right upper extremity (UE) after discharge from the hospital one year after stroke. At examination, no voluntary movement was observed, and only a slight muscular contraction in the forearm and the upper arm and a hand movement that was characterized by a flexor synergy pattern were detectable. Tactile sensation was severely impaired throughout the UE. KiNvis was applied for 15 min, and voluntary movement, in the form of elbow joint flexion, appeared thereafter. The patient commented that, during this experience, he felt as if he remembered how to move his hand, and that he also felt capable of recalling this movement after KiNvis. Patient 2 was a 65-year-old male in-patient with a putaminal hemorrhage that had occurred 9 weeks earlier, and was incapable of voluntarily using his involved left UE. Tactile sensation was slightly impaired, and the muscular tone was slightly enhanced. After KiNvis, the range of motion, measured during voluntary execution of hand grasping and opening, was observed to increase.

CONCLUSION

As we have observed the acute effects of KiNvis on motor behavior in patients with stroke, this technique may be considered as a useful therapeutic option for such patients. Further studies focusing on the long-term effect of KiNvis on sensory-motor recovery are required to verify its effectiveness. However, I will additionally report chronic effects of KiNvis in this presentation.

MEDIAL GASTROCNEMIUS AND SOLEUS MUSCLE-TENDON UNIT, FASCICLE AND TENDON INTERACTION DURING WALKING IN CHILDREN WITH CEREBRAL PASLY

[1] **Lee A Barber**
[1]The University of Queensland
Corresponding author email: l.barber@uq.edu.au

INTRODUCTION

During gait in typically developed (TD) individuals, the muscles of the calf contract at levels that maintain a relatively constant muscle fibre length while the more compliant Achilles tendon acts like a spring to absorb and return energy during each step[1]. However the calf muscles of individuals with cerebral palsy (CP) adapt in response to spasticity to become smaller, weaker, more resistant to stretch, have increased antagonist co-contraction and the Achilles tendon becomes longer[2,3]. These neuromuscular adaptations of the calf in CP could reduce muscular force generation capacity and contribute to altered gait kinematics, however it is difficult to know what impact these spasticity driven adaptations will have on fascicle or tendon behaviour. This study investigates the in vivo function of the medial gastrocnemius (MG) and soleus (SOL) muscle-tendon units (MTU), fascicles and tendons during walking in children with CP and an equinus gait pattern.

METHODS

14 children with CP (age 10±3years, 9 males, GMFCS I=8, II=6), and 10 TD (age 10±2years, 6 males) undertook full body 3D gait analysis and simultaneous B-mode ultrasound images of the MG and SOL fascicles during level walking. Fascicle lengths were analysed using a semi-automated tracking algorithm and MTUs using OpenSim. Statistical parametric mapping (two-sample t-test) was used to compare differences between groups, ($p<0.05$).

RESULTS AND DISCUSSION

In the CP group MG fascicles lengthened during mid-stance gait and remained longer into late-stance compared to the TD group ($p<0.001$). CP MG fascicles shortened less during stance (1.16±1.47mm) compared to the TD group (4.48±1.94mm, $p<0.001$). In the CP group the MG and SOL MTU and tendon were longer during early- and mid-stance ($p<0.001$). Ankle power during push-off ($p=0.015$) and positive work ($p<0.002$) and net work ($p<0.001$) were significantly less in the CP group.

During walking in children with CP the MG muscle fascicles lengthened during mid-stance and, in contrast, the TD MG fascicles maintain a relatively constant length. The large plantar flexor moment and amount of negative work (energy absorption) being performed by these muscles during early-stance is in contrast to energy being absorbed by the dorsiflexors in TD heel-toe walking. While some of this energy is returned from the tendon during push-off, the overall net shortening of the fascicles is not sufficient to generate additional positive work and hence results in significantly less ankle net work across the gait cycle in the CP participants.

Fascicle lengthening is indicative of an eccentric action of the muscle, the external force on the muscle being greater than the force that the contracting muscle is generating and resulting in energy being absorbed by the muscle rather than the tendon. MG muscle fascicles lengthen in the CP children may be due to reduced muscle strength due to the smaller muscle size, selective neural activation, antagonistic co-activation resulted in insufficient force to maintain the fascicle length and stretch the tendon during the energy absorption phase. Secondly it may be that the series elastic tendinous structures are too stiff to be stretched by the forces generated by the muscle contractile tissue. The changes in MG fascicle length in the CP participants across the stride shows a resemblance to a lower magnitude MTU pattern and may suggest that the active and passive components of the MG MTU act somewhat uniformly.

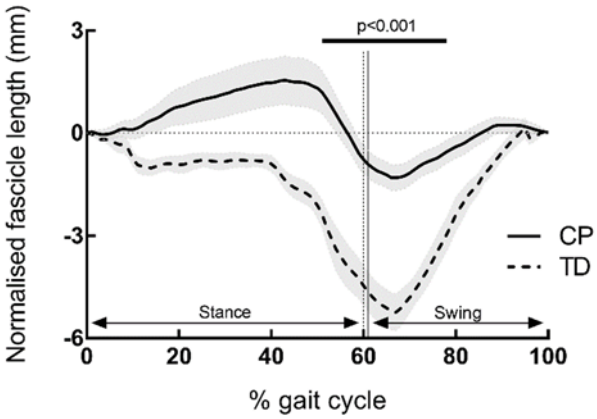

Figure 1: Medial gastrocnemius fascicle length during the walking gait cycle (0-100% foot contact to foot contact, vertical line toe-off). Mean±SEM. Positive values are lengthening; negative values are shortening. Lines and p values above plots show significant difference between groups during the proportion of the gait cycle.

CONCLUSIONS

The eccentric action of the CP MG muscle fascicles during mid-stance walking is consistent with reduced strength of the impaired muscle. Neuromuscular adaptations of the impaired CP calf muscle may result in greater reliance on aponeurotic and tendon structures passive elastic energy storage and return for forward propulsion during equinus gait. The findings of the interaction between the contractile (fascicle) and non-contractile (tendon) elements in the calf muscle of children with CP walking with equinus gait informs surgical, pharmacological and conservative management decision making to improve walking ability in children with CP.

MONTORING FLUID FLOW IN AN INTERVERTEBRAL HYDROGEL DISC- A MAGNETIC RESONANCE IMAGING AND FINITE ELEMENT STUDY

[1]**Pujitha Silva**, [2]Stuart Crozier, [2]Martin Veidt, [3]Mark Pearcy

INTRODUCTION

Hydrogels are porous fluid saturated polymeric structures showing similarities to the intervertebral disc (IVD). Hydrogels under compression has been studied and modelled successfully using Finite Element Modelling (FEM) to better understand the mechanism of load transfer within the intervertebral disc and the role of fluid [1]. Water exists in three different states within these tissues, as *bound*, *intermediate* and *bulk water*. Bulk water referred to also as free or mobile water that is of particular interest from a load carriage point of view. Magnetic Resonance Imaging (MRI) has been used to monitor water content changes noninvasively in deforming animal IVD's with compensation made for deforming tissues [2]. Although MRI relaxation constants *T1* and *T2* are sensitive to water [2,3] no clear relationship has been established between them and the level of water content in the deforming IVD.

This paper investigates the relationship between MRI relaxation constant *T2* and water in a bi-component hydrogel IVD under compression, with a view to establish a basis for quantify the fluid content within biological IVD's.

METHODS

Compression MRI Studies

Bi-component PVA hydrogel discs, were synthesized according to [1] and tested in a specially designed non-ferromagnetic compression device (Figure 1a), placed inside the RF coil of the MR imager and pneumatically driven. The applied pressure was controlled to within ± 0.01 MPa.
In total four samples were compression tested and imaged in a total of six tests, with the longest lasting 19 hours and the shortest 7 hours. All the samples were subjected to a load of 200 N as in [1], Repeat tests on some of the specimens were performed after a minimum of two weeks of recovery in a bath of water. Each of the samples was reweighed at the end of the loading time to determine the fluid loss.

All imaging was done using 12 cm gradients in a 4.5T Oxford instruments horizontal bore magnet interfaced with a Bruker Biospec spectrometer. Imaging was carried out in two planes. For *T2* weighted imaging, a Carr-Purcell-Meiboom-Gill (CPMG) sequence was employed with contiguous 1mm slices reconstructed to 256 x 256 grid and a 5 cm square FOV. To obtain T2 maps, eight echo times (TE), ranging from 14 ms to 160 ms and repetition time TR =4s were employed. A least-square fit of a single exponential was used to extract T2 from the multi-echo data.

Finite Element guided tissue compensation

Axisymmetric poroelastic finite element models were developed according to the procedure in [1]. For each deformation state shown in the MR images, the corresponding finite element mesh that matched the axial deformation and gave the best overall geometrical fit was superimposed on to the MR image, similar to [2]. Each finite element bound region was considered a Region of Interest (ROI) for comparison purposes. Given the symmetrical loading and the axial symmetry in the material properties, only the right hand side was analyzed for each image. The disc height measurements were made from each scan (Figure 1a, length A-B) accurate to ± 0.2mm using an image processing tool.

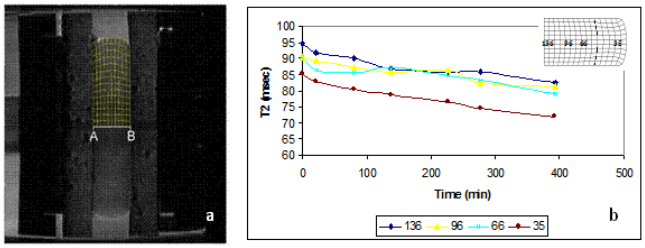

Figure 1: a), Hydrogel loaded in compression device with corresponding FE mesh superimposed for comparison b) *T2* variation for selected elements in the mid sagittal region during the loading history

RESULTS AND DISCUSSION

T2 values consistently showed a higher value in the nucleus region compared to the annulus and decreased with increased loading time (Figure 1b). In the repeat tests *T2* levels changed in relation to the level of hydration of the sample, with a higher *T2* value for an increase in weight. Furthermore the pattern of *T2* changes across the axial and sagittal directions of the disc both in the nucleus and the annulus indicated a strong relationship with the load influenced fluid flow, also confirmed by the FEA fluid flow predictions.

These results indicate a strong relationship between the *bulk water* content and *T2* for the PVA hydrogels. A change in *T2* shows a corresponding inverse change in compressive stress in the hydrogel disc.

CONCLUSIONS

T2 appears to be a good predictor of the overall water content in the disc and a change in *T2* indicates a change in the *bulk water* content of the hydrogel disc.

WILL THE HERNIATION PATHWAY BE AFFECTED BY AN ANNULAR PUNCTURE? AN IN VITRO STRUCTURAL INVESTIGATION

[1]**Vonne M. van Heeswijk**, [2]Peter A. Robertson, [1]Ashvin Thambyah and [1]Neil D. Broom

INTRODUCTION

Discography involving an annular puncture has been reported to increase both the risk of degeneration and herniation compared to untreated discs 10 years post treatment [1]. While the longer-term prospect of degeneration arising from an annular puncture has received considerable attention it remains unclear whether a puncture places the disc at greater risk of immediate or short-term herniation. Because new herniations in discs previously subjected to discography are reported to occur most frequently at the site of puncture [1] it raises the question whether localised damage created by an annular puncture can redirect the herniation pathway and thus increase the immediate risk of it occurring at the puncture site independent of any longer term degenerative changes.

METHODS

Healthy mature ovine lumbar spines were dissected in three motion segments consisting of spinal levels L1-L2, L3-L4 or L5-L6. Extraneous soft tissues and the vertebral posterior elements were removed but the facet joints were retained intact. The posterolateral annulus of the disc was punctured with either a 25-gauge (n = 8) or an 18-gauge (n = 8) needle until approximately half the disc's anterolateral-posterolateral diameter to reach the nucleus. Prior to puncturing, the needle was coated in India ink in order to leave a visible trace of the puncture. The 25-gauge needle was chosen because of its use in discography [2, 3] and the 18-gauge needle provided a size-related comparison. Using a custom-built rig each motion segment was then placed in a flexed posture of 10° and compressed at 40 mm/min up until the first audible sign of disc wall failure [4]. Each mechanical test was video-recorded with the camera viewing the lateral aspect of the disc in order to capture any visible evidence of nuclear extrusion from the puncture. The herniated discs were then formalin-fixed and decalcified. Progressive macro-level transverse sections of the entire disc volume were obtained and systematically analysed in order to gain a global understanding of the herniation pathway and the influence of the annular puncture on it.

RESULTS AND DISCUSSION

Externally visible nuclear extrusions at the posterolateral puncture site did not occur in any of the 25-gauge samples. Transverse sectioning of the discs also showed that there was no association between the 25-gauge puncture site and disc disruption/herniation in all eight samples. In contrast, four of the eight 18-gauge samples contained externally visible nuclear extrusions from the puncture. Nuclear material was actually observed to migrate through the 18-gauge puncture in six of the eight motion segments tested of which four had become externally visible, see an example in Figure 1. Further, even when the disc was punctured with the larger 18-gauge needle a high prevalence of disruption at the lateral inner annulus was observed.

Figure 1: Image of a transverse sectioned 18-gauge punctured disc. Nuclear material has extruded through the puncture (indicated with the black India ink) and had become externally visible (indicated with the white arrow).

By employing the 25-gauge needle for puncturing the smaller ovine disc, a size also used in discography, we have in fact inflicted a greater scale of structural disruption than would be expected from using the same needle in the much larger human disc. This has enabled us to investigate disc behaviour under more demanding disruptive conditions thus increasing the study's potential clinical relevance.

CONCLUSIONS

The immediate risk to herniation at the puncture site is dependent on the needle diameter used. The lack of influence of the 25-gauge needle on the herniation pathway suggests that the annulus is, to a degree, over-structured so as to provide a 'factor of safety' sufficient to cope with moderate overloading. Even with the puncture damage, the lateral inner annulus was most prone to disruption under the mechanical conditions employed.

ULTRASTRUCTURAL ORGANIZATION OF THE ELASTIC NETWORK WITHIN THE DISC ANNULUS FIBROSUS

Javad Tavakoli, John J. Costi
Biomechanics & Implants Research Group, The Medical Device Research Institute, School of Computer Science, Engineering & Mathematics, Flinders University, SA
Corresponding author email: javad.tavakoli@flinders.edu.au

INTRODUCTION

The annulus fibrosus (AF) of the disc contains a well-organized elastic network that appears to enclose collagen bundles. Light microscopic studies have revealed that elastic fibres of the intra-lamellar region are aligned predominantly parallel to the collagen fibres, while the inter-lamellar matrix (ILM) —located between adjacent lamellae of the AF— consists of a complex structure of elastic fibres [1]. The organization of elastic fibres in partition boundaries (PB), which are located between adjacent collagen bundles within the lamellae, is unknown; however, their presence was reported using histologically prepared AF samples [2]. Although these light microscopic studies revealed that elastic fibres were found throughout the AF, none were able to provide the fine-scale and ultra-architectural details of the elastic fibre network. Therefore, the aims of this study were twofold. First to present an ultrastructural analysis of the elastic fibre network across the AF (ILM, intra-lamellar region and PB) using Scanning Electron Microscopy (SEM) and second to compare the elastic fibre orientation among the above three regions.

METHODS

Adjacent sections (thickness = 30 µm, length = 10 mm) were cut from the anterior AF at angles of 30° and 0° to the transverse plane using a cryostat microtome from each of four ovine discs. All samples were digested in 0.5 M NaOH solution and sonicated for 15 min at 37 °C, prior to post-processing in distilled water at 70 °C for 5 min to remove collagen fibres, leaving the elastic network intact. All samples were then dried in a vacuum oven at 37℃ and -80 kPa and prepared for SEM imaging. The SEM images were analyzed to determine the distribution of fibre orientation, as measured relative to the tangent to the circumferential direction, using ImageJ software. A univariate ANOVA was conducted, having a dependent variable of orientation and a fixed factor of AF region using an alpha of 0.05, with post-hoc multiple comparisons conducted using a Bonferroni adjustment on alpha.

RESULTS AND DISCUSSION

A loose network of elastic fibres was observed in the intra-lamellar region (Figure 1a-30), having almost parallel large fibres (0.3-0.5 µm diameter) and very fine interconnecting fibres of less than 0.3 µm diameter. Visualization of elastic fibres was not possible in the intra-lamellar region when the sample preparation cutting angle was 0° (Figure 1a-0). In the ILM (Figures 1b) and PB (Figures 1c), elastic fibres create a dense network that includes thick and thin fibres. The thick elastic fibres have a diameter of approximately 1-2 µm; however, the diameter of thin elastic fibres was approximately 0.1 µm. These thick and thin elastic fibres appear to create a web-like meshwork that connect together. Fibre orientation measurements revealed that three symmetrically organized angles of orientation were detected in all regions (45°, 0° and -45°), with the majority of fibres orientated near 0°, having an overall mean (SD) orientation of 8.3° (1.8°).

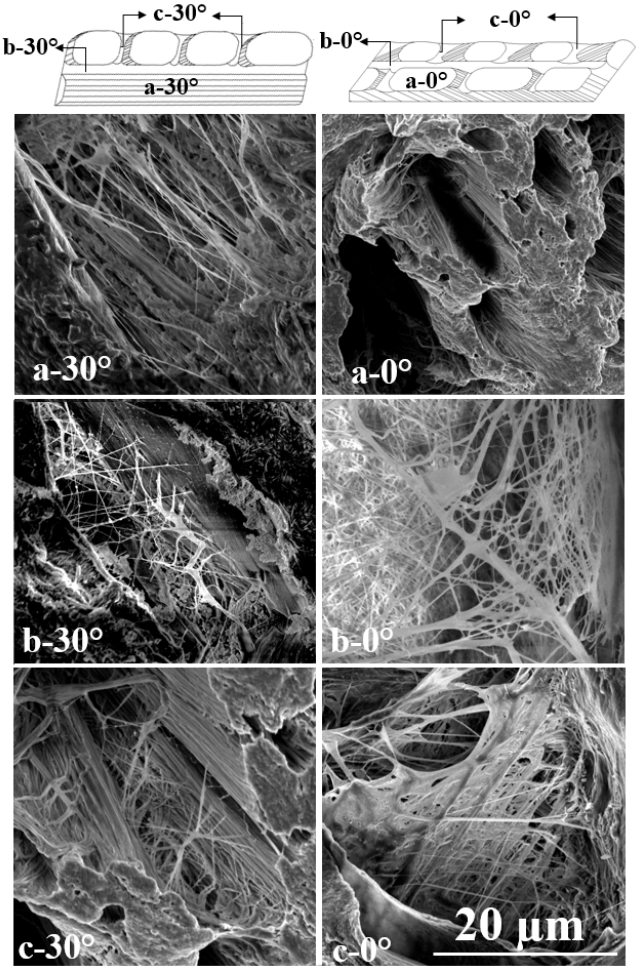

Figure 1: Ultra-structural organization of elastic fibres in (a) intra-lamellar region, (b) ILM and PB, at cutting angles of 30° and 0° to the transverse plane.

Statistical analysis showed that the orientation of fibres was not significant either between- or within- intra-lamellar, ILM and PB regions (p= 0.154).

CONCLUSIONS

The results demonstrated that collagen bundles of the AF lamellae were surrounded by a network of elastic fibres. The organized network's role is probably mechanical and may serve to contribute to AF integrity during loading.

COLLAGEN FIBRIL ALTERATION IN DEGENERATIVE ANNULUS FIBROSUS

Ting Liang, Zong-Ping Luo
Orthopaedic Institute, Department of Orthopaedics, The First Affiliated Hospital of Soochow University, Soochow University, Suzhou, Jiangsu, China
Corresponding author email: zongping_luo@yahoo.com

INTRODUCTION

The intervertebral disc (IVD) degeneration is the main cause of the low back pain. However, the precise mechanism of the IVD degeneration remains unrevealed, especially on the nanoscale. Abnormal loading is thought to be one of the contributing factors IVD degeneration. The purpose of this study was to explore the alternation of individual collagen fibril in annulus fibrosus after degeneration and to discuss the intervertebral disc degeneration pathogenesis at the nanoscale.

METHODS

Twenty 12-week-old male SD rats were randomly assigned into one of four groups. One group of rats was subjected for baseline study of intact discs. The other three groups of rats were instrumented with an external device that applied bending of 40º between the eighth and tenth coccygeal vertebrae and different compression loadings of 1.8, 4.5, 7.2N respectively. After bearing loading for two weeks, target discs were harvested, sectioned for staining with hematoxylin/eosin and atomic force microscopy (AFM) scanning. The significance of differences between the study groups was obtained using analysis of variance (ANOVA).

Statistical significance was set at $P \leq 0.05$.

RESULTS AND DISCUSSION

The typical histological images of annulus fibrosus on the concave side in both intact and degenerative IVDs indicated significant disorder and decrease of cell numbers in the annulus fibrosus after bearing loading and suggested the induction of the structural rupture and the degradation of intervertebral disc. The diameter and the elastic modulus measurement results revealed region-dependent variations for both the intact and degenerative discs. After bearing 4.5N, the average fibril diameters increased significantly compared with the intact IVDs except inner layer in convex, and the fibrils stiffened significantly in inner layers and middle layers in both sides. After bearing 7.2N, the average fibril diameters showed significant increases in all sites compared with the intact IVDs, and also stiffened significantly in inner layers and middle layers in both sides. Meanwhile, for each single region, the average diameters and modulus showed mildly increasing trend with the increasing compressive loading from zero (intact IVD) to 7.2N, respectively. The variations of collagen network's nano-structural in collagen fibrils might render the annulus fibrosus more susceptible to structural failure, and allow the herniation of the nucleus pulposus[1].

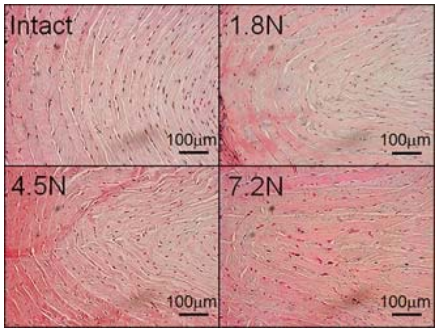

Figure 1: The representative histological images of annulus fibrosus on the concave side.

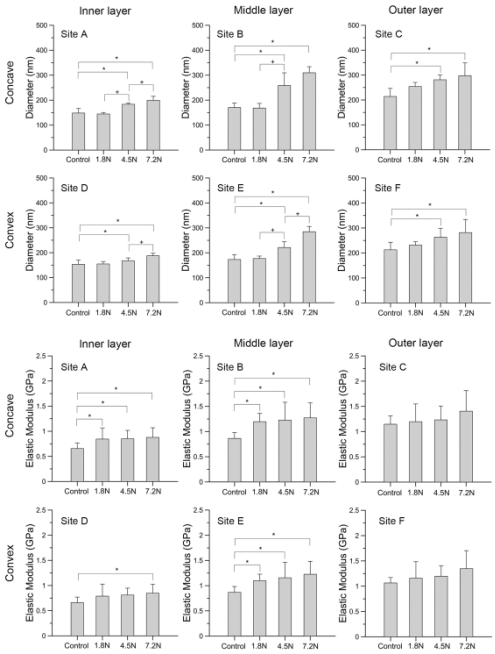

Figure 2: The diameters and the elastic modulus of collagen fibrils with different compressive loadings.

CONCLUSIONS

This study firstly reported the structure and biomechanics at nanoscale from different regions of the annulus fibrosus in degenerative IVDs. The results of this study indicated that the degeneration was not only associated with the disorder at microscale, but also the collagen fibrils alteration at nanoscale, leading possibly to changes in the mechanical and physiological environment around the annulus fibrosus cells.

P001 - INFLUENCE OF EXPERIENCE IN VR SPACE ON PERORMANCE IN REAL SPACE

[1]**Masahiro Shigeta**, [1]Toshiki Iduka, [1]Shinya Yanagita, [1]Hiroshi Mizoguchi, [1]Hiroshi Takemura [1] Faculty of Science and Technology, Tokyo University of Science, Japan
Corresponding author email: 7513059@ed.tus.ac.jp

INTRODUCTION

Recently, VR devices are rapidly spreading, and researches on the influence of VR on the human body are being needed. The influence of VR on the human body is studied such as VR sickness [1], and there are reports that visual effect of VR affects tactile [2]. These kinds of research are increasing, however a lot of things have not been explored yet. In this study, we investigated the influence on the motion after leaving the VR space. Considering the illusion caused by the visual information in the VR space, it is sufficiently conceivable that the motion after leaving the VR space is changed. In this paper, we investigated whether the experience in the VR space like real space affects performance in real space or not. For this experiment, we used darts based on the study of Ikegami et al. [3].

METHODS

20 darts beginners participated and wore a motion capture system (NOITOM Ltd. Perception Neuron). First, they threw darts for 4 minutes, rested for 2 minutes, threw darts for 4 minutes again, and rested 5 minute in real space. After that, they threw darts or did bowling for 4 minutes, rested for 2 minutes and threw darts or did bowling for 4 minutes in the VR space. After they rested for 5 minutes again, they threw darts and rested same as first. In the VR section, they threw darts aiming for the center of the darts board and determined the score by the stuck position. We defined the score as following; the center double circle (BULL) was 1 points, the inner half of the inner thick circle was 2 points, outer half was 3 points, inner thin circle (triple) was 4 points, the inner half of the outer circle was 5 points, outer half was 6 points, outer thin circle (double) was 7 points, outer darts board was 8 points. Higher score means worse performances. In the VR section, they wore HMD (HTC Co., Ltd. Vive) with motion capture simultaneously and threw the real darts same as real space. 10 subjects played VR darts, and the others played VR bowling. The VR darts were designed to almost never get stuck on the darts board. In addition, threw darts in real space when throwing darts in VR space. VR bowling was done to evaluate whether the result of darts after VR is due to VR itself or VR darts. In addition, they performed calibration of the motion capture in the 5-minute rest to compensate for sensor slippage other than before the experiment.

RESULTS AND DISCUSSION

In Figure.1, the horizontal axis shows the results of all subjects' darts from 1st to 15th, 16th to 30th, 31th to 45th ... and the vertical axis shows their average point.

Before the VR section, the score of the 1st to 15th throws is higher than the score after the 16th throw ($p<0.001$). In this study, the subjects were mostly darts beginners, and wore the motion capture system on body and fingers. Therefore, this results are expected to take a time to get used to the system.

The results of the VR darts subjects demonstrated a significant difference between the Before VR Darts' score of 1st to 15th throws and the After VR Darts' one ($p<0.01$), however the results of the VR bowling subjects did not demonstrated such the tendency ($p>0.80$). The results suggest that darts in the VR space affected darts in real space.

The After VR Darts' score of the 1st to 15th throws is higher than the After VR Darts' score after the 16th throw ($p<0.005$). It can be expected that the subject got used to the original environment and corrected the dart's trajectory. Therefore, the influence from VR was found to be temporary.

In addition, from the analysis results of motion capture data, we also found that the motion in playing the VR darts affects the motion of After VR Darts. The influence appeared strongly just after the VR darts, and thereafter the influence got nearly gone. The experimental results suggest that the experience in the VR space affected the performance in real space. The method can be apply for improving the performance in real space.

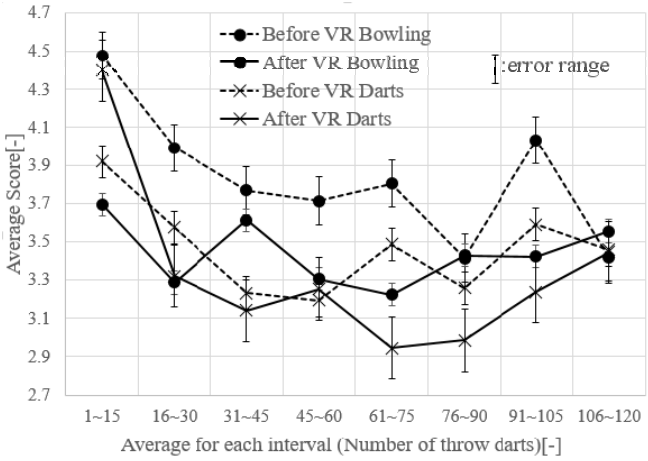

Figure 1: Darts score

CONCLUSIONS

In this study, we investigate the effect of experience in the VR space on the real space. The verification experimental results suggest that the experience in the VR space affect the performance in the real space. Furthermore, we found that its influence was quickly vanished by adaptation

P002 - BIOMECHANICAL DETERMINANTS OF BREAST COMFORT DURING RUNNING

[1] **Erica Buckeridge**, [2]Jordyn Vienneau, [1]Sian Slawson, [1]Sarah Manson, [1]Robert Gathercole

INTRODUCTION

Breast displacement in the vertical axis is considered a key contributor to exercise induced breast discomfort (1-3). In fact, reductions in this single variable is commonly how sports bra performance is evaluated. However, more recently the importance of multi-planar breast analysis has been emphasized by Scurr et al., who found sports bras provide multi-directional support during running (1). Furthermore, the notion that displacement is a key predictor of discomfort during physical activity has yet to be conclusively ascertained (3).

This study explores the multi-planar kinematics of breast motion (i.e. 3D displacement, velocity and acceleration) during running. This is done with the aim of identifying the key predictive markers of breast discomfort during physical activity, and to quantify the contributions of these kinematic predictors to overall perceived comfort.

METHODS

Nineteen physically active females participated in this study (mean ± SD: 23.6 ± 3.7 yrs, 165.8 ± 5.9 cm, 68.2 ± 8.9 kg). The measured bra size of each subject was either 32DD, 34D or 36C, resulting in a consistent 'breast volume' across all subjects. They performed 2 x 60 second running trials at 10 km/h on a treadmill while wearing a compression sports bra (lululemon athletica, Energy sports bra). A 15 cm visual analog scale (VAS) was used to obtain breast comfort ratings, with 0 cm representing *lowest overall comfort*, and 15 cm representing *highest overall comfort*. VAS scores were obtained following the run trials.

Kinematic data was collected using an infra-red motion capture system. A reflective marker was placed on the right nipple over the material of the sports bra to track breast motion. A torso co-ordinate system was defined by markers on the right and left clavicles, anterior-inferior aspect of the right and left 10th ribs, T1, T10, and suprasternal notch. The nipple marker was transformed into the torso co-ordinate system, and its 3D position was expressed relative to the supra-sternal notch.

Nipple range of motion, as well as peak nipple velocity and peak nipple accelerations were calculated for each recorded run stride in the medio-lateral, anterior-posterior and vertical axes. These variables were entered as predictor variables into a stepwise multiple linear regression, while breast comfort ratings were entered as the dependent variable. The quality of the regression model was evaluated through assessments of R^2 values. All statistical analyses were performed in Matlab.

RESULTS AND DISCUSSION

The multiple regression identified two kinematic variables to be important in describing breast comfort during treadmill running; peak vertical nipple acceleration and peak anterior nipple acceleration. The mean and standard deviations of these predictor variables, as well as the dependent variable, are listed in Table 1. With these predictor variables, the model achieved an R^2 value of 0.43, thus explaining 43% of the total variance in breast comfort during running.

Table 1: Descriptive statistics of the dependent and predictor variables, in addition to regression equation constant and coefficients.

Variable	Mean	p-value	Regression coefficient
Breast comfort	8.1 ± 3.3 cm		
Peak downwards acceleration	23.4 ± 7.3 m/s^2	0.01	-0.30
Peak anterior acceleration	15.0 ± 5.1 m/s^2	0.04	0.29
(Constant)			10.29

These results indicate that multi-planar accelerations of the breast are a more powerful predictor of comfort than the commonly considered vertical displacement. This has important implications around future sports bra design and development, where interventions to enhance breast comfort during running could be achieved by specifically targeting the reduction of multi-directional peak accelerations.

It is important to note that the key kinematic variables in this study explained only 43% of variance in breast comfort. This supports the notion that comfort is a highly complex measure that requires multi-factorial consideration of diverse variables. For example, tactile properties, aesthetic appeal, thermoregulatory capabilities and fit of the bra are just some of the other parameters likely to influence breast comfort, and must be considered in our fundamental assessments of sports bra performance and comfort.

CONCLUSIONS

Acceleration exhibited the strongest relationship with breast comfort. However, comfort is multidimensional and must be defined by more than biomechanical performance.

P003 - RELATIONSHIPS BETWEEN WALKING SPEED AND T-SCORE WITH GAIT PARAMETERS DURING STAIR ASCENT IN OLDER WOMEN WITH LOW BONE MINERAL DENSITY

INTRODUCTION

Osteoporosis is a systemic skeletal disease identified by decreased bone mineral density (BMD) and bone loss [1], increasing the risk of possible fractures. Day-to-day load bearing activities, such as stair climbing, can promote bone formation and help maintain bone mass [2]. However, negotiating stairs is more physically and mechanically challenging than level walking and presents a greater risk of falling. A fall on stairs can have devastating consequences especially for older women with low BMD.

The aim of this study was to explore the relationships between gait parameters and stair walking speed and T-score in older women with a range of T-scores (healthy when T-score is within ±1 SD of mean, osteopenic between -1 to -2.5 SD of the mean and osteoporotic below 2.5 SD) during stair ascent.

METHODS

45 older women women including 13 with healthy BMD levels, 26 osteopenic and 6 osteoporotic [mean (SD): age 67.3 (1.4) years; height 161.4 (4.9) m; mass 63.5 (8.6) kg] were recruited from the Hull and East Yorkshire NHS Trust. Twelve motion capture cameras (Qualisys, Sweden) and two force plates (Kistler, Switzerland) were synchronised to capture 3D kinematic and kinetic data during stair ascent on a custom-built 5-step staircase while participants ascended at their preferred speed, without the use of the handrails. Force plates were embedded into steps 2 and 3.

Gait data were analysed in Visual 3D™ musculoskeletal modelling software (C-Motion, USA) and normalised to the gait cycle starting with foot contact. Multiple regression analysis using Stata (Texas, USA) explored the explained variance (R^2) in gait variables of interest, such as temporal-spatial parameters, joint kinematics and powers attributable to speed and femoral neck T-score with $P<0.05$ indicating statistical significance.

RESULTS AND DISCUSSION

The mean (SD) stair ascent speed was 0.65 (0.1) $m \cdot s^{-1}$, which was faster than most age- and gender-matched peers [3], explained the variance (R^2=9-47%) ($0.001 \geq p \leq 0.01$) in most temporal-spatial, kinematic and kinetic parameters ($p \leq 0.001$). Inclusion of T-score to the regression model did not increase the explanatory power of models, except for stride width (R^2=11% of the shared variance, Table 1).

The significant relationship between speed with T-score and stride width may suggest women with low BMD adjust their stride parameters in order to enhance dynamic stability to avoid any unexpected falls during stair walking. T-score did not predict any variability in double limb support time, leaving it primarily under the influence of stair ascent speed. Speed also explained considerable variance in most joint powers (R^2=13-38%) ($0.001 \geq p \leq 0.01$). Highly significant slope coefficient (B) for H1 and A1 power bursts suggested escalation in power generation and absorption respectively, if and when speed was increased. As gait speed is an indicator of overall physical ability and musculoskeletal function, our findings suggest that speed presented a stronger relationship with gait parameters than T-score.

Table 1: Magnitude of explained variance (R^2) in temporal-spatial gait parameters explained by gait speed (GS) alone, gait speed with T-Score (GS & TS). Blue shaded areas indicate significant findings whereby the point estimate of the regression slope (B) was significantly different from 0 at the following alpha levels; *p<0.05, **p<0.01, and ***p≤0.001. H1 is a concentric contraction of the hip extensors and A1 is an eccentric contraction of the ankle plantarflexors, both during weight acceptance.

Gait Parameter	Mean (SD)	Predictor variable	R^2 %	Predictor variable	SLOPE COEFFICIENT (B)
Stride Width (m)	0.08(0.02)	GS	9	GS	0.04**
		GS & TS	20	TS	0.01**
Double Limb Support Time (s)	0.22(0.07)	GS	35	GS	-0.215***
		GS & TS	35	TS	-0.006
Knee Flexion (°) (loading response)	70(5.4)	GS	16	GS	-11.2***
		GS & TS	16	TS	0.15
H1 (W/Kg)	2.18(0.8)	GS	18	GS	1.945***
		GS & TS	18	TS	-0.676
A1 (W/Kg)	-0.68(0.5)	GS	38	GS	-1.712***
		GS & TS	39	TS	0.077

CONCLUSIONS

Speed remains the most important variable to explain most of the variance within the temporal-spatial gait parameters, kinematic and joint powers in older women ascending stairs. Our findings suggest faster stair ascent, beyond 'comfortable' speed, but done with caution (including light handrail use), could help increase the mechanical loading on the lower limbs and have a positive effect for maintaining BMD.

INTRODUCTION

Pregnancy involves important changes in the body of pregnant woman. A consequence of these changes is pain that occurs at the lower levels of the spine. Pain may range from a simple discomfort to an impossibility of carrying out ordinary and/or professional tasks. The objective of this research is to show whether pregnancy affects the activity of the back extensor muscles of the trunk (Spinalis Thoracic : ST and Longissimus Lumbarum : LL)

METHODS

Thirty (30) women, mean age (25,8 ± 5,79 years), height (158,43 ± 7,63 cm), weight (57,56 ± 9,60 kg) and weeks of pregnancy (22,03 ± 9,96) were recruited. Inclusion criteria were : to be 18 years or older, Beninese, sedentary and in a normal pregnancy. Informed consent was obtained from all subjects. Surface EMG of the muscles of interest was recorded for 60 seconds in ventral decubitus position. Total Power Spectrum (TPS) and Root Means Square (RMS) were computed and percentage of fibre recruitment was determined. A questionnary is administered at each prenatal clinic to determine whether or not the women has pain. Statistical analysis (parametric t test for the TPS et RMS variables and the ratio comparison test for the recruitment percentage) was conducted with software GraphPad PRISM 5. The differences are significant at $p < 0,05$

Experimental protocol

The women is positioned in ventral decubitus on a chair the trunk suspended in the void with for trunk - thigh angle held at about 20° from the vertical. The electrodes are placed 2 cm laterally on the dominant and non dominant side of T8 for Spinalis thoracic and 4 cm of L1 for Lumbar longissimus. The test consists of holding the trunk horizontally, arms crossed over the shoulders for 60 seconds.

RESULTS AND DISCUSSION

The study revealed that the total power of the spectrum (TPS) and Root mean squart (RMS) of the various muscles vary according to the state of the woman (back pain, no back pain) and according to the trimesters of pregnancy. It also showed that the level of recruitment of fibres of these two muscles varies with the evolution of the pregnancy.

Table I. Level of recruitment of fibres in the suffering pregnant women of pain (PWP) and non suffergers (PW)

	PW (n = 13) m ± s	PWP (n = 17) m ± s
ST R	**15% ± 9**	**10% ± 4**
ST L	**12% ± 4**	**11% ± 7**
LL R	**21% ± 9**	**18% ± 5**
LL L	**17% ± 4**	**13% ± 5**

Spinalis thoracique right (STR) ; Spinalis thoracique left (STL) ; Longissimus lombaire right (LLR) ; Longissimus lombaire left (LLL).

Pregnancy induces the increase in the body mass observed in the pregnant woman, involving the activation of extensor muscles of the trunk [1, 2]. The weight of the abdomen generate an increase in the curve of the lumbar (anteriorly) and increase the activity of the trunk extensors muscles. Micro traumatisms of conjunctive tissues consequence of the forces developed by the trunk extensors muscles to oppose forward flexion, result from postural modifications due to pregnancy or by micro mobility of joints related to the increased laxity of pelvic ligaments [3].

CONCLUSIONS

The study reveals the influence of the pregnancy on the biomechanical capacities of the trunk extensors muscles. It indicates that the changes (morphological and physiological) related to pregnancy are reflected on the locomotor system.

ACKNOWLEDGEMENTS

Our thanks with all those which took part in this study, in particular, pregnant women, technicians and doctors who allowed his realization.

P005 - DESIGN AND DEVELOPMENT OF SIX-POSITION FEET TEMPLATE FOR PERIPHERAL NEUROPATHY DIABETES TESTING

[1]**Suwiphat Chalongwongse**, [1]Pittawat Thiuthipsakuland, [1]Najpol Tejapijaya, [1]Pongsakorn Prakunaumnuay, [1]Jackrit Suthakorn,Ph.D, [2] Chumpon Wilasrusmee,M.D. and [1]Choladawan Moonjaita

INTRODUCTION

On November 2016, World health organization (WHO) show that around 422 million adults in the world are diabetes. Half of diabetes patients develop peripheral neuropathy requiring intervention resulting in hospitalization and subsequently this may lead to amputations. However, diabetic patients with peripheral neuropathy can survive and live as normal people if they are treated in right way and on time. To classify risk the level of a patient, normally sensory and motor function of the peripheral nervous system is evaluated by technicians with monofilament device. The monofilament device produces a sensational response by touching and pressing on patient's skin. According to this method, we are interested in developing a robotic system for peripheral neuropathy diabetes testing following previous work [1]. The new version of robotic system is being developing.

Six test positions are focused on here and are added to the template of the robotic system. The six test positions consist of three positions at the middle area of the feet (metatarsals bone), one position at the heel area (Calcaneus bone), one position at the big toe area (First phalange bone) and one position at the little toe area (Fifth phalange bone) as shown in figure 1(a). To develop an optimal robotic system with compact dimension, a universal template for various size of foot and also both left and right feet is the challenged.

METHODS

The template was designed and developed on 50 volunteers, with feet in between 35-45 of European size. The suitable areas of all test positions are determined for each foot of volunteers, especially the two test positions of big toe and little toe. These two positions provide a long range of adjustment between left and right side. The hypothesis of the experiment is that the three test positions at middle area of foot are stable position and the rest are the area that we need to find an adjustment area. Different templates were developed for the experiment with purpose of 'study on adjustment area of feet between 35-45 Euro with both left and right side'. 10 templates were designed and implemented for experiment.

In the experiment, volunteers were asked to put their foot on the templates, then fit the posture of the foot on all six test positions and ask them for comfortability of their foot. Rating are no point for template that cannot fit their foot on six test positions, one point for template that can fit their foot on but uncomfortable feel and two point for template that can fit their foot on with comfortable feel.

Scores and comments were recorded for researchers. To define the solution of the template, statistical methods were applied to give a preliminary analysis. Then specific cases were customized for the template to cover as many cases as possible.

RESULTS AND DISCUSSION

Result from the experiments show that the three test positions at the middle area of feet can be fixed positions, including with the heel position. Big toe and little toe test positions require a long range for adjustment with some angle slope for left and right side to be changeable. However, there are a few cases that do not fit the template, so specifically modifications are applied to the template to make it fit as many cases as possible. The modified template was test on volunteers again and the results show that the template had more than 85% accuracy. The final solution of template consist of three test positions at middle area of feet and heel test position as fixed positions on the template and two test positions of big toe and little toe as adjustable positions to fit with each person's feet. The adjustable positions of big toe and little toe are 60 mm long range with +10 degree and -10 degree slope from the center line as show in figure1(b).

(a) (b)

Figure 1: a) Six test positions, b) Template of six-position feet template for peripheral neuropathy diabetes testing.

CONCLUSIONS

This work is a study on a feet template for peripheral neuropathy diabetes testing. The template consist of six test positions; three fixed positions at the middle area of feet, one fixed position at the heel area, one adjustable position at the big toe area and one adjustable position at the little toe area. The template is designed to fit both left and right feet at 35-45 Euro foot size. The result show that the template has more than 85% accuracy.

P006 - CONSTRUCTION OF CORNEA SCAFFOLDS BY USING SUPERCRITICAL EXTRACTION

[1]**Wen-Hsin Chang**, [2]Fan-Wei Tseng, [3]I-Chen Peng, [1]Shu-Wei Wu, [2]Dar-Jen Hsieh, [3]Yi-Hsun Hunag, and [1]Min-Long Yeh

INTRODUCTION

More than 10 million individuals worldwide suffer from corneal blindness due to the lack of cornea donors. [1] Clinically, the main method to recover eyesight is corneal transplantation. Bioengineering scaffolds (synthesized scaffolds) are always lack of the native structure and the tensile strength. Porcine corneas are native tissue and we can get them around the world. In order to remove heterogeneous cells that could cause immune reaction, chemical detergents are used to wash out cell debris traditionally. However, those detergents may remain in grafts that are harmful to hosts. [2] Supercritical fluid has high transfer rate and high permeability. Using this technique to remove cells has no possibility of chemicals remaining in the tissue. The aim of this study is to prepare decellularized porcine corneas (DPCs) by supercritical carbon dioxide extraction ($SCCO_2$) and Triton X-100 for tissue engineering. After that, we will compare different scaffolds by physical and biochemical methods.

METHODS

Porcine eyeballs were got from slaughterhouse and were frozen until use. After peeling from eyeballs, corneas were soaked in deionized water and hypotonic saline solution and shaking at room temperature. Corneas were decellularized by supercritical fluid extraction. 0.1N NaOH was used to restore the transparency and washed with deionized water. Corneas were then deswelled and stored in glycerol until use. On the other hand, after deionized water and hypotonic saline solution treatment, corneas were decellularized with 0.2% Triton X-100 for 6 hr shaking at room temperature. Decellularized corneas were washed in deionized water overnight with shaking and then stored in glycerol.

Corneal transparency was assessed directly with eyes. The mechanical properties, moduli and maximum load, were determined with a tensile test machine. Corneal structure was observed with scanning electron microscope (SEM) and hematoxylin-eosin (H&E) stain. 4',6-diamidino-2-phenylindole (DAPI) stain and Blood & Tissue Genomic DNA Extraction Miniprep System were used to estimate DNA residue. Glycosaminoglycans (GAGs) content was estimated with Dimethyl methylene blue (DMMB) assay. Immunohistochemistry (IHC) was used to stain glycoprotein, fibronectin and laminin.

For the cytocompatibility, mouse embryo fibroblast cells (NIH3T3) were cultured on $SCCO_2$- or Triton-treated scaffolds. Dulbecco's Modified Eagle's Medium (DMEM) was replaced every 2-3 days. Cell proliferation rate was quantified by WST-1 assay at 1, 4, 7, and 14 days.

RESULTS AND DISCUSSION

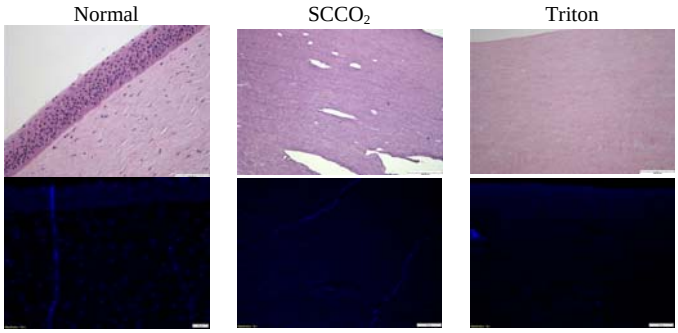

Figure 1: H&E and DAPI staining of normal, $SCCO_2$- and Triton-treated corneas.

H&E and DAPI stain show that there is no DNA remains in the tissue. DNA residue decreases after decellularization. Corneal scaffolds become clear after deswelling in glycerol. DPCs have porous structures which pore size of $SCCO_2$-treated scaffolds is the largest. The moduli and the maximum load of $SCCO_2$-treated scaffolds are the lowest. Nevertheless, they are still can withstand clinical suture and do not cutting. GAGs play an important role for keeping H_2O molecules. Although DMMB assay indicates that GAGs content is significantly decreased after decellularization, corneal scaffolds still have pores to keep water. In addition, it is uncomfortable to patients if a graft contains too much water and too thick when transplantation. IHC shows that fibronectin appears at stroma which is identical to previous study. However, we didn't observe laminin which should be present at subepithlial layer. It may be stripped off when we removed epithelial cells. In cytocompatibility test, cells do attach to the scaffolds and proliferate as the time goes on.

CONCLUSIONS

Using supercritical extraction as decellularized method is an efficient process to corneas without the concern of chemical residue. $SCCO_2$-treated scaffolds maintain the transparency, have enough strength for suturing and can support cell adhesion and proliferation. This technique has the potential to overcome the problem of corneal graft shortage.

P007 - IN VITRO ENZYMATIC DEGRADATINO MEASUREMENT OF HYALURONIC ACID IMPLANTS USING RHEOLOGY

Chun-Jen Chien, Shih-Wen Fang, Yu-Ting Fang, Shou-Chieh Huang, Yu-Pen Chen, Der-Yuan Wang, Hwei-Fang Cheng
Division of Research and Analysis, Food and Drug Administration, Taipei, Taiwan, R.O.C

INTRODUCTION

Hyaluronic acid (HA) is an anionic, non-sulfated glycosaminoglycan natural linear polysaccharide composed of alternating D-glucuronic acid and N-acetyl-D-glucosamine with β (1, 4) interglycosidic linkage. It has been reported that hyaluronic acid, which a glycosaminoglycan (GAG) richly present in cartilaginous tissues have stimulatory effects on extra cellular membrane biosynthesis, cell migration, and phenotypic maintenance of chondrocytes and nucleus pulposus cells. Because of its less immune rejection, HA can be used to correct disorders in the fields of rheumatology, ophthalmology and wound repair. Monitor the mechanical properties and degradation time of HA implant products is very important for their applications in biomaterials as a commercial medical device.

The aim of this study we establish the methods which can examine the degradation property of hyaluronic acid products by elastic module, storage module, and complex viscosity (η*). According to the European Pharmacopoeia (EP 1472) and ASTM International (ASTM F2347-11) Dische's carbazole technique was the major method to detect the glucuronic acid released during degradation. However, it would not be significant observed the phenomenon of hyaluronic acid degradation. Therefore, we attempt to determine the degradation pattern by rheology. In this study, 6 kinds of hyaluronic acid products were bought from the clinical for test the rheology of degradable hyaluronic acid [1,2].

METHODS

In Vitro Enzymatic Degradation

Bovine testes hyaluronidase (Sigma-Aldrich, H3506) was added into phosphate buffer saline (pH 7.4) with the concentration at 100 U/ml in an incubator at 37℃ for 10 minutes. Then 0.1 ml of the bovine testes hyaluronidase with 200 mg of HA filler was incubated at 37℃ for in vitro enzymatic degradation. With specified time interval, the reaction was stopped by adding 2 ml HCl (0.1N) into the solution, then filtered through a 0.45 μm filter. Finally, the HA degradation product in the solutions collected at each interval were measured through the glucuronic acid content on the basis of dische's carbazole technique [3].

Rheology Measurement

The Rheometer (TA Instrument, ARES-G2) was used to determine the rheology. The HA filler after in vitro enzymatic degradation treatment was placed on a 25 mm diameter parallel stainless steel plate. The gap was 0.5 mm. The temperature was heated to 37℃, then keep the status for 30 seconds. The strain was set to 5% and the frequency sweep was from 0.02 – 50 Hz [4,5].

RESULTS AND DISCUSSION

The quantities of glucuronic acid releasing revealed that HA implant products were degraded after 24 hours within hyaluronidase. The results of fluid mechanics was shown in table 1, it has significant decreasing on elastic module (G'), storage module (G'') and complex viscosity (η*) after 24 hours in vitro enzymatic degradation. The 6 kinds of HA fillers used in plastic surgery and reconstruction could not resist the enzymatic degradation. Most HA fillers shows that 90 to 99 % glucuronic acid releasing, and 80 to 99 % decreasing of rheological property compare to the original status.

Table 1: The rheology properties of HA fillers showed substantial decline after 24 hours in vitro enzymatic degradation treatment.

Sample	G' at 2.5 rad/s			G'' at 2.5 rad/s			Complex viscosity at 2.5 rad/s		
	0	24	%	0	24	%	0	24	%
1	16829.10	10.88	-99.94	3682.59	0.66	-99.98	4869.12	4.35	-99.94

CONCLUSIONS

In this study we successfully developed the fast high-throughput in vitro enzymatic degradation within rheology properties measurement technique. The Dische's carbazole technique result showed that 90 to 99% glucuronic acid was released after 24 hours incubation with hyaluronidase. In addition, the rheology also showed significant decreasing in elastic module, storage module and complex viscosity. Therefore, 6 kinds of hyaluronic acid fillers which used in plastic surgery and reconstruction couldn't resist the in vitro enzymatic degradation for 1 day. The preliminary results in this study can evaluate the degree of degradable in hyaluronic acid by rheology, but we still need more kinds of HA implants to verify time-dependent degradation simulation by rheology.

P008 - EFFECT OF SURFACTANT ADDITION ON THE THRESHOLD OF IRREVERSIBLE ELECTROPORATION

[1] **Keishiro Fukunaga**, [1] Kosaku Kurata, and [1] Hiroshi Takamatsu
[1]Kyushu University, Fukuoka, Japan
Corresponding author email: takamatsu@mech.kyushu-u.ac.jp

INTRODUCTION

Irreversible electroporation (IRE) is attracting attention as a less-invasive therapy to treat tumors. By delivering a train of short and intensive electric pulses to a tissue, this method gives irreversible nanopores to cells around the electrodes. A major factor affecting the IRE outcome is a distribution of the electric field because the cell breakage is induced by the potential difference across the cell membrane. In a clinical application, the applied voltage reaches as high as a few kilovolts, and thus, general anesthesia is required for the treatment to avoid discomfort contractions of muscles [1]. The reduction of the applied voltage is desired for decreasing the burden on patients.

Since the mechanism of IRE is based on perforation of the cell membrane, addition of surfactants would be a promising method to interfere a repairing process of the damaged membrane and to decrease the applied voltage [2]. Therefore, in this study, we examined the effect of surfactant addition on the threshold of IRE.

METHODS

Agarose gel containing NIH3T3-3 fibroblasts was used as a tissue phantom. The cells were mixed in the agarose sol with and without 10% DMSO as a surfactant and then solidified in a plastic vessel (20 mm in inner diameter and 42 mm deep) with a pair of 1-mm-diameter stainless steel electrodes. The 20-mm-long electrodes were electrically conductive for a length of 10 mm from the tip, and the remaining length was insulated. The initial cell density was 2×10^5 cells/ml.

A train of rectangular-shaped electric pulses at 1 kV was applied to the tissue phantom using a commercial electroporator (ECM830, Harvard Apparatus). Keeping the pulse width and interval constant at 10 μs and 1 s, respectively, the effect of the added DMSO was examined. After the application of 30, 60, 90, 120, and 150 pulses, 1-mm thick section at the middle of the electrode was sliced and then stained with calcein-AM and propidium iodide (PI) to examine cell viability. Calcein-AM emits a green fluorescence in the cytoplasm of living cells whereas PI emits a red fluorescence in the nuclei of dead cells. The ablation area occupied by PI-positive dead cells was quantified by Image J software.

The electric potential and the electric field around the electrodes were calculated by solving the Laplace equation [3]. The numerical solutions were obtained using a finite element analysis program Marc and pre/post-processing software Mentat (MSC Software Corp.). The obtained electric field was compared with the distribution of the dead cells observed in the experiments.

RESULTS AND DISCUSSION

Double-fluorescent micrograph of the sectioned tissue phantom showed that red-fluorescent dead cells distributed around the electrodes, and there was a clear boundary between alive and dead region. The contour lines of electric field were narrower at the middle of the electrodes and looked like a horse bean.

Figure 1 shows the ablation area as a function of the pulse repetition. The ablation area was normalized by the area between the electrodes; the product of the electrode diameter and the center-to-center distance of the electrodes. The ablation area increased with the pulse repetition, and reached an upper limit at 120 pulses. Addition of DMSO achieved 17.2 % larger ablation area than the control group.

The outer edge of the ablated region closely resembled the shape of the electric field obtained by the numerical analysis. By comparing the experiments and analysis, we obtained the value of the critical electric field corresponding to the outer edge of the ablation region. The critical electric field of the DMSO-added sample (0.87 kV/cm) was 10.8 % smaller than that of the control (0.98 kV/cm). The threshold of IRE was successfully reduced but not significantly enough by the addition of DMSO. Further study is therefore needed to minimize the threshold of IRE.

CONCLUSIONS

Experimental and numerical studies revealed that addition of 10% DMSO decreased the critical electric field required for IRE by approximately 10%.

P009 - TEMPERATURE CHANGES IN SERIAL CASTING IN THE TREATMENT OF CLUBFOOT

[1]Bob Giesberts, [1]Edsko Hekman, [2]Patrick Maathuis and [1,2]Bart Verkerke
[1]University of Twente

INTRODUCTION

Idiopathic clubfoot (*talipes equinovarus*) is a congenital deformity of the foot. The common treatment consists of serial manipulation and casting, known as the Ponseti method, which is started in the first week after birth. After an average of five cast changes and often a percutaneous Achilles tenotomy the deformity is corrected [1]. An abduction orthosis is worn for several years to prevent relapse.

The application of plaster cast includes soaking the roll in lukewarm water which starts the exothermic curing reaction. After the plaster has cured the surplus water evaporates, which is an endothermic process. Heat is drawn from the surrounding but also from the patient. One case study describes observed hypothermia after the application of a plaster jacket for immobilization of the cervical spine [2].

In a survey among parents (unreported, 49 respondents) a number of parents mentioned that their child seemed to feel cold the first hours after a new cast had been applied.

The aim of current study is to investigate the temperature changes underneath the cast in the treatment of clubfoot with the Ponseti method.

METHODS

A 1-wire DS1825 digital thermometer (*Maxim Integrated*, San Jose, CA, USA) was used to measure the temperature underneath the cast. The sensor was placed underneath the sole of the foot and attached to a custom made data logger which stored time and temperature data every 10 minutes for a full week.

Dip duration was calculated as the time from the moment the first maximum was reached until the temperature reached the mean value of the last 6 days. T-Tests were used to test the temperature difference for statistical significance.

According to the Medical ethical evaluation committee of the UMCG the study does not fall under the Medical Research Involving Human Subjects act.

RESULTS AND DISCUSSION

Preliminary results of the first seven measurements in four subjects (age 2-30d, all boys, 2 bilateral) are presented in Figure 1.

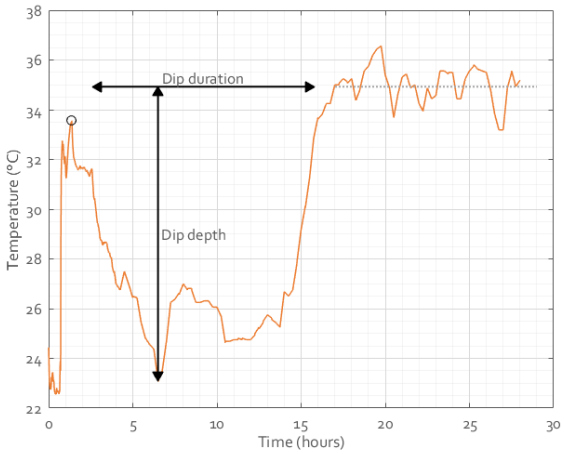

Figure 1: Typical measurement of the temperature underneath the cast during the first 24 hours after casting.

After an initial temperature increase after the application of the plaster cast, a decrease was visible in all measurements ($p < 0.000$). This dip reached a minimum of 23-33°C and lasted 5.9-16h before reaching a relatively stable 34-37°C.

During the ISB2017 the additional results of the remaining scheduled measurements will be presented.

CONCLUSIONS

A considerable decrease in skin temperature was observed after the application of long leg casts in the treatment of clubfoot. Especially in bilateral cases this might cause discomfort or even hypothermia.

INTRODUCTION

In this study, NobelActive (NA) implants (Nobel Biocare AB, Gothenburg, Sweden) were used to investigate the biomechanical effects of platform switching as well as implant diameter in peri-implant bone. By previous studies, the design of NA implant featuring self-tapping and bone-condensing properties could increase primary stability and potentially allowed this kind of implant more effective for immediate placement in fresh extraction sockets and for immediate loading [1-4]. The NA implant contains a built-in platform switching concept aiming for peri-implant bone maintenance; however, it is not yet well understood how it may affect the biomechanical environment of peri-implant bone.

The purpose of this study was to investigate the effects of loading types and implant diameter in bone strain and to elucidate which is the determining factor especially for immediately loaded implant with platform switching.

METHODS

The 3.5mm, 4.3mm, and 5.0mm diameters of NobelActive (NA) implants (Nobel Biocare AB, Gothenburg, Sweden) with a length of 11.5mm were applied and labeled as NP 3.5 implant, RP 4.3 implant, and RP 5.0 implant. The diameters of abutment (Snappy ™ abutment, Nobel Biocare AB, Gothenburg, Sweden) for NP 3.5 implant, RP 4.3 implant, and RP 5.0 implant are 3.0mm, 3.4mm, and 3.4mm, respectively. Although RP4.3mm and RP5.0mm have different implant diameters in 4.3mm and 5mm respectability, their implant platforms are both 3.9mm in diameter, which makes them possessing the same degree of platform switching around 0.5mm after 3.4mm of diameter of abutment was used. Therefore, the NP3.5, RP4.3 and RP5.0 implants all have the same degree of platform switching in 0.5mm.

The specimens of rectangular synthetic trabecular bone and 2-mm-thick synthetic cortical layer (Sawbones model 3401-02 and 1522-05; Pacific Research Laboratories, Vashon, WA, USA) and were prepared as experimental bone model. Two kinds of 190N of occlusal loading including a vertical force and a 30-degree lateral force were applied onto the prosthetic abutments by a universal testing machine (JSV-H1000; Japan Instrumentation System).

Rectangular rosette strain gauges (KFG-1-120-D17-11L3M3S; Kyowa) were stuck onto the crestal cortical region with cyanoacrylate cement (CC-33A; Kyowa) at both the buccal and lingual sides of the implant. Signals of the 3 independent microstrains εa, εb, and εc recorded by the rosette strain gauge were sent to a data acquisition system (NI CompackDAQ; National Instruments) to calculate the maximum (εmax) and minimum (εmin) principal microstrains.

RESULTS AND DISCUSSION

Upon vertical loading, the peak values of the principal microstrains of bone were similar on the buccal and lingual sides. Under vertical loading, the RP5.0 (-1312.77±64.79) implant group exhibited lower bone strain around the implant neck than the NP3.5 (-1682.89±307.79) and RP4.3 (-1817.21±111.12) implant groups. However, when comparing RP4.3 and NP3.5 implant groups, RP4.3 distributed approximately 8% higher strain in bone than NP3.5.

When lateral loading was applied to the three groups of implants, the NP3.5 (-2895.77±214.07) implant group showed the highest bone strain in the bone surrounding the implant, followed by the RP4.3 (-2164.95±161.87, approximately 25% reduction) implant, and the RP5.0 (-1573.93±139.33, approximately 45% reduction) implant group demonstrated the lowest.

CONCLUSIONS

The benefit of embedding wider diameter of implant is obvious for decreasing the bone strain around the implant during both lateral and vertical loadings. Platform switching seems to have a special effect in reducing bone strain only under vertical load in NP3.5mm implant as compared to those in RP 4.5 implant.

P011 - MUSCLE FATIGUE BASED ON THE MECHANOMYOGRAPHY DURING FUNCTIONAL ELECTRICAL STIMULATION

[1] **Min Jo**, [1]Youngjae Jung, [1]Jesung Ryu, [1]Indra Erdenebat and [1]Youngho Kim

INTRODUCTION

Functional electrical stimulation (FES) uses low energy electrical pulses to generate muscle contraction and support impaired function like grasping, standing, walking and bladder voiding. One of the most important problems in using FES is muscle fatigue, because of the electrical stimulation raises muscle fatigue faster than the voluntary contraction. Therefore, FES has risks by over stimulation, such as decrease in the ability of contraction, mild tremor and muscle tissue damage [1]. Thus, the management of muscle fatigue is necessary for the rehabilitation with FES.

Typical representative methods of detecting muscle fatigue are electromyography (EMG) and mechanomyography (MMG). The EMG is a reliable tool for the assessment of neuromuscular activation. However, EMG is sensitive to external noises because it records the electric potential generated by muscle cells. The MMG measures mechanical oscillations of muscle contraction. Thus, MMG is robust to electrical noise. The purpose of this study is to measure muscle fatigue quantitatively during FES using MMG in order to determine the feasibility to apply to the patients.

METHODS

Five healthy male (age: 27.4±2.5 years) subjects with no history of lower extremity orthopedic, neurological or vascular problems participated in this study. The experiment was performed to imitate foot drop treatment. The FES (EMGFES 2000, Cybermedic, Korea) was controlled by the foot switch. Electrical stimulation was applied during mid stance (end of heal contact) to heal contact with 60Hz frequency, 240μs pulse duration and 30mA amplitude. MMG sensor (LIS311, STMicroelectronics, USA) was used to measure the 3-axis accelerations (x: mediolateral, y: longitudinal, z: superoinferior). It was placed on the left tibialis anterior between electrical stimulation pads which were attached along the muscle fiber direction. All recordings were performed during treadmill walking. Subjects were walking on the treadmill for 15 minutes with a constant speed of 3.5km/h.

MMG signals were recorded at a sampling rate of 1 kHz. They were bandpass filtered (8-100Hz) and removed power noise (60Hz) prior the signal analysis. Filtered MMG signals were normalized by SVM (Signal Vector Magnitude). The MMG signal was analyzed using the convex hull algorithm [2]. The calculated convex hulls were averaged in groups of 30 to see trends.

RESULTS AND DISCUSSION

Convex hull area in the sagittal (yz-) plane and convex hull volume were significantly decreased according to the repetition of electrical stimulation. Convex hull area of transverse (xz-) and frontal (xy-) plane have no significant difference (Figure 1).

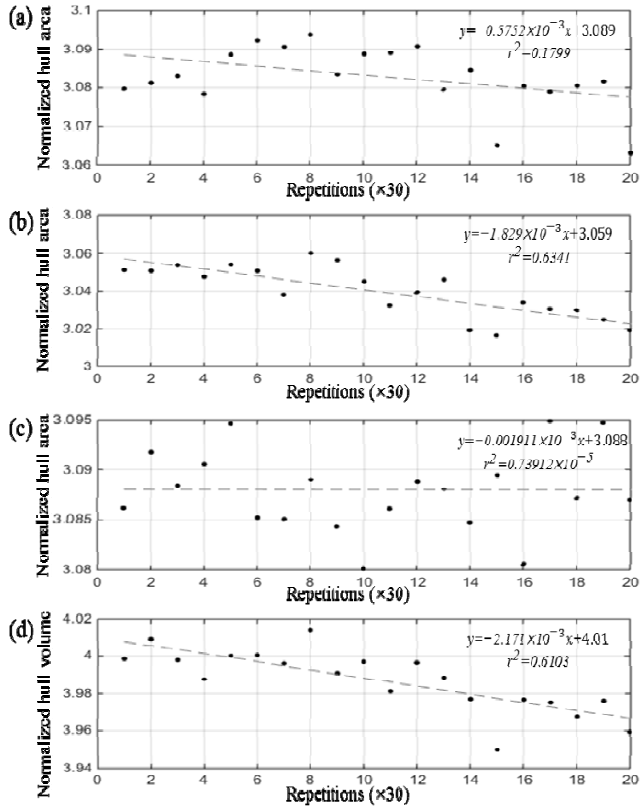

Figure 1: Linear representations of normalized hull area and volume of 3-axis MMG during electrical stimulation. (a) Normalized hull area in the xy-plane; (b) Normalized hull area in the yz-plane ; (c) Normalized hull area in the xz-plane ; (d) Normalized hull volume of 3-axis MMG

CONCLUSIONS

In this study, MMG signals during electrical stimulation were analyzed to defensive muscle fatigue using the convex hull algorithm. The convex hull area and volume were decreased with the repetition of electrical stimulation. This study demonstrated that MMG would be useful to feedback muscle fatigue during FES.

P012 - BIODEGRADABLE NANOFIBROUS MEMBRANE ATTACHED WITH GOLD-NANOPARTICLES FOR BONE REGENERATION

INTRODUCTION

Poly(lactide-co-glycolide) (PLGA) is a biocompatible and biodegradable polymer that has been widely used in devices for tissue engineering and drug delivery applications. Gold nanoparticles (GNPs) have also been used as biomaterials and have been found to have a positive effect on bone formation. In this study, we designed and prepared a thiolated PLGA (PLGA-SH) nanofibrous sheet for binding with GNPs using a simple process. The objective this study was to design a manufacturing process for PLGA-GNPs nanofibrous sheet. This sheet can find many applications within the field of tissue engineering, more specifically orthopedic materials. The manufactured membrane was characterized by thermogravimetric analysis (TGA), Field emission scanning electron microscopy (FE-SEM), energy dispersive X-ray spectroscopy (EDX), X-ray photoelectron spectroscopy (XPS), Attenuated total reflectance fourier transform infrared spectroscopy (ATR-FTIR), and ultraviolet/visible spectroscopy (UV-vis). It was also evaluated for cytotoxicity and osteogenic effects using human adipose derived stem cells (hASC).

METHODS

The process for generating PLGA-GNPs is shown schematically in Figure 1. After attaching the GNPs onto the PLGA sheet (PG-H, PLGA-GNPs), the sheet was cleaned three times with distilled water. An un-coated control PLGA sheet (PLGA-SH) also underwent the same washing process. The sheets that had been treated using different concentrations of GNPs-solutions were observed by FE-SEM at 3.0 kV and 10,000 X magnification. XPS was utilized to determine the GNPs-bound on the surface of the PLGA sheet. TGA was performed under a 100 ml/min high purity nitrogen flow. The temperature was increased at a rate of 10 °C /min until it reached a maximum of 800 °C. The PLGA, PLGA-SH and PLGA-GNPs sheets were also analyzed by ATR FT-IR.

The hASC were seeded on the PLGA-SH and PG-H fibers in 48 well culture plates at a density of 1×10^4 cells/ml. The viabilities of hASC cultured on PLGA-GNPs were evaluated by using the EZ-Cytox and were checked at 24 and 48 hours. The morphology of cells grown on PLGA-GNPs sheets were observed using CLSM.

The hASC were seeded onto PLGA-SH, PG-L and PG-H in 48 well culture plate at a density of 1×10^4 cells/sample in the GM. After 2 weeks, the samples were treated with 40 mM Alizarin Red-S staining solution at 37 °C under 5% CO2 for 30 min. These samples were observed by digital camera and G-scope (Genie Tech, Korea). Then, these were treated with 10% 1-hexadecylpyridinium chloride and the absorbance was measured by using a microplate reader at 540 nm for a quantitative analysis.

RESULTS AND DISCUSSION

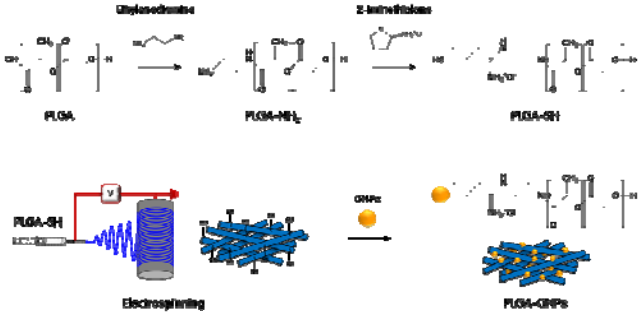

Figure 1: Schematic diagram of PLGA-GNPs nanofiber production.

In the cytotoxicity test, hASC that had been cultured on the PLGA-SH sheet for 24 hours were used for this test. The experimental groups were categorized based on the concentration of GNPs solution that was used for attaching the GNPs on the PLGA sheet. After 2 weeks of hASC culture in OM, the osteogenic effects of PLGA-SH, PG-L, and PG-H were evaluated, both qualitatively and quantitatively, by Alizarin Red-S staining analysis. When hASC differentiate into osteoblasts, they produce calcium to make bone. The deposited calcium is stained red by Alizarin Red-S solution. The PG-L and PG-H showed a darker red as compared with the control group. This is because of increased calcium deposition. Additionally, the amount of calcium deposition was increased even further when the amount of GNPs attached was increased. These results were also confirmed by the quantitative experiments. As a result, we established that PLGA conjugated GNPs have a higher osteogenic effect as compared with PLGA without GNPs.

CONCLUSIONS

In summary, nanofibrous composites having thiol-end groups were prepared using electrospun PLGA. GNPs were attached to these composites. Additionally, the amount of the particles attached was adjustable, and these particles were well dispersed. We plan to perform live-cell experiments using human adipose derived stem cells in order to investigate the effectiveness of this membrane as a biomaterial in the future. The membrane is expected to be highly biocompatible and functional. Thus, PLGA-GNPs can be useful materials for bone regeneration and have additional usage as a controlled release carrier for drugs attached to the GNPs.

P013 - SELECTIVE CELL FATE OF GALLIC ACID MODIFIED MICRO ARC OXIDATION COATING ON BIODEGRADABLE ZK60 ALLOY

[1]**Hung-Pang Lee**, [1] Ming-Long Yeh
[1] National Cheng Kung University
Corresponding author email: mlyeh@mail.ncku.edu.tw

INTRODUCTION

Magnesium and its alloys draw much attention to orthopedic application because of its mechanical properties and biocompatibility. However, the rapid corrosion rate and alkaline environment may induce the tissue inflammation. Thus, the surface modification is the promise strategy to prolong the degradation period and increase its bio-compatibility. Micro arc oxidation (MAO) forms a ceramic coating which enhances the corrosion resistance of the alloy significantly.[1] Moreover, the porous and rough interface promotes osteoblast-like cells (MG63) adhesion in comparison to fibroblast cells (NIH 3T3). Gallic acid is a natural compound extracted from tea with anti-inflammation and antibacterial properties.[2] In our result, gallic acid has selective cell fate function between osteoblast-like cells and fibroblast cells. Therefore, gallic acid modified micro arc oxidation coating may promote MG63 proliferation and adhesion, while minimizing inflammation and fibrous encapsulation.

METHODS

Experimental material adopts ZK60 magnesium alloy with chemical components (wt%) including Zn 5.5%, Zr 0.4% and the remaining contents of Mg. The samples are polished with finer grades of emery paper up to 5000 grades and rinsed in distilled water before MAO process. The electrolyte is composed of 12 g/l Na_2SiO_3, 5g/l NaOH and 6 g/l NaF prepared with deionized water. The device for MAO process consists of DC power supply, electrolytic bath and cooling system. The process adopts the current static mode with 0.02 A/cm^2 and the duration is about 5 minutes. After rinsing, the sample are immersed in 5g/l gallic acid ethanol solution for 24 hours, and then rinsed with distilled water and ethanol.

The surface morphology of the coating is studied by scanning electron microscopy(SEM). The phase and the composition are measure with x-ray diffractometer(XRD) and X-ray photoelectron spectroscopy (XPS) respectively. The corrosion resistance tests are carried by electrochemical test. A conventional three-electrode electrochemical cell was used for the polarization test with a platinum counter electrode and a saturated calomel electrode (SCE) as the reference electrode. The tests were performed in revised simulated body fluid (r-SBF) solution.

Mouse embryo fibroblast cells (NIH 3T3) and osteosarcoma cells (MG63) were used to examine the cytocompatibility. All cells were cultured in Dulbecco's Modified Eagle's Medium (DMEM). For the cell viability test, cells were cultured in 96-wells plates at 2000 cells/100µl of medium in each well and incubated for 24 h to allow initial cell adhesion. The medium was then replaced with experimental extract solution. Then, the viability rate is quantified by celltiter96-kit (Promega, USA).The morphology of cells adhesion is investigated by SEM observation. The cells are seeded on the coating for 12 hours, then fixed by 4% paraformaldehyde solution and dehydrated by ethanol.

RESULTS AND DISCUSSION

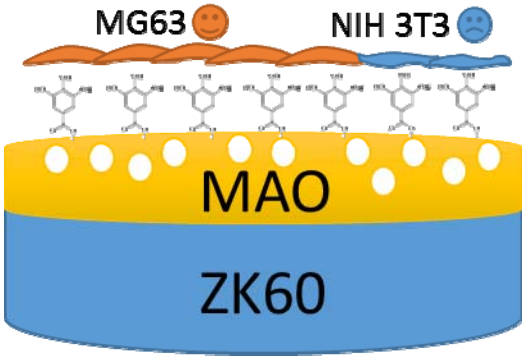

Figure 1: Schematic illustration of the selective cell fate coating.

The morphology of the coating is porous and the pore size is approximately 1µm. The compositions are mainly magnesium oxide, magnesium hydroxide which may form petal-like structure to increase the surface area and little magnesium silicate. In the x-ray photoelectron spectroscopy, the ratio of carbon is increased after the samples immersed in gallic acid solution. Moreover, in the high resolution spectra, gallic acid bonds onto the MAO oxide coating mainly through its carboxyl group to build a stable bonding. The corrosion current density is decrease from 10^{-5} to 10^{-7} A/cm^2 after the MAO process. Also, the anchoring process won't break the coating structure but instead increase corrosion resistance slightly. The cell viability tests show that osteoblast-like cells are more likely to grow in the environment added gallic acid. In contrast, NIH 3T3 fibroblast may be suppressed by gallic acid.

CONCLUSIONS

The MAO coating is effective way to protect corrosion solution invading the substrate which declines the corrosion rate and make cell easier to attach to implant's surface. Furthermore, the porous and petal-like structure provide gallic acid more anchoring site to functionalize the surface. In present result, the coating has potential ability to approach selective cell fate between osteoblast-like cells and fibroblast cells. It may promote the bone recovery and inhibit fibrous encapsulation.

P014 - COMPARISON OF CORE SUTURE METHODS USING CYCLIC LOADING IN FLEXOR TENDON REPAIR

[1] **Chika Miyamoto**, [1] Raita Miyaji [1] Takeshi Shimoto [2] Atsushi Ishikawa
[2] Hidehiko Higaki [3] Gou Miake [3] Naoya Kozono [3] Takamitsu Okada

INTRODUCTION

For the medical treatment of damage or rupture in the flexor digital tendon, finger flexor tendon suture surgery is used. In previous studies, various core suture methods have indicated that important factors affect biomechanical properties, including the number of suture strands [1]. Recently, asymmetric sutures have been reported to be effective [2]. We report that the condition where there is least resistance to gapping for the asymmetric placement of core suture in two tendon ends is favored at the repair site and when 3 mm or more asymmetry is used. This condition produces such beneficial effects more than a normal 6-stranded core suture [3]. However, it was not compared with other famous core suture methods. Therefore, this study was aimed to evaluate the strength in three types of core suture methods under cyclic load testing.

METHODS

Porcine flexor tendons were used in this study because their structure is similar to that of human flexor tendons. We sutured a porcine flexor tendon by using a combination of three types of core suture methods and interlocking cross-stitch peripheral suture. The three types of core suture methods used were the 3 mm Asymmetry technique [3], the Triple loop tsuge technique [4] and the Yoshizu #1 technique [5].

This experiment was performed under cyclic loading using an evaluation simulator that our research group developed [6]. Immediately after completion of the sutures, the sutured tendons were mounted on a custom-made cyclic loading machine. Both tendon ends were gripped using two upper and lower clamps to prevent slippage. The initial distance between the upper and lower clamps was set to 40 mm. A load cell was attached to the upper clamp to record the load added to the tendon. A custom-made software program on a personal computer was used to control the desired force, cycle speed and number of cycles. The resolution of load and displacement were 0.616 N and 0.004 mm, respectively.

A 2 N preload was applied to each of the sutured tendons. The tendons were tested with an initial load of 10 N for 500 cycles. If no evidence of failure was noted after the 500 cycles, the force was increased by 5 N for each additional 500 cycles. This procedure was continued until rupture occurred. The sutured tendons were pulled at a constant distraction rate of 300 mm/min. The values of the fatigue strength was presented as means and standard deviation (SD). Fatigue strength was defined as the product of force applied and the number of cycles until rupture occurred [7].

RESULTS AND DISCUSSION

All of the sutured porcine tendons failed by suture breakage. There were no knot failures. The mean fatigue strength of the tendons with the Triple loop tsuge technique and the Yoshizu #1 technique were almost similar. The tendons with 3 mm asymmetry had significantly greater fatigue strength than the tendons with the Triple loop tsuge technique and the Yoshizu #1 technique ($p < 0.01$) (Figure 1). The Triple loop tsuge technique and the Yoshizu #1 technique are symmetric core sutures. We consider that the reason for the superiority of the asymmetric suture is that, in the cross-section, the six transverse sutures that pass through an asymmetric core suture repair were elliptical, while the cross section that the six transverse sutures pass through in a symmetric core suture repair were round. Therefore, we speculate that the tensile strength per unit area in the asymmetric core suture repair was lower than that in the symmetric core suture repair. We also consider that the asymmetric six-strand core suture repair configuration prevented the concentration of stress in a particular transverse area, and that it provided additional strength.

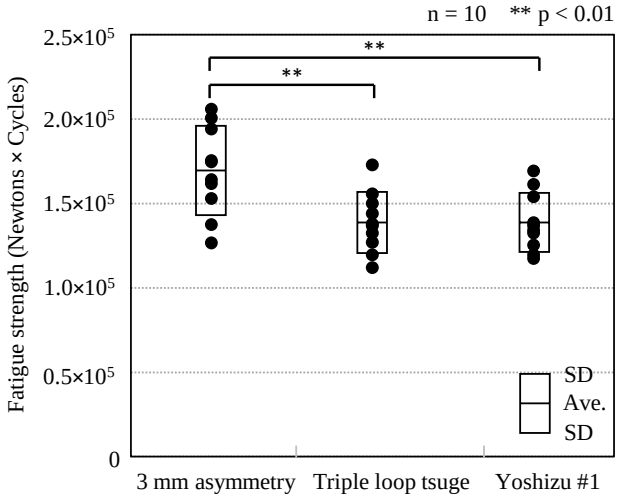

Figure 1: Comparison of the fatigue strength versus suture technique.

CONCLUSIONS

We compared the strength in the 3 mm asymmetry technique and the symmetry methods of Triple loop tsuge technique and Yoshizu #1 technique under cyclic load testing. Our results support that the 3 mm asymmetry is needed to produce beneficial effects.

INTRODUCTION

Tissue engineering is a new approach to solve the problems of lost tissues and organs due to accidents or diseases. Tissue scaffold are the synthetic chitosan bioresorbable polymer matrices that are functional substitutes to replace missing or malfunctioning human tissues and organ like liver skin, cardiac valves, to provide a temporary substrate to which the transplanted cells can adhere. Utilization of computer-aided design technologies in tissue engineering has evolved in the development of a new emerging field of computer-aided tissue engineering (CATE) which helps in fabrication of tissue scaffolds with desired pore size and mechanical strength [1-3]. We are mainly concerned on modeling, fabrication and characterization of porous tissue scaffolds in tissue engineering. We had developed the various porous tissue scaffolds model in CAD software package Pro E wildfire 2.0 with different porosity and perform there stress and strain analysis by providing them the characteristics of chitosan Tensile modulus (E Gpa) is 1.08 ± 0.04, Tensile strength (Mpa) is 37.7 ± 4.5, Elongation at break (%) is 49.5 ± 5.6 The analysis is done for the cartilage tissue growth.

.METHODS

CATE is computer aided imaging technologies comprising of CT scan, MRI, FMRI, CAD/CAM and other modern design and manufacturing technologies. Modelling and simulation of porous scaffold is done with Pro-E and ANSYS respectively, with. Using CATE, the intricate 3-D architecture of porous composite chitosan tissue scaffolds is realized and fabricated scaffold with reproducible accuracy in pore size and strength with the help of solid free-form fabrication (SFF) to assist biologists in studying growth and development of organ like skin, liver, cardiac valve etc. our work is mainly focused on cartilage cells growth on chitosan scaffolds. As shown in (Figure 1). Two types of shapes are taken for the development of Computer Aided Design model that are Cylindrical and Cubical. The designing is done in CAD Pro E wildfire 2.0 package and all files are converted the IGES format. The designing is done to obtain the different porosity according to which the cell can easily be penetrated in to scaffolds easily.

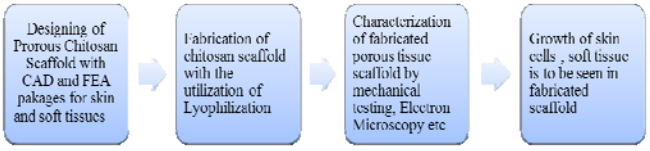

Figure 1 Methodology for fabrication of scaffolds with the help of Computer Aided Tissue Engineering.

RESULTS AND DISCUSSION

When Force F is applied in X direction with speed of deformation is 0.1 mm/sec on a tetrahedral meshed element scaffold surface which is fabricated with the chitosan shown deformation and can withhold the load of cartilage tissue growth also porosity will increase then mechanical strength will also decreases

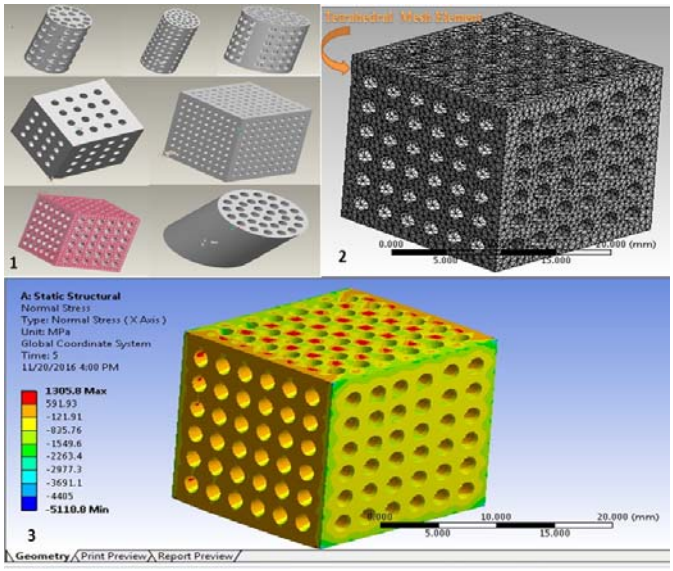

Figure 2: 1. Model of different porous scaffolds, 2. meshed element, 3. stress in X direction.

CONCLUSIONS

In this research article we concluded that CATE is an important tool for predicting the effect of pore size of chitosan composite scaffold for cartilage tissue on its mechanical strength as the pore size of scaffold increases in mechanical strength decreases (Figure 2). CATE will be helpful in the fabrication of Chitosan tissue scaffold for bone and soft tissue like liver, heart, ear, skin and cancer cell growth etc. with exact porosity and mechanical strength

P016 - EVALUATION TECHNOLOGY FOR PLURIPOTENCY OF MOUSE EMBRYONIC STEM CELLS USING UV/OZONE GRADIENT SURFACE MODIFICATION

[1] **Asuka Shinagawa**, [1] Kohei Kasai, [2] Kohei Sasano and [2]Shogo Miyata

INTRODUCTION

Pluripotent stem cells, such as embryonic stem cells (ESCs) and induced pluripotent stem cells (iPSCs), are characterized by their pluripotency and capacity for self-renewal. They are considered to be important as cell sources for regenerative medicine.

These stem cells easily lose the pluripotency by disturbance such as errors in cell culture technique. Therefore, it is important to evaluate the maintenance of pluripotency during expanding culture. The conventional evaluation methods for pluripotency, such as PCR, alkaline phosphatase (AP) staining, immunostaining for pluripotency markers, tend to cause human errors in results. Moreover, the procedure of these methods are complicated. Therefore, a simple and low cost evaluation method of pluripotency is strongly required.

In this study, we focus on UV/ozone surface modification. The UV/ozone treatment modifies the hydrophilic property and molecular structure of polystyrene surface by the oxidization of ozone and oxygen radicals generated by UV irradiation. Previous our studies reported the influence of UV/ozone treatment on adhesion and proliferation of mouse ESCs (mESCs) [1]. From the results, it was considered that the pluripotency of stem cells would relate to cell adhesion on the UV/ozone-modified substrates.

The purpose of this study is to establish an evaluation method of pluripotency using UV/ozone gradient surface modification of polystyrene cell culture substrates, and to evaluate pluripotency based on difference in the distribution of mESC adhesion on the UV/ozone gradient surface-modified substrates.

MATERIALS AND METHODS

UV/ozone surface modification was performed by a cell arrayer (EKBIO-1100, Ebara Jitsugyo Corp.). Polystyrene dishes were irradiated by UV lamps at wavelength of 185 nm and 254 nm. The distance between the substrate and lamps was 40 mm and the treatment was performed at 25 ºC. The polystyrene substrate was covered by a mask to shut out UV ray. The mask was moved by a stepper motor to expose the substrate gradually to UV ray. The stepper motor was controlled by a system design software (LabVIEW, National Instruments). The mask was moved 20 mm for 6 min to modify the surface gradually by UV/ozone treatment.

Mouse ESCs (ES-EB3, Riken BRC, Japan) were cultured on the UV/ozone gradient surface-modified substrates. Two experimental groups were prepared for the experiments. In LIF(+) groups, mESCs were cultured in GMEM, 10%FBS, 1% Antibiotic-Antimycotic, 0.1mM Non Essential Amino Acid, 1mM Sodium pyruvate, 0.1mM 2-mercaptoethanol, 1000U/ml LIF and 10μg/ml Blasticidin S, to maintain their pluripotency. On the other hand, in LIF(-) groups, mESCs were cultured in the culture medium without 1000U/ml LIF and 10μg/ml Blasticidin S to lose their pluripotency.

The viability of mESCs cultured on UV/ozone gradient surface-modified substrate was assessed by calcein-AM staining. The rate of cell adhesion in each image was calculated by measuring the area of cell adhesion using ImageJ software (NIH).

RESULTS AND DISCUSSION

The cells in LIF(+) group, which demonstrated pluripotency mainly, adhered to the area around 3 minutes of UV irradiation (Figure 1a). On the other hand, the cells in LIF(-) group, which lost pluripotency, adhered to the whole area, not depending on the UV irradiation time (Figure 1b). Due to the difference in distribution of mESCs adhesion, it was possible to distinguish between pluripotent cells and non-pluripotent cells. This suggests that the presence or lack of pluripotency could be related to the distribution of adhesive mESCs cultured on UV/ozone gradient surface modification.

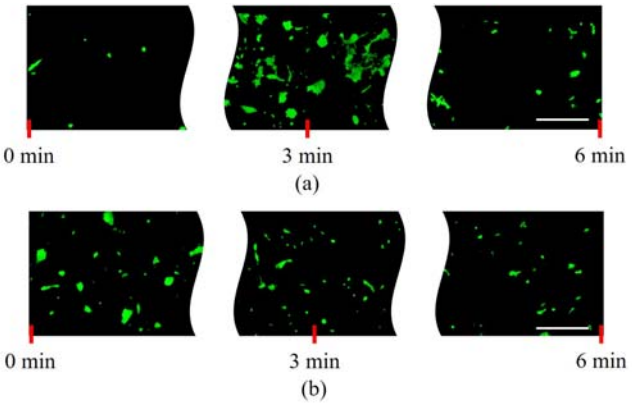

Figure1: Mouse ESCs cultured on the UV/ozone gradient surface-modified substrates. Mouse ESCs cultured in (a) LIF(+) and (b) LIF(-) groups. Scale bar : 400μm.

CONCLUSIONS

The method of UV/ozone gradient surface modification was established. It could be possible to evaluate pluripotency of mouse ESCs by using UV/ozone gradient surface modification.

P017 - RELATIONSHIP BETWEEN MECHANOMYOGRAM AND BODY TREMOR IN A BICEPS BRACHII MUSCLE

[1] **Aya Shirai**, [1]Tota Mizuno, [1]Naoaki Itakura, and [1]Kazuyuki Mito
[1]The University of Electro-Communications

INTRODUCTION

Mechanomyogram (MMG) is an evaluation system of a muscle function objectivity and non-invasively. There are several different recording methods such as a microphone, an accelerometer sensor and piezoelectric contact sensor [1]. In the method using an accelerometer sensor, MMG is evaluated from a vertical accelerated velocity to the muscle fibers. However, a body tremor is caused by a muscle contraction, and MMG is influenced by this. In this study, we discuss the relationships between the body tremor and MMG in a biceps brachii muscle.

METHODS

Four healthy male participated in this study. The subjects were seated in a chair, and performed isometric contractions of the right elbow at the elbow joint angle of 90 degrees. They maintained for seven seconds at 20, 40, 60 and 80 percent of the maximum voluntary contraction (%MVC). MMG were recorded using three-axis accelerometer (size: 10×10×10 mm), and pasted on the right biceps brachii muscle belly. The axes were vertical (MMG), orthogonal, and horizontal to the muscle fibers then. The body tremors were recorded using one axis accelerometer (size: 4×4×13 mm), and pasted on the anterior surface of the right wrist and the right head of the humerus (shoulder). Each axis was vertical to the skin. The signals were recorded at sampling rate of 4 kHz, and the band-pass filters were 1-100 Hz. In the data analysis, the data for 6.144 seconds were extracted, and root mean square (RMS) of the amplitude, the power spectral density, median power frequency (MDF) were calculated.

RESULTS AND DISCUSSION

In RMS of MMG that is the vertical axis of the muscle belly, the values were increased with an increase in the muscle contraction during 20 to 60 %MVC. However, the value of 80 %MVC were decreased or didn't change compared with 60 %MVC. Up to 60 %MVC, the number of motor unit (MU) recruitment and the firing rates of MU are increased with increasing the muscle contraction, and RMS values that is index of the muscle amplitude were increased. The other side, the muscle gets tetanized because of the high firing rates in the high muscle contraction, so the value didn't change in 80 %MVC [2].

In MDF of MMG, the values didn't change or decreased with increasing the muscle contraction. On the other hand, Orizio et al. reported that MDF were increased with increasing the muscle contraction [3]. Figure 1 shows the typical power spectral density of MMG and body tremors (shoulder) at 20 and 80 %MVC. In MMG, the distribution of the power spectral showed multiple peak, and the first peak showed from 10 to 20 Hz at all the muscle contraction. Then, the second peak above 20 Hz shifted high frequency with increasing the muscle contraction. In contrast, the distribution of the body tremor existed from 10 to 20 Hz at all muscle contraction. For this reason, it is suspected that MMG frequencies under 20 Hz are evaluated from the body tremor. To exclude the influence of the body tremor, MMG signals performed the high-pass digital filters of 20 Hz, and MDF recalculated. As the result of this, MDF values were increased with increasing the muscle contraction in MMG. It is considered as the factor that there are slow twitch (ST) fiber and fast twitch (FT) muscle fibers in muscle fibers. The frequency of ST fibers is lower than FT fibers, and they are used in low muscle contractions. On the other hand, FT fibers are used in high muscle contraction. Consequently, MDF were increased.

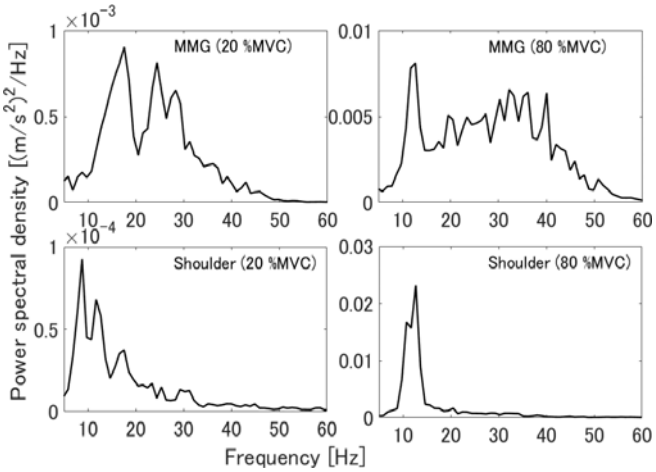

Figure 1: Typical power spectral density of MMG and body tremor (shoulder) at 20 and 80%MVC.

CONCLUSIONS

This aim of this study was to clarify the relationships between the body tremor and MMG in a biceps brachii muscle. As the results, the spectral distribution of the body tremor existed from 10 to 20 Hz, and it wasn't related to the muscle contraction. On the other hand, the first spectral peak of MMG showed from 10 to 20 Hz, and the distribution above 20 Hz was shifted high frequency with increasing the muscle contraction. From the above, it is suspected that MMG frequency under 20 Hz was evaluated from the body tremor, and it is need to be the high-pass digital filters of 20 Hz.

INTRODUCTION

The serious damage and denaturation in hair follicle would lead to alopecia which is difficult to heal with pharmaceutical products. Therefore, hair regeneration technologies are required for the treatment of alopecia. Previous studies reported tissue engineering approaches for the hair regeneration. In those studies, clumps of stem cells and hair tissue-derived cells were cultured *in vitro* and transplanted *in vivo* to regenerate hair tissue. However, these approaches required *in vivo* regeneration process. The purpose of this study is to regenerate hair follicle by only *in vitro* process by simulating *in vivo* cellular organization. Three-layered gel micro-bead culture containing fetal mouse epidermal cells, mouse ES cells and cytokines was established to simulate "native" hair follicle structure (Figure 1a).

METHODS

To simulate the cellular organization of hair follicle, fetal mouse epidermal cells and mouse ES cells were seeded and cultured in gel micro-beads. Moreover, to promote the proliferation and differentiation of cells, basic fibroblast growth factor (FGF-2) was added to the core layer of gel-beads. Firstly, the core layer of gel-beads was formed by alginate gel containing FGF-2 (400 ng/ml) on culture dish. The second layer was formed by collagen gel containing mouse ES cells (3.0×10^6 cells/ml) to cover the core layer. The third layer was formed by collagen gel containing fetal mouse epidermal cells (3.0×10^6 cells/ml) to cover the second layer. The three-layered gel beads were cultured in follicle dermal papilla cell growth medium (PCGM) containing 1% fetal bovine serum (FBS), 0.5% insulin transferrin triiodothyronine mixed solution, 1% bovine pituitary extract and 0.5% Cyproterone acetate during the first 7-day culture, and cultured in GMEM containing 10% FBS and 1% Antibiotic-Antimycotic after the first 7-day culture. The beads were cultured for 49 days.

The cultured gel-beads were fixed by 10% formalin neutral buffer solution, embedded in paraffin, sliced into 3 μm thick sections. The sections were stained with hematoxylin-eosin and immunostained for cytokeratin, smooth muscle actin.

To evaluate the diffusion of FGF-2 in the three-layered gel beads, an experimental model using fluorescence dextran was established. The core layer was formed by alginate gel containing the dextran (M.W.10000) in each well of 96-well plate. The second and third layers were formed by collagen gel without cells to cover the core layer. 400 μl ultrapure water was poured into each well and the fluorescence intensity of dextran in the water was measured. The concentration of dextran diffusing into water was calculated by the measured fluorescence intensity with fluorescence spectrophotometer. In addition, numerical analysis of diffusion phenomenon was performed with the conventional simulation software (COMSOL Multiphysics v5.2).

RESULTS AND DISCUSSION

As shown in Figure 1b, the concentric keratinized circle-like structures were recognized in the cultured beads. These structures resembled the "native" mouse hair follicle and were also positively immunostained with the cytokeratin (Figure 1c). From these results, it was considered that hair follicle-like structures were regenerated in the beads. Moreover, smooth muscle fiber-like structures were recognized in the region surrounding the hair follicle-like structures. These structures were positively immunostained with the smooth muscle actin (Figure 1d). In the "native" hair tissue, smooth muscle fibers called arrector pili muscle exist around the hair follicles. It was supposed that these structures in the cultured beads might be the arrector pili muscle. The results of this study suggest that the hair follicle and the arrector pili muscle could be regenerated using our three-layered gel bead culture.

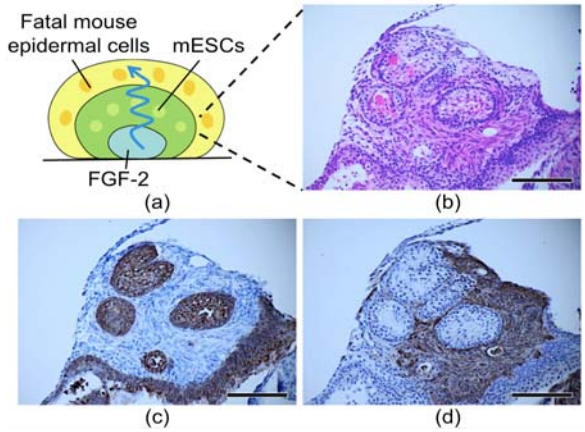

Figure 1: (a) Schematic of three-layered gel micro-beads simulating hair follicle and histological images of gel beads, (b) hematoxylin-eosin, (c) cytokeratin, and (d) smooth muscle actin, scale bars: 100 μm.

Moreover, from the results of experimental and numerical analyses, the fluorescence dextran contained in the beads was released within 2~3 hours. Therefore, it was supposed that the effect of FGF-2 was limited within 2~3 hours.

CONCLUSIONS

It was suggested that the hair follicle-like structures could be regenerated by only *in vitro* process using our three-layered gel bead culture containing mouse ES cells, fetal mouse epidermal cells and FGF-2. Moreover, It was supposed that the effect of FGF-2 in three-layered gel beads was limited within 2~3 hours from the start of culture.

P019 - INFLUENCE OF DAILY SQUATTING EXPOSURE ON KINEMATICS OF DEEP SQUAT

[1] **Bela Agarwal**, [2] Robert van Deursen and [3] Rajani Mullerpatan

INTRODUCTION

Deep squatting is adopted for self care, instrumental activities of daily living, leisure and occupational activity in India and other parts of the world. However western life style is gradually replacing squatting with upright postures. Considering the value of deep squatting as a self-loading functional activity to improve lower limb strength and balance in rehabilitation programs [1], it was of biomechanical interest to explore natural adaptations in lower limb joints and kinematic pattern of squatting among people with varying level of exposure.

Literature reports biomechanical demands of partial squat stress on ACL, PCL and knee adductor moments [2]. However, deep squat has been studied largely as a sport activity and as an occupational risk factor for development of knee osteoarthritis. Although kinematics of deep squat are described [3] effect of habitual squatting on kinematics of lower limb joints among healthy adults with varying squatting exposure requires further exploration.

METHODS

Kinematic analysis of 26 participants aged 30-45 years was performed. Eight non squatters (NS) i.e. people who do not squat for any activity, 10 people who deep squat for activities of daily living (ADLS) - and 8 occupational squatters (OS) - people who sustain deep squatting for occupational activity for long duration of time (>1 hour/day) were recruited. Joint angles were captured with 12 infra-red Bonita cameras and 3 AMTI force plates. A full body plug-in-gait model with 4 additional spherical reflective markers (14mm) on left and right iliac crests and medial femoral condyle were used to capture 3D motion. Five trials of deep squat were captured at 250Hz. Squat was performed with one foot on each force plate and, arms outstretched. Markers obscured during deep squat were filled within Vicon Nexus and joint axis was aligned using an anatomical calibration trial. Data were filtered with a Butterworth filter at a low pass cut off frequency of 6 Hz.

RESULTS AND DISCUSSION

Demographic characteristics of 3 groups are presented in Table 1. Joint angles were similar on both sides (p=0.120-0.988) except hip rotation. Hip internal rotation was greater on left compared to right in NS (p=0.017). Data from right joint angles were considered for further analysis. Greater thoracic flexion was observed in NS compared to ADLS and OS (p=0.04). Non squatters demonstrated greater anterior pelvic tilt whereas ADLS and OS maintained deep squat with a posterior pelvic tilt (p=0.03). All participants performed deep squat using hip flexion-abduction-internal rotation. Non squatters were asymmetrical with respect to hip rotation whereas OS were symmetrical. Highest knee flexion was demonstrated by OS followed by ADLS (p=0.029). Thoracic flexion, pelvic tilt and knee flexion were significantly different in three groups after adjusting BMI as a covariate ($p<0.05$).

Variable	Non Squatters n=8 Mean(SD)	ADL Squatters n=10 Mean(SD)	Occupational Squatters n=8 Mean(SD)	p-value
Age yrs	35.6 (4.6)	34.2 (4.1)	41.8 (7.5)	0.042
Height m	1.58 (0.11)	1.62 (0.12)	1.54 (0.10)	0.331
Mass kg	64.8 (7.7)	57.9 (16.9)	49.0 (13.9)	0.086
BMI kg/m^2	25.9 (3.1)	21.7 (4.2)	20.39 (4.4)	0.025*
Squat exposure min	0.0	15.0(6.2)	106.8(40.3)	0.000*
Thorax ^{0}	33.5 (12.6)	22.3 (7.9)	22.9 (5.4)	0.027*

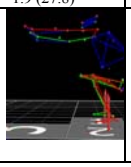
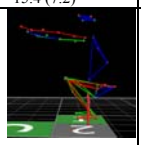
Knee IR ^{0}	35.6 (15.5)	33.6 (18.5)	37.8 (19.0)	0.886
Ankle DF ^{0}	33.3 (31.3)	45.2 (6.2)	41.7 (7.7)	0.389
Foot prog	-1.9 (27.8)	-15.4 (7.2)	-15.9 (8.3)	0.177
				





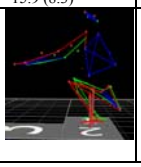


Table 1: Joint angles in NS, ADLS and OS groups at maximum knee flexion during deep squat
* indicates significant difference at $p \leq 0.05$

Ability of habitual squatters to sustain squat with lower trunk flexion and posterior pelvic tilt and higher knee flexion indicates better postural control. Most non-squatters were unable to perform foot flat squat indicating shorter tendon length of ankle plantar flexors. However, differences in ankle dorsi-flexion were non significant. Knee flexion angle was highest in OS indicating soft tissue adaptation to longer duration of squatting exposure.

CONCLUSIONS

Longer exposure to deep squatting activities appears to result in increased knee flexion, erect trunk and posterior pelvis tilt during deep squat. Occupational squatters performed squat primarily in sagittal plane whereas non squatters had greater motion in transverse plane. Further research is required to determine whether this is likely to affect loads encountered by knee joint.

P020 - SUBJECT-SPECIFIC COMPARISON OF GROUND REACTION FORCES IN AN OSTEOGENESIS IMPERFECTA PATIENT WITH A NORMAL SUBJECT

[1] **Subham Badhyal**, [2]Sandip Dhole, [2]Nirmal Raj Gopinathan, [2]Mandeep Singh Dhillon, [1]Anshu Dhar Jayal, [1]Jitendra Prasad

INTRODUCTION

Osteogenesis Imperfecta (OI) is a genetic disorder which causes frequent bone fractures [1-2]. The OI affected bones are fragile and deformed therefore, improvement in existing implants may help in reducing the frequency of fractures [3]. The improvement may be brought in through the knowledge of realistic loading, which can be obtained from gait of an OI patient. This will help the engineers to understand and design optimal implants/prostheses. Ground reaction forces play an important role to calculate various intersegmental forces and moments, which determines the mechanical environment [4]. We hypothesize that mechanical environment in OI may be different from normal. Improved knowledge of this mechanical environment will be helpful for clinicians to understand and plan the course of their action with improved implants/prostheses.

Clinical gait analysis becomes an important tool to assess and understand the various musculoskeletal pathologies which affect the ambulation. The data obtained from gait analysis aids in understanding and differentiating the ambulatory patterns in normal and pathological subjects. This further helps in the surgical management and rehabilitation of the patients. The various temporal and spatial parameters also help to develop new technologies for treatment and rehabilitation.

This study aims to investigate the ground reaction forces of an OI patient. The observed force magnitudes and patterns were compared with the age matched normal subject.

METHODS

Two ambulatory children were included for this study: 1 OI patient (8 years, 19.5 kg, 123 cm, male) and 1 normal subject (9 years, 26 kg, 137 cm, male). The selection of normal subjects was based on the criterion that they had no previous history of any type of musculoskeletal problems. The testing protocol for both patients and normal subjects was approved by the Institutional Ethics Committee at the Post Graduate Institute of Medical Education & Research, Chandigarh. Written informed consent was obtained from all the participants or legal representatives.

3D kinematics was recorded with the help of 18 reflective infrared markers using Helen-Hayes protocol. BTS GAITLAB system (BTS Bioengineering, Italy) with 6 infrared cameras (500 Hz) and 16 force plates (1000 Hz) was used to acquire both kinematics and kinetics data. The subjects walked at a self-selected speed. The ground reaction forces were expressed as percentage body weight (% BW) whereas gait cycle was expressed in percentage gait cycle (% Gait Cycle).

RESULTS AND DISCUSSION

We observed a clear difference in gait cycle of normal subject and OI patient (Figure 1). In particular, the maximum mean vertical ground reaction force for normal subject was 150% BW; whereas, for OI patient it was around 105 % BW. In addition, a double humped profile was imprecise in case of OI patient.

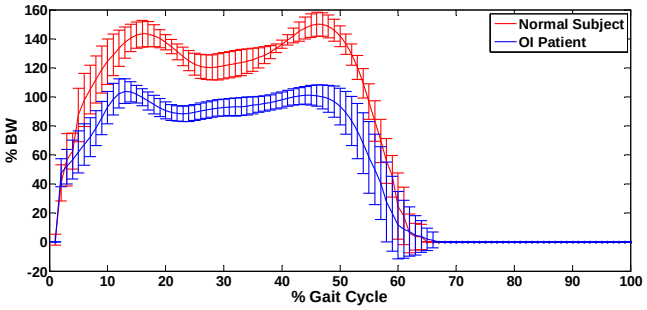

Figure 1: Variation of vertical ground reaction force in a normal subject and an OI patient during a gait cycle.

The observed differences in the gait cycles support the hypothesis that there should be a different biomechanical environment for an OI patient. The difference may be an outcome of the common complications linked with OI patients, such as muscle weakness [5]. Besides this, an inherent cautiousness related to falling down may also be another reason.

The present study is a preliminary work to understand deviations in gait cycle due to Osteogenesis Imperfecta. Based on the findings, it is suggested to recruit more subjects for firm validation of the present study.

CONCLUSIONS

An accurate estimation of ground reaction forces in terms of magnitude and profile during a gait cycle will provide a useful insight to the clinicians and engineers about locomotion in OI patients. This will also help in carrying out subject specific finite element simulations, prosthesis and implant designing for subject specific surgical intervention and rehabilitation.

INTRODUCTION

Historically, patients with knee osteoarthritis (knee OA) has been viewed exclusively as a knee problem. Recent findings have indicated association between decreased function of the foot and knee OA [1]. Researchers have hypothesized that elderly who demonstrate toe grip strength weakness would exhibit increased falling risk [2]. To date, no studies have tested toe grip strength and operational capability in patients with knee OA of pre- and post-operative total knee arthroplasty (TKA). The aim of this study was to investigate whether operational capability are affected by toe grip strength in patients with knee OA of pre- and post- operative TKA.

METHODS

The subjects were 30 knees of 26 patients with knee OA in pre- and post- operative TKA. Their age, height, and body weight (mean ± standard deviation) were 73.6 ± 5.0 years, 154.9±6.8 cm, and 62.7±6.7 kg, respectively. All participants provided their written informed consent before participating. In this study, toe grip strength (TGS), the timed up and go test (TUG), 10m walk test (10m walk), sex, age, weight, height and femoral tibia angle (FTA) were analyzed among all subjects in pre- operative TKA and discharge. All subjects were discharged by 4 weeks after surgery. The sitting positions were used in the measurement of toe grip strength. For the sitting position, the subjects were instructed to sit with the trunk vertical and the hip and knee joints at 90° [3]. In the statistical analysis, multiple regression analysis (stepwise method) was used to investigate whether TGS was independently associated with TUG or 10m walk, using basic characteristic (sex, age, weight, and height, FTA) and TGS as the dependent variables in pre- and post- operative TKA. In addition, the relationship between TUG, 10 m walk and TGS in pre- and post- operative TKA was investigated by Pearson's correlation coefficient. All statistical analyses were performed using SPSS software (version 22.0, SPSS Inc., Chicago, IL), and the significance level was set at 5%.

RESULTS AND DISCUSSION

Pre- operative FTA, TGS, 10 m walk and TUG values ± standard deviation were 182.9 ± 6.7 °, 9.0 ± 4.3 kg, 10.9 ± 2.4 sec, and 11.1 ± 2.4 sec, respectively. Post- operative FTA , TGS, 10 m walk and TUG were 174.7 ± 1.8 °, 8.3 ± 3.8 kg, 13.3 ± 2.6 sec, and 15.5 ± 4.0 sec. As a result of multiple regression analysis, the influence factor of 10 m walk in post-operation, height and TGS were extracted, and the standard partial regression coefficients were -0.36 and -0.48 in order. In TUG, only the TGS was extracted, and the standard partial regression coefficient was -0.57. However, there was no influence factor in 10 m walk and TUG in post- operative TKA. Also, there was no significant correlation between TUG, 10 m walk and TGS before and after the operation.

From the results of this study, it was found that the ability of the knee OA patients to move improves with increasing TGS. Regarding the TGS, Misu et al. [4] reported extended the stride length at walking, and Kabe et al. [5] reported that there are functions for supporting and modifying the center of gravity in loading motion. Since 10 m walk is a walking task in the linear direction, I think that the height, TGS related to the stride length, these was extracted as an influential factor. On the other hand, TUG is a motion that is required to straight walking and sit-to-stand, turning direction. During sit-to-stand and turning direction motion, weight bearing is required. So it was thought that only the TGS was extracted as an influence factor. Influence of TGS was not recognized in the operational capability at discharge. The reason for this is that the toe flex muscle works most strongly at the terminal stance phase of walk, and provides the driving force of the lower limbs. However, it is reported that the quadriceps muscle strength, which is said to be strongly active in the earlier walking phase, is significantly lower than before the operation at 1 month after TKA [6]. Therefore, it was thought that it was due to not being able to obtain the driving force from the toes by not being able to shift to the terminal stance accompanying it.

CONCLUSIONS

In results of this study, it was suggested that the TGS is closely related to improving the ability to move in patients with knee OA. Our data are useful as reference data obtained from knee OA, and may make it facilitate to design treatment practice. For TKA afterwards, I thought that consideration including quadriceps muscle strength and continued prospective study are necessary.

P022 - A BIOMECHANICAL MODEL FOR THE IDIOPATHIC SCOLIOSIS USING SPINAL TRACTION DEVICES

[1,2] **Joao Fialho**

INTRODUCTION

Biomechanical models of the human spine, including idiopathic scoliosis, have been studied by several authors such [1, 2] or even more recently [4, 5].

In [7], the portion of the human spine involved in a scoliotic curve is modeled as a uniform flexible column of homogeneous isotropic material, creating a curved beam column as mechanical analog. This proposed model fail to include the interaction between the human spine and the spinal musculature and other supporting structures. This interaction was later included in [3]. By introducing the flexural rigidity factor (EI), the author shows that the behavior of the articulated human spine could be simulated by a continuous spine model.

In [6] a spine-orthosis model is presented. This two-dimensional model describes the interaction of the spine with the orthotic stabilization device and is viewed in the frontal pane. Throughout the paper the authors establish the mathematical model comprised by a differential equation and assumptions on the boundary conditions. However the mathematical model used cannot explain or cover the forces involved in a spinal traction device, such as the Antalgic Trak Technology. These type of devices have very specific features and characteristics that must be incorporated in the model, or read from the model as a specific output in order for the therapy to be as successful as possible.

To better illustrate this relation, an individual test case is presented, where all the parameters and setup are presented.

In addition a final discussion illustrating the relation between the force applied and the angle on which to perform the pull, is included.

METHODS

The methods used throughout this paper rely on mathematical modeling of the forces involved in spinal direction devices, through the use of differential equations.

To model such devices a differential equation, along with the appropriate boundary conditions are presented. Analytical methods are used to obtain the solution and an analytical approach on the relation between the parameters is also presented.

RESULTS AND DISCUSSION

A spinal traction device is designed to take all the weight and pressure of the spine while simultaneously applying a downward or upward traction force to move the spine into its proper position.

These devices are designed to bring the vertebrae into a proper vertical alignment, in order to eliminate a lateral curvature.

The patient takes a seated position in the chair. The head is fixed, such that no weight pressure is applied on the cervical spine and the waist is strapped. The chair is designed to provide stabilization to the posterior thoracic rib arch, while simultaneously incorporating decompression and traction to the spine.

To the best of our knowledge, no existing model incorporates all of these features. Especially due to the absence of a continuous transverse load, the model presented in [6], cannot be directly applied. Hence, based on these features, the mathematical model for spinal traction devices is presented.

The amount of parameters that can be customized or adjusted tend to vary from device to device, however the main 3 parameters to be discussed in this paper are traction force, angle of traction and location on the cervical spine.

CONCLUSIONS

In this study the mathematical model for spinal traction devices is presented.

By applying the appropriate changes and considerations it was also possible to read from the model the necessary outputs to setup the proper therapy. Therefore this model emphasizes on getting the individual information about force, angle and location on the cervical spine, for each patient, based on its initial scoliotic curve, weight and also pain sensitivity to the force applied.

For each individual case it is possible to establish all of these parameters and also, a relation between angle and force to apply, making the therapy, tailor cut for each patient's needs.

P023 - COMPARISON OF SCAPULAR KINEMATICS IN PARAPLEGIC PERSONS WITH AND WITHOUT SHOULDER PAIN

[1 2] **Michel Bekker**, [1 3] Ursina Arnet, [1]Wiebe de Vries, [4 5]Lucas van der Woude and [2 6]Dirkjan Veeger

INTRODUCTION

Shoulder pain is a major problem for persons with a spinal cord injury (SCI), due to their high dependency on their upper extremities for mobility, participation and performing activities of daily life (ADL). The prevalence of shoulder pain in the general population and in the SCI population are respectively 7-27% [1] and 30-70% [2].

The causes of shoulder pain in SCI are most likely multifactorial and risk factors as gender, lesion characteristics and activity level have been identified [3]. Earlier research has related subacromial impingement syndrome, a common cause of shoulder pain and limited range of motion, to an increased retraction, medial rotation and posterior tilt of the scapula in an able-bodied population [4]. However due to differences in posture, muscle paralysis and demands and use of the upper extremities between an able-bodied and SCI population, these results cannot be used without consideration.

METHODS

Thirty persons with chronic paraplegia (lesion level Th2-L5) who were dependent on their manual wheelchair for ADL participated in the study. Study participants were matched in pairs of pain occurrence by gender and age and assigned to either the pain or no-pain group based on self-reported pain on a VAS (cutoff <4 for no pain).

Prior to the experiment, reflective markers were attached to the upper extremity and thorax and bony landmarks were palpated and digitized in accordance with the ISB guidelines [5]. Kinematic and kinetic data were unilaterally collected on the most painful side during the experiment with an optoelectric camera system and an instrumented wheelchair wheel.

Bony landmarks were reconstructed with respect to their marker cluster during a static pose in the anatomic position, frontal-plane arm elevation and submaximal wheelchair propulsion on a level treadmill. Rotation matrices were constructed and decomposed to Euler angles in accordance with the ISB guidelines [5].

RESULTS AND DISCUSSION

In the anatomic position, the pain group showed 34.8° ± 3.2° of scapular protraction, 7.4° ± 2.8° of scapular medial rotation and 6.4° ± 4.1° of scapular posterior tilt. In the no-pain group, these values were respectively 35.4° ± 4.1°, 6.9° ± 3.9 and 7.2° ± 1.8°. These differences are not significant.

During arm elevation in the frontal plane from 30° to 70° of TH elevation, the pain group showed on average 2.4° less protraction, 0.9° less medial rotation and 1.8° more anterior tilt, however these differences are not significant.

In Figure 1, scapular kinematics of both groups are shown during a time-normalized wheelchair propulsion cycle at 4km/h and 20W. There is a tendency towards increased retraction, medial rotation and posterior tilt, yet no significant difference.

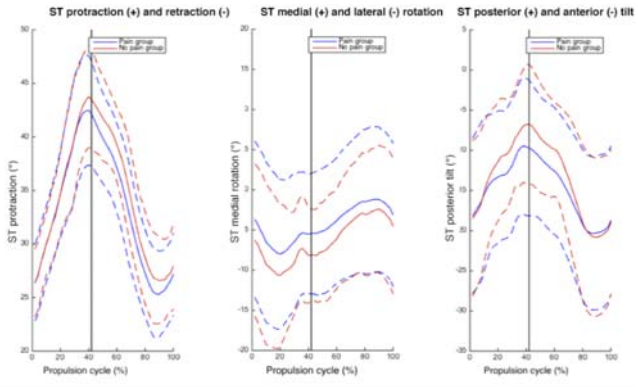

Figure 1: Scapular kinematics in paraplegic persons with and without shoulder pain during time-normalized wheelchair propulsion cycles. The vertical lines indicate the end of the propulsion phase start of the recovery phase.

CONCLUSIONS

Initial findings of scapular kinematics show a trend towards findings in the able bodied population but no statistical significant differences were found between the pain and no-pain group. Further in-depth analysis of the data could help in explaining these findings. However, current results indicate that findings in an able-bodied population do not directly apply to persons with an SCI.

P024 - MECHANICAL ENERGY FLUCTUATIONS DURING GAIT PATIENTS WITH DROP FOOT

[1] **Michalina Błażkiewicz**, [1]Ida Wiszomirska and [1]Andrzej Wit
[1]Józef Piłsudski University of Physical Education in Warsaw, Poland
Corresponding author email: michalinablazkiewicz@gmail.com

INTRODUCTION

Walking is an action with an extremely low energy cost. In a clinical gait analysis, mechanical energy is the gait variable which can validate the energetic state of the disorder of patient's movement. One of the simplest methods of estimating the amount of work performed in human gait is observe the motion of the centre of mass of the body (CoM), which in the sagittal plane is similar to the motion of a pendulum [1]. In case of pathologic gait energy cost can increase and it is related to the increase of external work by the muscles involved in moving the centre of mass of the body. Drop foot is a complex syndrome, with multiple interactions between joints and muscles [2]. The disorder is characterized by a lack of voluntary control of ankle dorsiflexion and subtalar eversion. This altered movement pattern can influence on mechanical energy expenditure. Therefore, the objective of this study was to identify available compensatory strategies in term of mechanical energy in persons with drop foot.

METHODS

The group of patients (DF) consisted of 10 persons with drop foot with a mean age=52.4±23.8years, h=175±2cm, m=73.8±13.4kg. The patients suffered from paresis of the common peroneal nerve caused by lumbar disc hernia. In contrast, the control group (C) consisted of 10 healthy subjects with a mean age of 29.6±9.7 years, h=174.3±8cm, m=74±8.6kg. Kinematic data of gait were collected at 100Hz using eight VICON system cameras. Reflective markers were placed using the full body 'Plug-in-Gait' marker set. The three-dimensional displacements of CoM were determined from VICON system. The linear velocity of CoM was calculated as the derivative of position with respect to time. Normalized potential (E_p) and kinetic (E_k) energy fluctuations were calculated according to equations [1]:

$$E_p = \frac{m \cdot g \cdot CoM(z)}{m \cdot g \cdot h} = \frac{CoM(z)}{h}, \quad E_k = \frac{1}{2} \cdot \left(\frac{v(t)}{\sqrt{gh}} \right)^2;$$

where: m - body mass, $CoM(z)$ – height of CoM, h – body height, v – absolute velocity of CoM and $g = 9.81 ms^{-2}$.

In order to demonstrate the difference between the energy curves for C and DF group, the indicators f_1 and f_2 were used for the analysis of the similarity of the profiles [3]:

$$f_1 = \frac{\sum_{t=1}^{n} |C_t - DF_t|}{\sum_{t=1}^{n} C_t},$$

$$f_2 = 50 \log \left\{ \left[1 + \frac{1}{n} \sum_{t=1}^{n} (C_t - DF_t)^2 \right]^{-\frac{1}{2}} 100 \right\}.$$

It is assumed that the curves are similar, when the value of f_1 is in the range from 0 to 15. While, if f_2 is near 100, the easier is demonstrate the similarity of profiles.

RESULTS AND DISCUSSION

The normalized potential and kinetics energy as a function of gait cycle for control (C) and drop foot (DF) groups is presented in Figure 1.

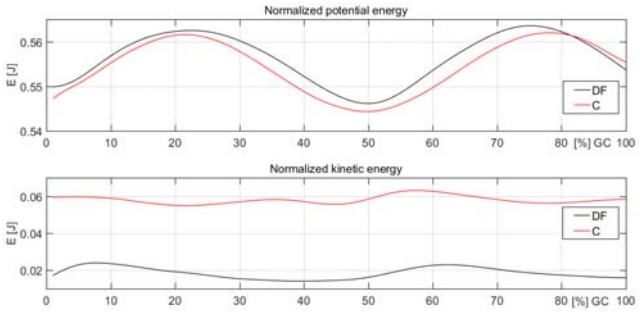

Figure 1: Mean changes in potential and kinetic energy for C- control and DF – drop foot groups.

The normalized potential energy curve oscillates around 0.55J for both of the analyzed groups (Figure 1), but the amplitude of oscillation is significantly smaller for the DF in compare C group (0.02 vs. 0.09). Looking at the kinetic energy curves, the normal values oscillate around 0.05, while around 0.01 in patients group. The amplitude in both groups is the same 0.01J.

For potential and kinetics energy profiles, the average indicator f_1 was 0.01 and 0.68 respectively, while f_2 was 100 and 99.98 respectively, which shows the highest similarity between the curves.

CONCLUSIONS

In this study, based on predictions of the body's CoM trajectory during walking, the components of total mechanical energy in normal and drop foot gait were determined as similar. This method measures the external work performed and no measure is made of the work performed to move the limbs relative to the trunk, and this is the highest limitation of this scheme.

P025 - COMPARISON BETWEEN SITTING AND STANDING POSITIONS ON ANTERIOR REACHING IN CHILDREN WITH CEREBRAL PALSY

[1] **Raquel de Paula Carvalho**, [1] Leiliane Mônika dos Santos Soares, [1]Juliana Maria Savazzi Geraldini Rozane, [1]Helga Tatiana Tucci
[1]Federal University of Sao Paulo
Corresponding author email: raquelpcarvalho@gmail.com

INTRODUCTION

Cerebral palsy (CP) refers to a group of permanent disorders due to a non-progressive disturbance during the process of brain maturation[1]. Studies have shown that children with CP perform a smaller displacement of center of mass during the anterior reach until the limit of stability in standing position compared to their peers of typical developing[2]. Will children with CP have similar performance during the anterior and sitting reaching compared to typically children,i. e., with increased base of support and lower center of mass? The purpose of this study was to compare the anterior reach until the limit of stability in standing and sitting position in CP and typically children.

METHODS

Twenty two children aged from 6 to14 years old participated of this cross-sectional study. Eleven children with spastic CP (levels I and II of the Gross Motor Function Classification System) were included in the group of CP (CPG) and paired by age and gender with eleven children with typical motor development who were included in the control group (CG). A three-dimensional kinematic analysis system (Dvideow©) with two video cameras was used to describe spatial trajectories of 1 marker attached on ulnar styloid process on dominant upper limb. Firstly, the children were placed in standing position in the calibrated volume center in front of a target placed to an approximately distance of 120% of the upper limb size. The child was guided to reach as far as possible toward the target without moving the foot from the floor. During the test the child was instructed to perform a 90º of shoulder bending, elbow and wrist extension in neutral position holding the position for 3 seconds; reach to the maximum range of motion and remaining in this position for 3 seconds; and return to the starting position. Three trials were collected. Secondly, the same protocol was applied to children in sitting position. The kinematic data were filtered and the kinematic variables were calculated using Matlab 7.9©. Total distance of reach (cm), time (s), mean velocity (m/s) and deceleration index (% - the ratio between time after the velocity peak and the total time of movement, multiplied per 100) were calculated. The lower the deceleration index, the greater the time spent to decelerate the movement of the arms.

Repeated measure ANOVA was conducted to compare CG and CPG and standing and sitting positions. Significance level of 5% was adopted. This study was approved by the Federal University of São Paulo Ethics Research Committee (n. 209.295). The parents gave permission for the participation of infants in the study by signing a consent form.

RESULTS AND DISCUSSION

The CPG showed lower distances ($p=0.001$), time ($p<0.01$) and mean velocity ($p=0.002$) and higher deceleration index ($p<0.01$) than CG (Table 1).

Table 1: Mean (standard deviation) of distance, time, mean velocity and deceleration index in standing (Sta) and sitting (Sit) positions for CPG and CG.

		CPG	CG
Distance (cm)	**Sta**	7.77(3.25)	14.70(6.02)
	Sit	12.11(4.47)	21.78(7.56)
Time (s)	**Sta**	2.11(0.37)	2.87(0.48)
	Sit	2.43(0.41)	3.23(0.43)
Mean velocity(m/s)	**Sta**	0.03(0.01)	0.05(0.01)
	Sit	0.05(0.01)	0.07(0.02)
Deceleration index (%)	**Sta**	95.58(5.77)	86.26(6.52)
	Sit	94.88(7.10)	84.03(5.33)

The high variability of muscle activation, which could stem from standards of abnormal muscle recruitment, high levels of co-activation and change in the muscle recruitment order in children with CP [3] justify their poor performance on the task**.** Typical children show greater movement control, once to perform the reach with greater speed proper muscle activation is required, resulting in larger distance achieved and more time required.

Both groups performed higher distances ($p<0.01$), time ($p=0.003$), and mean velocity ($p<0.01$) in sitting than standing position (Table 1). There were no differences for interaction group vs position for all variables and between positions for deceleration index.

In sitting position, the center of mass moves forward inside a greater base of stability and, consequently, the child has a better balance. Otherwise, in standing position the center of mass move near to the limit of stability, showing more instability. To adapt daily activities in sitting positions for children with CP can improve their performance.

CONCLUSIONS

Children with cerebral palsy, even with mild impairment, show lower anterior displacement and movement control during the reach in standing and sitting position, suggesting balance deficit. Sitting was better than standing position during reaching until the limit of stability and it can be an alternative to improve the balance of typically and cerebral palsy children during reaching tasks.

P026 - ANALYSIS OF ELECTROMYOGRAPHIC ACTIVITY OF WRIST MUSCLES BEFORE AND AFTER CONSERVATIVE TREATMENT IN PEOPLE WITH CARPAL TUNNEL SYNDROME: PRELIMINARY RESULTS

[1] **Danielle S Figueiredo**, [2]Marcia A Ciol, [1]Maria C Santos, [1]Letícia A Silva and [1]Helga T Tucci
[1] Federal University of São Paulo
[2] University of Washington
Corresponding author email: dani.figueiredo16@yahoo.com.br

INTRODUCTION

Carpal tunnel syndrome (CTS) is a compressive and symptomatic neuropathy of the median nerve at the level of the carpal tunnel [1]. Factors such as prolonged postures in flexion, extension and ulnar deviation of the wrist can increase intracarpal pressure and compression of the median nerve, contributing to the development of CTS [1,2]. Strategies that reduce the activation of wrist extensor muscles and muscles that perform ulnar deviation may reduce the clinical symptoms of CTS. The purpose of this study was to evaluate whether a 45-day conservative treatment could reduce the electromyographic activity of flexor carpi ulnaris and extensor carpi radialis muscles in people with CTS.

METHODS

Eight volunteers with medical diagnosis of mild/moderate CTS who had an electrodiagnosis exam to confirm the level of STC underwent a treatment of 45 days of nocturnal use of commercial wrist orthosis combined with gliding exercises for tendons and nerve. Data were collected before and after the treatment. The electromyographic activities of the extensor carpi radialis (ECR) and the flexor carpi ulnaris (FCU) were measured on the dominant upper limb of the participant during a task performed with the arm positioned in the scapular plane while the person held a halter weighting 5% of their body weight. The task was performed according the following instructions related to markings on a table: (a) move the hand from point A until reaching the halter ("reach" phase); (b) pick up the halter ("holding" phase) at point B; (c) move halter to point A ("elbow flexion" phase) and (d) then place it at point B ("elbow extension" phase). The phases of the task were delimited by a trigger. The task was performed three times, with intervals of 30 seconds. The myoelectric signals of the ECR [2] and the FCU [3] were sampled with disposable Ag/AgCl bipolar electrode (20mm inter-electrode distance) connected to a sensor (Miotec©, RS, Brazil). The reference electrode was fixed in the sternum. A channel was used as a trigger. The sensors and trigger were connected to an electromyograph with 16-bit A/D converter board, frequency of 2kHz per channel and simultaneous acquisition. The row electromyographic signal were filtered at a frequency bandwidth of 20-500Hz. Subsequently, the electromyographic signal was windowed in each phase of the task and then normalized by the mean value of three maximal voluntary isometric contractions of the respective muscle obtained in muscle function test. Data were compared through descriptive and visual analysis. The study was approved by the Ethics Committee (nº 1.309.591) and submitted to the Brazilian Registry of Clinical Trials (RBR-74rqnz).

RESULTS AND DISCUSSION

The means of electromyographic normalized activity for ECR and FCU muscles decreased in all phases of the task from pre- to post-treatment (Table 1). In disorders such as CTS, the reduction of ECR and FCU activity may contribute to the reduction of CTS symptoms [1,2]. In addition, ECR has a greater demand for activation in manual gripping tasks, even in people without musculoskeletal wrist disorders [4]. For people with CTS, this reduction in muscle activity can improve functional performance on tasks that require wrist stabilization.

CONCLUSIONS

The proposed conservative treatment was effective in reducing the normalized electromyographic activity of the ECR and FCU muscles. Although limited, this preliminary finding suggests that a study with other clinical tools and larger sample size should be performed to assess the possible benefits of the proposed treatment.

INTRODUCTION

In the last congress (ISB 2015, Glasgow), we reported that the motion of subtalar joint was quite simple, i.e., both plantar-dorsi flexion and inversion-eversion were on the same motion axis. This means clinically extreme importance. For example, in the treatment of fractures of tarsal bones, especially of talus, navicular and calcaneus, orthopedic surgeons as well as physical therapists should consider this motion in the operation and in the postoperative rehabilitation, respectively. Unlike other joints, however, it is very difficult to find out this motion axis on body surface. Therefore, the purpose of this study was to find this motion axis from the landmarks of body surface.

METHODS

After informed consent, 20 ankle joints of 10 healthy male volunteers (age, 32.5±5.0 years; height, 170.9±3.2 cm; weight, 65.3±2.1 kg) underwent low-dose CT in 3 positions (Fig.1; 40° plantar flexion, neutral, and 20° dorsiflexion). 3D pose of the fibula relative to the tibia in each position was analyzed by our originally developed software, and was calculated by Euler's method (Fig.2). Then 3D motion of the ankle was visualized in animation. Next, we adopted "tuberosity of navicular" and "groove for fibularis longus" as landmark.

Fig 1: Three ankle positions for low-dose CT (40° plantar flexion, neutral, and 20° dorsiflexion).

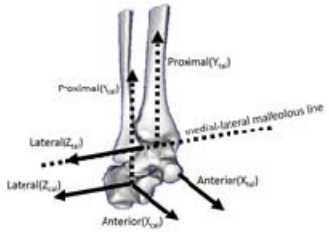

Fig 2: Triaxiality definition of each bone

RESULTS

When ankle was in plantar flexion, calcaneus was rotated mostly varus in all cases. The average rotation angle of calcaneus against talus was 5.1±1.7° in varus, 1.0±0.8° in plantar flexion, and 0.8±0.7° in external rotation. The motion axis between the two bones, talus and calcaneus, were 48.3±5.8° anteriorly declined against tibial long axis and 75.8±6.1° laterally rotated against medial-lateral malleolous line, respectively on average. Interestingly, the angle between this "talocalcaneal" motion axis and the line connecting tuberosity of navicular and groove for fibularis longus was almost vertical; 92.0±2.9° on average (Fig 3).

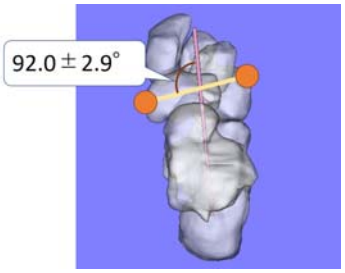

Fig 3: 3D reconstructed CT image of tarsal bones. The angle between "talocalcaneal" motion axis (pink line) and the line connecting tuberosity of navicular and groove for fibularis longus (yellow line) was almost vertical.

DISCUSSION AND CONCLUSIONS

In this study, we clarified that subtalar joint moved mostly varus-valgus along with ankle dorsi-plantar flexion, with the motion axis almost vertical to the line connecting tuberosity of navicular and groove for fibularis longus. Since the inversion muscle attaches to tuberosity of navicular, whereas the eversion muscle passes groove for fibularis longus, it should be physically efficient for "couple of force" that the connecting line of these two bony landmarks vertically intersects talocalcaneal motion axis. Moreover, both two bony landmarks can be observed easily on body surface, which provides useful information for orthopedic surgeons as well as physical therapists.

INTRODUCTION

Clubfoot is generally treated by the Ponseti method [1]. The deformity is reduced step-wise. Each interval starts with the manual manipulation of the deformed foot according to a strict protocol, after which a plaster cast is applied to the foot in (partially) corrected position. After on average five to six steps the corrective treatment is finalized, usually requiring an Achilles tenotomy upon completion, followed by a bracing period of several years.

The rationale behind the length of the time interval (seven days) in clubfoot treatment is unclear. There seems to be no scientific reason for this specific duration, nor have we found studies seeking to establish an optimum interval length. In contrast, in treatment of hand contractures the optimum interval is suggested to be 2 days [2], and for treating joint contractures in cerebral spasticity patients, 1 to 3 days [3].

Thus, the question arises whether the casting treatment duration can be potentially be shortened by reducing the interval length.

METHODS

We performed a systematic review of the literature regarding the influence of the cast change interval on the effectivity of the method. Search terms included “clubfoot”, “Ponseti”, and “duration”. The result is as follows:

- 346 studies were retrieved through Scopus, PubMed, COCHRANE, WebOfKnowledge and Google Scholar
- 38 more studies were retrieved through other sources (e.g. reference lists)
- *359 studies remained after duplicates removed*
- 265 studies were excluded by title and abstract (inappropriate objectives e.g. bracing, review, meta-analysis, case-study, conference abstracts, conversations, no Ponseti treatment
- *94 full-text remained for further investigation*
- 87 studies excluded for reasons of:
    - No control group
    - Modifications to the Ponseti method
    - Non-idiopathic clubfeet
- *7 studies included for review*

The resulting 7 studies were further screened for possible bias (e.g. selection bias, reporting bias).

Among the factors that were extracted are cast change interval, number of casts, treatment duration and failure rate (failure defined as post-casting Pirani score > 1 [4]). Findings were assessed and ranked according to levels of evidence (strong/ moderate/ limiting/ conflicting/ no).

RESULTS AND DISCUSSION

The results are summarized in Table 1

Table 1: Relationship with cast interval

	Nr of studies	Range	Best evidence synthesis
Casting interval	7	7 (N) 2.3 - 5 (S)	
Average #of casts	7	4 - 5.25 (N) 4.15 - 7.4 (S)	Strong evidence no relationship
Duration (days)	6	24 - 57.4 (N) 16 - 23.8 (S)	Strong evidence positive relationship
Failure	5	0 - 16% (N) 0 - 15% (S)	Strong evidence no relationship

N = Normal interval; S = Shortened interval

A shorter casting interval results in a shorter treatment duration, but a lower limit is to be expected. It should be noted that no long term results are presented. Further biomechanical analysis is needed to interpret the results and to give a theoretical basis for an optimal interval.

CONCLUSIONS

We have found strong evidence that, while maintaining the Ponseti-method, the casting interval can be reduced by at least several days. Since this will not have an effect on the required number of casts the treatment duration will be decreased, without deterioration of the short-term clinical outcome.

P029 - DOES HMB PRESERVE STRENGTH AND MUSCLE MASS IN MUSCHLES EXPOSED TO BOTOX TREATMENT

INTRODUCTION

Botulinum toxin type-A (Botox) induces a dose-dependent muscle paralysis by preventing acetylcholine release at the neuromuscular junction[1].
Currently, Botox injections have been applied in clinical setting with the primary aim to relax hyperexcitability of peripheral nerve terminals, such as patients with cerebral palsy or following a stroke[2]. Additionally, Botox can be used in experimental settings to mimic muscle weakness[3] as seen following injury or in elderly. Botox-induced muscle weakness models can also be used to test strategies for preventing or reversing loss of strength and muscle mass.

β-hydroxy-β-methylbutyrate (HMB) is produced in animals and humans from the amino acid Leucine. Studies have shown that HMB supplementation can slow muscle protein breakdown following resistance exercise, and increase gains in lean body mass and strength in a dose-dependent manner. Additionally, HMB has been used as a dietary supplement during rehabilitation following injury, bed rest studies, and hospitalized patients as an attempt to mitigate further loss in strength and muscle mass[4]. Despite its ever growing popularity as a diet supplement to prevent muscle wasting, there have been conflicting results regarding the efficacy of HMB to prevent muscle weakness during muscle atrophy.

The purpose of the present study was to determine the effects of dietary HMB supplementation on strength and muscle mass following a single Botox weakness induced injection into the quadriceps femoris of New Zealand white (NZW) rabbits.

METHODS

Twenty-one, one year old, female NZW rabbits were divided as follow: (1) Control (n=7); (2) Botox (n=7); (3) Botox+HMB (n=7). Control group rabbits received an equal volume of saline injection as the experimental group rabbits which received a single intramuscular Botox injection (3.5U/kg) unilaterally into the quadriceps femoris musculature. Two months following the injections the rabbits were evaluated for primary outcome measurements of muscle mass and knee extensor strength in the injected and contralateral non-injected muscles. Muscle mass was assessed by weighing the muscles and maximal isometric knee extensor strength was measured via femoral nerve stimulation. A two-way ANOVA was used to assess knee extensor strength and muscle mass with the main factors group (control, Botox, and Botox+HMB) and leg (injected and contralateral non-injected) (α=0.05).

RESULTS AND DISCUSSION

There was no difference in muscle strength between saline and contralateral non-injected limbs of the control rabbits. Following Botox injection, there was a significant reduction in strength of the injected limb of the Botox group compared to the control group rabbits. Furthermore, there was no difference in strength between injected Botox and Botox+HMB group rabbits. Lastly, there was a significant loss in muscle strength on the contralateral non-injected limb of Botox rabbits, but Botox+HMB had similar values as control rabbits (Fig. 1).

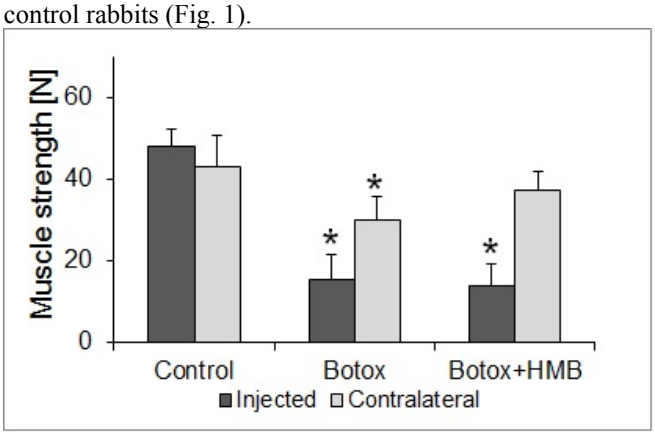

Fig 1 Mean muscle strength (±1 SD) for injected (dark bars) and contralateral non-injected (light bars) for control, Botox, and Botox+HMB group rabbits. (* compared to control).

There was no difference in muscle mass between saline and contralateral non-injected limbs of control group rabbits. Following Botox injection there was a significant loss of muscle mass in muscles of the injected limbs of the Botox and Botox+HMB groups with no difference in muscle mass between these groups (Fig. 2). While there were also no differences in the contralateral musculature as a whole, the contralateral rectus femoris muscle in the Botox+HMB group was significantly larger than in the Botox alone group.

As this study only utilized one dosage of HMB and one dosage of Botox, it is unknown if the other dosages may have yielded different results.

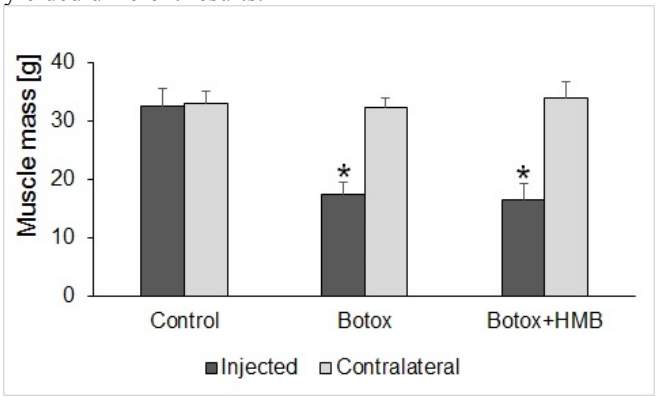

Fig 2 Mean muscle mass (±1 SD) for injected (dark bars) and contralateral non-injected (light bars) for control, Botox, and Botox+HMB group rabbits. (* compared to control).

CONCLUSIONS

HMB supplementation did not prevent loss of muscle strength and mass in the Botox-injected musculature, but prevented strength loss in the contralateral non-injected muscle. These data also indicate that an intact neuromuscular junction may be necessary for the metabolic effects of HMB on muscle.

P030 - EFFECTS OF REGIONALLY SELECTIVE ACTIVATION OF TRUNK MUSCLES ON STERNAL TILTING MOTION IN THE SAGITTAL PLANE DURING DEEP BREATHING

[1] **Riho Higashi**, [1] Yukisato Ishida, [1] Fujiyasu Kakizaki
[1] Graduate School of Health Care Sciences, Bunkyo Gakuin University, Tokyo, Japan
Corresponding author email: riho.higashi@gmail.com

INTRODUCTION

Our group has been finding that there are several patterns of movement of the thorax, which are dependent on regionally selective activation of specific trunk muscles [1, 2]. Patterned movements of the thorax may contribute to not only body balance but also respiration. A patterned movement of the thorax is accompanied with sternal tilting in the sagittal plane. In patients, the pattern of sternal tilting is often biased in a specific way by muscle activation order or muscle contraction direction. We have observed that the tilting movement of the sternum occurs during deep breathing, with implications for the presence of some link between sternal tilting and respiration. The impairment of this link may be a factor of deterioration of posture or motion of the trunk. Determination of the direction of the sternum tilting movement can infer the muscle activity pattern affecting thorax shape change, and may be of help to create physiotherapy programs. Here we investigate effects of regional activities of trunk muscles on the sternum tilting movements during deep breathing to understand the kinetic chain in thorax upon selective activation of abdominal and back muscles.

METHODS

Subjects were 18 healthy adults (24.3 ± 2.2 years old). Using medical stimulator, mild electric stimuli of an intensity rated as 3 on the modified Borg scale were applied two ways: one simultaneously to two regions of the upper back bilaterally and frontal abdominal muscle group (UAP stimulation), and the other to two regions of bilateral upper chest and lower back muscle group (ULP stimulation). Using 3-D motion analysis system (ViconMX), sternal tilting motions were captured with markers on jugular notch (JN), xiphoid process (XP) and spinous processes of 1st (T1) and 7th thoracic vertebra (T7). Sternum tilting angle between sternal axis (JN-XP) and thoracic vertebra axis (T1-T7) was measured during deep breathing with or without electrical stimuli (TEST or CNTL, respectively), and changes in the tilting angle (TEST/CNTL x 100, %) were regarded as the sternum tilting motion. A cycle of inspiration was normalized as 100% in time. Paired *t*-tests were used for statistical analyses.

RESULTS AND DISCUSSION

Deep breathing generally elicited the sternum forward tilting. During inspiration time of 0 to 20%, sternum tilted forwards with similar magnitudes, nearly 100% tilting ratio in CNT and TEST (UAP and ULP stimulations) conditions (Fig. 1). During 20 to 40% time the tilting motion dissociated between TEST conditions of UAP and ULP stimulations. With UAP stimulation, sternum kept forward tilting or the forward tilting was enhanced ($p<0.01$). During ULP stimulations, sternum forward tilting was abated in 20 to 40%, and sternal forward tilting was reduced during 40 to 50% ($p<0.01$) (Fig. 1).

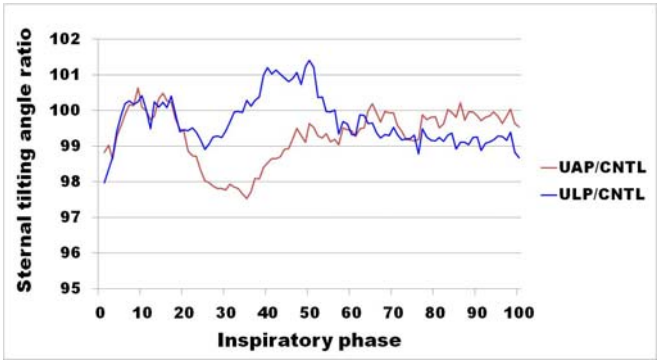

Figure 1: Sequential changes in the ratio of the sternal tilting angle at deep inspiration with UAP, and ULP stimulation. UAP: a pattern of stimulation onto upper back and lower muscle group. ULP: stimulation onto upper chest and lower back muscle group.

The results show that the sternum forward tilting motion occurs over the inspiratory phase. Particularly, the maximum forward tilting is brought about in the early phase of inspiration, and during the latter half phase the forward tilting motion is weakened. Activation of different trunk-regional muscles affects to the forward tilting during inspiration. UAP stimulation augments the tilting in the early phase of inspiration, but ULP stimulation mostly attenuates the tilting motion. Understanding these patterns of thoracic movements during inspiration, specifically grasping the difference among individuals, may be valuable for planning better therapeutic intervention in clinics.

CONCLUSIONS

The results of this study show that the forward tilting motion of the sternum is dependent on the trunk muscle activity pattern associated with inspiration. Intervention-induced alteration in sternal motion suggests the potential to know how to clinically evaluate the thoracic malfunction leading to the better approach to patients.

P031 - CHANGES IN RISK FACTORS FOR LOWER EXTREMITY INJURY TO THE CHANGE OF DIRECTION AFTER SINGLE LEG LANDING

[1]Jong-Bin Kim, [1]Ji-Seon Ryu, [1]Suk-Hoon Yoon, and [1]Sang-Kyoon Park
[1]Korea National Sport University, Seoul, Korea
Corresponding author email: spark@knsu.ac.kr

INTRODUCTION

Frequent injuries occur in lower limb joints when landing on a single leg with sudden change of direction in sporting events [1]. The purpose of this study was to investigate kinematic and kinetic analysis of landing biomechanics when changing directions after single leg landing. Thus, the purpose of this study was to investigate changes in biomechanical injury risk factors of lower extremity joints by changing direction after single leg landing and tried to understand injury mechanism in sporting activities.

METHODS

Eleven male subjects in their 20s (Age: 24.6±1.7 years, Height: 176.6±4.4cm, Weight: 71.3±8.0kg) participated in this study and they were landed with the right foot during the test. 7 infrared cameras (Qualisys, Sweden) with a sampling of 200Hz, one force platform (AMTI, USA) with a sampling of 2000Hz, and one accelerometer (Noraxon, USA) with a sampling of 500Hz were used to collect the data. Accelerometer was attached to the tibia of the subject. As for the experimental procedure, subjects were told about direction to go after landing in advance before performing single leg drop landing by using right foot only from the height of 30 cm and go in the direction that they already know.

This process was conducted ten trials for each direction; 1. Landing (LAD); 2. Right 45° cutting after landing (LRC); 3. Right 45° direct after landing (LRD); 4. Forward step after landing (LFS); 5. Left 45° cutting after landing (LLC).

Event 1 represents initial contact after landing. Event 2 represents peak vertical ground reaction force while event 3 represents maximal flexion angle of the knee after landing. Variables include the range of lower limb joints (ROM), peak joint moment, peak joint power, and peak vertical ground reaction force, and peak vertical acceleration. One-way repeated measure ANOVA with Bonferroni corrections was conducted with a significant level of .05.

RESULTS AND DISCUSSION

The impact of lower limb joints depending on change of direction after landing appeared high at LAD (Landing) and LLC (Left 45° cutting after landing) when the vertical value of ground reaction force was peak value (E2) and there appeared a significant difference ($F=9.36$, $p=.00$). The peak value of vertical acceleration gauge appeared high at LAD and LLC, but there appeared no significant difference. There was no statistically significant difference in joints power, but greater negative power results appeared at LAD and LLC. The range of lower limb joints appeared low in LAD showing 49.77±7.16° in ankle joint and in LLC showing 50.36±5.67° in knee joint in terms of sagittal plane. The difference was significant (for ankle joint $F=3.15$, $p=.02$; for knee joint $F=14.18$, $p=.00$). The peak joint moment appeared high at LLC showing 1.47±.64 Nm/kg in ankle joint and LAD -2.05±1.02 Nm/kg in knee joint. The difference was significant (for ankle joint =4.30, $p=.01$; for knee joint $F=5.70$, $p=.01$). Regarding the injury mechanism of lower limb joints, most injuries of the ankle occur in anterior talofibular ligament (ATFL) when repeated landing with plantar flexed and inverted ankle joint [2] while anterior cruciate ligament (ACL) of the knee injured due to hyperextension and valgus in knee joint and axial rotation of femur and backward translation motion in the tibia when the foot was fixated firmly on the ground [3].

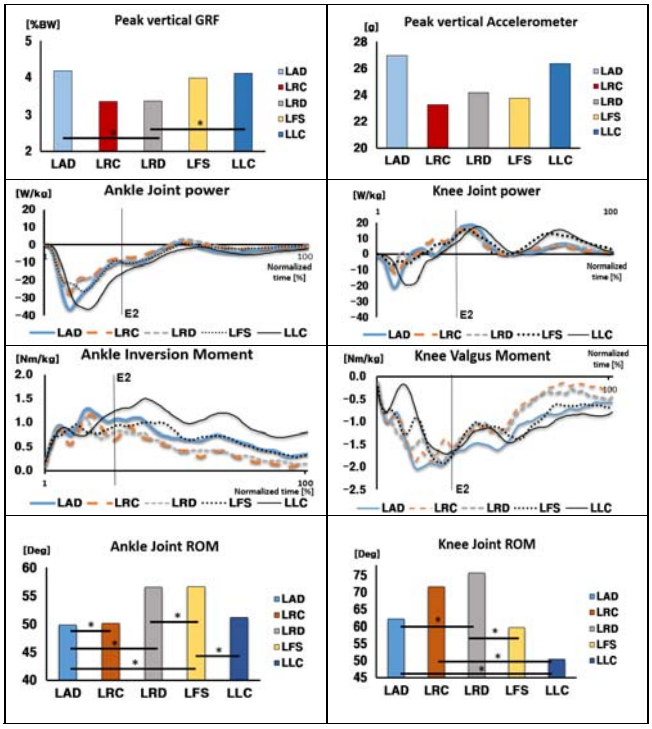

Figure 1: Comparisons between the conditions (*p<.05).

CONCLUSIONS

It was concluded that joint injuries were more likely to occur in the leftward direction (i.e. LLC) than in the rightward direction based on high vertical ground reaction force and impact from the accelerometer. The level of joint injury risk was also high during a single leg landing without changing direction (i.e. LAD) because of high joint moment (i.e. ankle inversion moment, knee valgus moment) compared with other conditions.

P032 - ASYMMETRY OF FOOT PRESSURE FOR TRANSFEMORAL AMPUTEES DURING GAIT IN REAL WORLD

Jeicheong Ryu, Jin-Ho Son, Gyoosuk Kim, Sungjae Kang, **Chang-Yong Ko**
Rehabilitation Engineering Research Institute of KCOMWEL
Corresponding author email: monamicyko@gmail.com

INTRODUCTION

The prosthetic socket is the most important compartment of the prostheses for transfemoral amputees [1]. Nowadays, the ischial containment socket (ICS) and anatomical socket (ANA) have been widely used as prosthetic socket for transfemoral amputee. Some studies have showed differences of biomechanical features between the sockets, such as range of motion of lower limb. Although transfemoral amputees are characterized by gait asymmetry, there have been few studies that investigated gait asymmetry during a gait in real-world environments. The aim of this study was to assess asymmetry of foot plantar pressure in transfemoral amputees during a gait in real-world environment considering prosthetic sockets (ICS)

METHODS

Seven male transfemoral amputees (174.1 ± 3.9 cm, 81.4 ± 11.0 kg, 46.0 ± 8.8-year-old, # of ICS: 3, # of ANA: 4) and 10 male healthy young adults (176.9 ± 2.5 cm, 72.3 ± 7.9 kg, 24.4 ± 2.0-year-old) were enrolled. A wearable foot pressure insole sensor was placed in the shoe (OpenGO science, Moticon, Germany). Participants were asked to walk at self-selected velocity in real-world environments that consisted of level, slope, stair and uneven terrain for a distance of about 1.6 km (Figure 1.). Asymmetry of foot plantar pressure and temporal parameters between sound and amputated feet and between left and right feet were calculated.

RESULTS AND DISCUSSION

Figure. 1 shows the comparison of symmetry of plantar pressure. Transfemoral amputees had higher asymmetry as compared with non-amputee participants. Significantly higher asymmetry in ICS was observed, while no significant differences between non-amputee and ANA was shown. Although there was tendency for greater asymmetry of stance phase in transfemoral amputee, (7.3 % in ICS, 6.4 % in ANA) than non-amputees (3 %), no significant differences were observed among groups ($p > 0.05$). Significantly larger asymmetry of double stance phase was observed in transfemoral amputees ($p < 0.05$). However, there were no differences between ICS and ANA ($p > 0.05$). These results indicate that asymmetry in transfemoral amputees during walking in real-world environments is larger than for non-amputees. Furthermore, the tranfemoral socket types appear to affect the magnitude of asymmetry.

In this study, only a few trasnfemoral amputees were involved which will have impacted the statistical power. Further studies with more subjects are needed.

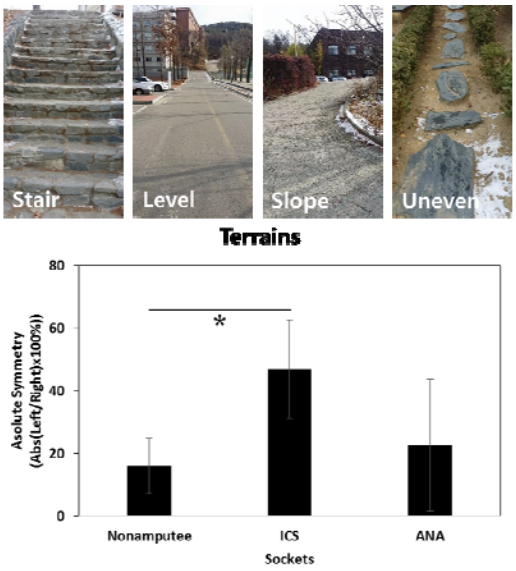

Figure 1: Terrains on real environment and comparison of symmetry of plantar pressure, *: $p < 0.05$.

CONCLUSIONS

In this study, the asymmetry between sound and amputated limb in transfemoral amputees during walking in real-world environments was evaluated. We confirmed a higher asymmetry in transfemoral amputees. Furthermore, socket type affected the asymmetry.

P033 - LOAD-SHARING OF THE LOWER LIMB JOINTS DURING WALKING IN PATIENTS WITH TOTAL HIP ARTHROPLSTY

[1] **Chien-Chung Kuo**, [2] Shih-Wun Hong, [2,3] Tung-Wu Lu and [1] Horng-Chaung Hsu

INTRODUCTION

Proper combinations of joint moments are necessary to prevent collapse of the lower limbs while balancing and supporting the body [1]. In the patients who received total hip arthroplasty (THA), the hip muscles affected may compromise the sharing of the loads and thus the whole body balance during walking. Identification of gait deviations and compensations in patients with total hip arthroplasty (THA) is important for the management of rehabilitation programs and risks of falls. The current study aimed to quantify the control of body support in patients with THA in terms of the total support moment (Ms) and contributions of individual joint moments to Ms during walking.

METHODS

Seven patients (5 females and 2 males; age: 55.8±12.5 years, height: 166.0±5.2 cm, mass: 70.5±18.3 kg) who underwent unilateral THA via an anterolateral approach for at least six months at the time of the gait experiment, and seven age- and gender-matched healthy controls (5 females and 2 males; Age: 50.5±11.2 years, height: 168.2±6.3 cm, mass: 68.3±14.1 kg) were recruited. Twenty-eight infrared retro-reflected markers were placed on specific landmarks of the pelvis-leg apparatus to track the motion of the segments during walking. Kinematic and kinetic data were measured using an 8-camera motion capture system (Vicon, Oxford Metrics, U.K.) and two force plates (AMTI, U.S.A.). The total support moment (Ms) of a limb was calculated as the sum of the net extensor moments at the hip, knee and ankle during stance phase. The contributions of the hip, knee and ankle to the first and second peaks of Ms (i.e., Ms1 and Ms2) were calculated by dividing the joint moment value by the corresponding peak values of Ms. An independent t-test was performed to compare the calculated variables between groups at a significance level set at α=0.05. All statistical analyses were performed using SAS version 9.1.3 (SAS Institute Inc., NC, USA).

RESULTS AND DISCUSSION

There were no significant differences between the THA group and normal controls in Ms1 and Ms2 (Table 1). Compared to the healthy controls, significantly increased hip and ankle contributions but decreased knee contributions to Ms1 were found in the THA group (Figure 1A). In addition, increased hip contributions but decreased ankle contributions to Ms2 were also found in the THA group (Figure 1B).

Similar Ms1 and Ms2 between the groups indicate that the lower limbs in the THA group were able to provide normal body supports during walking. However, this was achieved via an altered contributions of the hip, knee and ankle. Hip and knee extensors played an important role in supporting the body when the Ms1 occurred during early stance of walking. In the THA group, greater hip and ankle contributions but lesser knee contributions for the Ms1 indicates that the function of hip extensors were not affected in the THA group but compensatory mechanisms of the knee and ankle were found. For Ms2, hip flexors and ankle plantarflexors played an important role in supporting the body during late stance. Decreased hip flexor (i.e., greater hip extensor contributions) and ankle plantarflexor moments were found in the patients with THA, suggesting that the function of hip flexors and ankle plantarflexor muscles were affected by THA surgery during late stance. Hip muscles affected by the THA may compromise the sharing of load at the hip and thus the whole body balance. Further postoperative rehabilitation is suggested for the patients following THA. Further studies on the effects of different surgical approaches on the support moments will be needed for improving treatment plans.

Table 1: Means (SD) of the first and second peaks of the total support moment (Ms1 and Ms2) in the patients with total hip arthroplasty (THA) and healthy controls

Variables	THA	Control	P value
Ms1(% BW*LL)	7.39 (3.75)	6.53 (3.17)	0.64
Ms2 (% BW*LL)	8.90 (2.51)	8.43 (2.02)	0.91

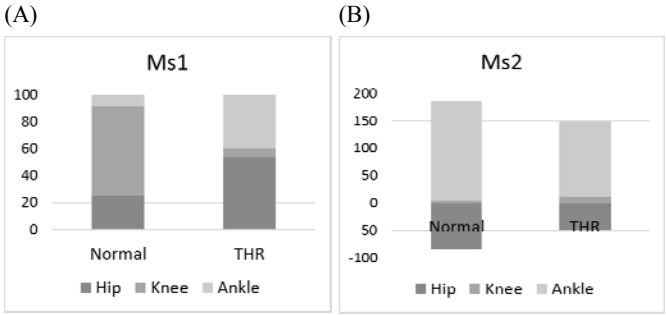

Figure 1: Individual joint contributions to the first (A) and second (B) peaks of total support moment (%) during walking in the normal controls and the patients with THR

CONCLUSIONS

Patients with total hip arthroplasty (THA) maintained normal lower limb supports to prevent collapse during walking via altered joint contributions, primarily to compensate for the hip muscles affected during surgery.

INTRODUCTION

Patients with Parkinson's disease (PD) would decrease the motor activity and increase the risk of falls [1]. Total support moments (Ms) have been used to quantify the changes of the combination of the joint moments as they vary during walking in patients with mild PD, indicating the impaired neuromuscular control of lower limb joints [2]. The contributions of individual joints to the total support moment (CMs) have been used to assess the mechanical strategy in healthy subjects, and in various patient populations [2]. However, no study has characterized quantitatively the effect of PD on the supportive synergies of the lower limb joints to produce necessary support for the stability and advancement of the whole body in patients with PD in terms of the Ms and CMs. The current study aimed to bridge the gap by quantifying the effects of mild PD on the inter-joint load-sharing during level walking, in terms of the Ms and CMs.

METHODS

Fifteen patients with mild PD (age: 61.3±6.4yrs, height: 159.9±9.2cm, weight: 61.3±6.4kg) and fifteen age and BMI-matched healthy adults (age: 61.8±6.4yrs, height: 158.5±4.8cm, weight: 59.0±13.9kg) participated in this study with written informed consent. Thirty-five skin markers were used to track the motions of the body segments by a motion capture system (Vicon 512, UK) while the ground reaction forces (GRF) were measured using two force plates (AMTI, USA). For the PD group, the stance phase of the affected limb was denoted as PD-A and that of the unaffected limb as PD-U. The total support moment (Ms) showed a characteristic pattern with two peak values (i.e., Ms1 and Ms2). The contributions of the hip, knee and ankle moments to Ms1 and Ms2 (i.e., CMs1 and CMs2) were calculated as percentages of the corresponding peak values of the Ms. Comparisons between groups for all the calculated variables were tested using mix-model analysis of variance (ANOVA) while those for PD-A vs. PD-U were tested using two-way repeated measures analysis of variance (ANOVA). A significance level of 0.05 was set for all statistical tests. All statistical analysis was performed using SPSS (version 11.0, SPSS Inc., USA).

RESULTS AND DISCUSSION

The Ms1 of PD-A were reduced significantly when compared to PD-U (p=0.03) and normal control (p=0.04). Both PD-A (p=0.02) and PD-U (p=0.01) showed significantly reduced Ms2 when compared with normal control. The Ms2 was significantly smaller in PD-A than PD-U (p=0.02).

The PD-A showed significantly increased contributions of knee (p=0.03) and ankle (p=0.04) to the Ms1 but reduced contributions of the hip (p=0.01) when compared to the PD-U and normal controls (Fig 1a). The PD-U group reduced significantly the contributions of knee to the Ms1 but increased the contributions from the hip and ankle when compared to the normal controls. In Ms2 (Fig 1b), the contributions of knee and hip of the PD-A (p=0.02) and PD-U (p=0.03) group were increased significantly when compared with the normal controls. The contributions of the hip (p=0.02) and ankle (p=0.01) of the PD-U were increased significantly when compared with the PD-A.

These results suggest that patients with mild PD adopted a hip strategy to support the body weight while standing with the unaffected limb during loading response. Therefore, the hip joint of the unaffected limb required more effort to maintain balance. The affected limb in PD increased the ratios but reduced moments at the distal joints. Impaired neurological pathway seemed to influence the performance of the patients with PD during level walking, and the necessary stability was provided mainly by the unaffected limb while the contralateral limb was affected by PD disease and unable to maintain sufficient stability.

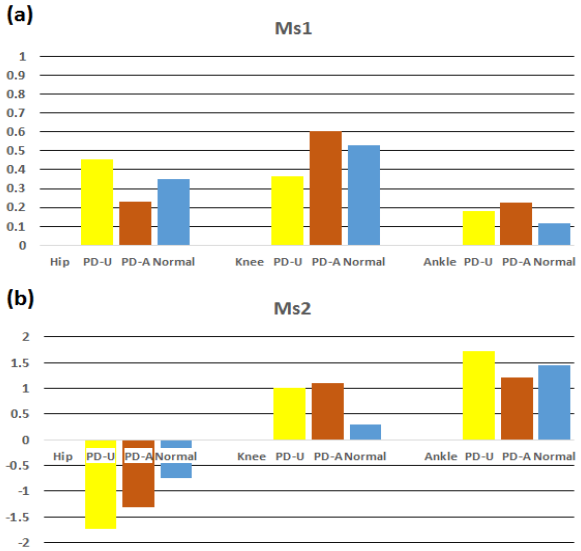

Figure 1: The contributions of the joints to the Ms1 and Ms2. (yellow bar: CMs of PD-U; brown bar: CMs of PD-A; blue bar: CMs of normal controls)

CONCLUSIONS

Patients with mild PD appeared to increase the effort produced at the hip joint of the unaffected limb to maintain body balance, especially following loading response of the affected limb. The necessary stability was provided mainly by the unaffected limb while the contralateral limb was affected by PD disease and unable to maintain sufficient stability. Therefore, proprioception training and muscle strengthening of the unaffected limb are necessary to maintain balance.

P035 - COMPARISIONS OF FIXATION FORCE OF THE PEDICLE AND THE CORTICAL VERTEBRAL SCREW UNDER LAMINECTOMY

[1]**Dai-Soon Kwak**, [1]Ho-Jung Cho, [1]Soyeon Kim and [2]Jae-Hyuk Shin

INTRODUCTION

Cortical Screw construct has been developed as an alternative to traditional pedicle screw system [1]. Diverse experimental results support biomechanical competency of the cortical screw construct in comparison with the pedicle screw system [2]. The biomechanical strength after total laminectomy however, has not been proved for the cortical screw system which is inserted in divergent trajectory. In this study, we compared biomechanical strength between the cortical screw and pedicle screw, from post-laminectomy lumbar vertebrae, in respect to pull out strength and toggle strength.

METHODS

120 pedicles from 60 lumbar vertebrae were included from 12 cadavers (male: 8, female: 4). The mean age of the cadavers was 73.4 ± 6.2 (range: 62 ~ 82). L spine CT scan was done from L1 through the sacrum in order to assess presence of deformity, previous surgical history, and the bone quality. 70 pedicles were included in the pull-out test, and the other 50 pedicles were included in the toggle test. Through conventional posterior midline approach, we exposed the vertebrae, inserted the pedicle screws into ipsilateral side, and the cortical screws to the contralateral side of each vertebra. Total laminectomy was done after insertion of the bilateral screws. The vertebra was harvested, cleared of the soft tissue, and prepared into the tester-jig, for measurement of the screw fixation force. Vertical pullout strength testing and toggle strength testing were performed to compare the fixation strengths from both sides. The load was applied and measured using the universal test machine (5567, Instron, MA), to measure the ultimate load. The ultimate load was compared between the pedicle screw group and the cortical screw group in the pullout test, and in toggle test, respectively.

RESULTS AND DISCUSSION

The pull out fixation force was superior in the cortical screws (n = 26: 748.83 ± 349.35 N) group, in comparison with the pedicle screws (n = 31: 682.25 ± 290.81 N) group. The toggle strength was superior in the pedicle screws (n = 23: 589.34 ± 285.82 N) group, in comparison with the cortical screw (n = 17: 553.51 ± 338.00 N) group. After the laminectomy, we selected vertebrae presenting intact bilateral screw insertion for the ultimate load analysis. In the pull out test, 25 vertebrae were selected for the analysis. The mean value was superior in the cortical screw group (718.92 ± 340.76 N), in comparison with the pedicle screw group (625.78 ± 287.10 N). The ultimate load was higher in cortical screws in 9 vertebrae, and in pedicle screws in 16 vertebrae. The group comparison showed no significant difference (p = 0.183). In the toggle test, 18 vertebrae were selected for the ultimate load analysis. The mean value was superior in the pedicle screw group (613.17 ± 311.70 N), in comparison with the cortical screw group (544.83 ± 329.97 N). The ultimate load was higher in pedicle screws in all (n = 18) vertebrae. The group comparison showed no significant difference (p = 0.145). Table 1 shows mean values of the sample tests from both pull out test, and toggle tests.

Table 1 comparison of fixation force: pedicle screw vs. cortical screw

Screw	Pullout test [N]			
	n	Mean	S.D.	P†
Pedicle	25	625.78	287.10	0.183
Cortical	25	718.92	340.76	
	Toggle test [N]			
Pedicle	18	613.17	311.70	0.145
Cortical	18	544.83	329.97	

†Wilcoxon signed rank test

CONCLUSIONS

In lumbar spine segmental total laminectomy, Cortical screw fixation in cortical bone trajectory provided equivalent pull out and toggle strength in comparison to pedicle screw system. This data supports justification of applying the cortical screw construct in multi-segment lumbar fusion, which includes intercalate vertebrae with total laminectomy.

P036 - BIOMECHANICAL EVALUATIONS OF THE NEW FEMORAL FIXATION DEVICE FOR ANTERIOR CRUCIATE LIGAMENT RECONSTRUCTION USING THE OUTSIDE-IN TECHNIQUE

[1]**Dai-Soon Kwak**, [1]Ho-Jung Cho, [1]Soyeon Kim, [2]Tae Soo Bae and [3]Tae-Kyun Kim
[1]The Catholic University of Korea
[2]Jungwon University
[3]Seoul National University Bundang Hospital

INTRODUCTION

The surgical outcome of anterior cruciate ligament (ACL) reconstruction seems dependent on tunnel position, choice of graft, and fixation device [1, 2]. Of these, the fixation device remains the source of greatest concern regarding ACL reconstruction, despite the availability of several devices. A new device, the T-anchor, was developed for ACL reconstruction and is implanted via the outside-in technique using hamstring grafts. The purpose of the present study was to compare the newer T-anchor with the established EndoButton Direct with respect to fixation site profile, graft-length adjustability, and graft-holding performance based on elongation after cyclic loading, load to failure, ultimate load, and mode of failure.

METHODS

15 matched pairs of knees were included (fresh cadavers). If one of the knees was assigned to the EndoButton Direct, the other knee was assigned to the T-anchor. Thus, there were 15 knees each in the EndoButton Direct and T-anchor groups. All specimens were kept moist with physiological saline solution throughout the experiment. The specimens were then measured to find out the length of the graft-device complex. After the measurement of the above-mentioned parameters, the medial femoral condyle of the specimen was resected so that it would not interfere with the graft that was exiting from the medial side of the lateral condyle. The femoral specimen was fixed with polymethyl methacrylate (PMMA) and was subsequently fixed to the base of the universal test machine (5567, Instron, MA). The other free end of the graft was held with a pneumatic grip at a distance of 30 mm from the exit of the femoral tunnel to mimic the intraarticular length of the ACL. Cyclic testing was performed by sinusoidal loading from 10 to 150 N at a frequency of 1 Hz for 1,000 cycles. Cyclic elongation was measured as the difference between the position of the grip in 10 N tensioning before and after the 1000 cyclic load. After a 20-minute recovery time, load to failure and ultimate load were measured at 200 mm/min loading till the complete failure of the specimen. After detachment from the frame, the specimens were visually inspected for mode of failure and the causes were classified into failure caused by the device and failure caused by the specimen.

RESULTS AND DISCUSSION

The fixation site profile was lower in the T-anchor group than in the EndoButton Direct group (2.3±0.4 mm vs. 4.7±1.0 mm, P<0.001). The length of the graft-device complex of the T-anchor specimens was longer than that of the EndoButton Direct specimens (125.0±8.9 mm vs. 115.0±8.7 mm, P<0.001). The mean cyclic elongation was lower for the T-anchor group when compared with the EndoButton Direct group (2.4±0.6 mm vs. 3.9±2.6 mm, P=0.015). There was no difference in ultimate load between the T-anchor (872.0 ± 216.8 N) and EndoButton Direct (826.0 ± 164.7 N) (P = 0.530). Regarding load to failure, there were no difference between T-anchor (808.0 ± 218.3 N) and EndoButton Direct (751.0 ± 231.2 N) (P = 0.609). However, the two groups differed in mode of failure during the load-to-failure test. In the T-anchor group, all the failures were due to the specimen (6 device migrations into bone, 9 clamp site ruptures); however, of the 15 knees in the EndoButton Direct group, 8 failures were caused by the device (5 device failures and 3 graft cut-throughs) and 7 failures were caused by the specimen (5 device migrations into bone, 2 clamp site ruptures) (P = 0.013). Midsubstance rupture was not observed in both groups.

Table 1: Comparison of fixation site profile, graft-length adjustability, and biomechanical properties between the two implants

Parameters	**T-anchor**	**EndoButton Direct**	***P*-value**
Profile (mm)	2.3 ± 0.4	4.7 ± 1.0	<0.001
Graft length	125.0 ± 8.9	115.0 ± 8.7	<0.001
Elongation after cyclic loading (mm)	2.4 ± 0.6	3.9 ± 2.6	0.015
Failure load (N)	808.0 ± 218.3	751.0 ± 231.2	0.609
Ultimate failure load (N)	872.0 ± 216.8	826.0 ± 164.7	0.530

CONCLUSIONS

In this cadaveric study, the new device, T-anchor, performed better than the EndoButton Direct with respect to the above-mentioned study parameters except for ultimate load and load to failure. Our results suggest that the T-anchor may be a suitable alternative for ACL reconstruction with hamstring grafts using the outside-in technique.

P037 - INTER-TESTER RELIABILITY OF LOWER EXTREMITY RATE OF FORCE DEVELOPMENT BY A HANDHELD DYNAMOMETER

[1] **Hanne Bloch Lauridsen**, [2]Lars L. Andersen, [3,4]Mikkel B. Clausen, [1]Jesper Bencke, [3]Kristian Thorborg, [3,4]Laura Krohn, [3]Lasse Ishøi and [4]Mette K. Zebis

INTRODUCTION

The ability to rapidly develop force is considered one of the most important strength parameters in functional performance and dynamic movements. Rate of Force Development (RFD) can be derived from a standardized maximal isometric contraction obtained by an isokinetic dynamometer. However, isokinetic dynamometry is costly and may have limited accessibility in clinical practice, thus why RFD, obtained by handheld dynamometry (HHD), could be a promising tool in the clinical setting. Previously, RFD measurements of knee flexion and extension, using HHD with no external bracing, have revealed unsatisfactory inter-tester reliability, therefore more fixated and less assessor dependent tests are needed[1]. The purpose of this study was to examine the inter-tester reliability concerning maximal voluntary contraction (MVC) and RFD strength assessments of knee extension and knee flexion using HHD with external bracing.

METHODS

30 healthy individuals (16 women), aged 23.8 ± 4.1 years were included. Two physiotherapist students (one female, one male) performed the measurements. The tester order and strength test order were randomized. Knee extensor strength was measured while subjects were lying supine with a foam roller (diameter 15 cm) placed below the knee to ensure a slight knee flexion. Knee flexor strength was measured while subjects were lying in prone position. A fist was placed below the centre of the tibia to ensure a slight knee flexion. In both positions the pelvis was fixated to the examination bed by a non-elastic strap. The HHD (Hoggan, MicroFET2) was placed on top of the lower leg in a distance corresponding to the width of two fingers above the medial malleolus. A non-elastic strap was attached from the HHD to either the examination bed (extension) or a sucker attached to the floor (flexion) to ensure that no knee movements would occur during testing. Each subject performed three knee extensions and three knee flexions. Subjects were instructed to perform all contractions as fast and forceful as possible. Peak MVC (N) and RFD (N/s) were measured for both knee flexion and extension. RFD was calculated for the first 100 (RFD100) and 200ms (RFD200) of the knee flexion/extension. Intraclass correlation coefficients (ICC) were used to quantify reliability. The dependent variables were tested for normal distribution (Shapiro-Wilk), and parametric tests were applied. Paired *t*-tests revealed that no systematic between-tester bias was present. To assess relative reliability, intraclass correlation coefficients (2.1, two-way random model, consistency definition) with the corresponding 95% confidence intervals (95% CI) were calculated.

RESULTS AND DISCUSSION

For RFD measurements of both knee flexion and extension, the highest ICC values were found for RFD 200 ms (0.927 and 0.859, respectively). ICC's for RFD100 were 0.888 and 0.830 for knee flexion and extension, respectively. MVC's showed ICC's of 0.910 and 0.929 for knee flexion and extension, respectively. The results imply that reliability of both RFD and MVC obtained by a HHD is high.

	Knee Flexion		**Knee Extension**	
	ICC	95% CI	ICC	95% CI
MVC	0.910	0.820-0.956	0.929	0.857-0.966
RFD100	0.888	0.779-0.943	0.830	0.673-0.915
RFD200	0.927	0.853-0.965	0.859	0.725-0.930

Table 1: ICC and 95% CI for knee flexion and extension.

CONCLUSIONS

Inter-tester reliability was high and suggests that a HHD can be used for assessing knee extension and knee flexion RFD. Future studies should investigate the validity of RFD obtained with HHD with external bracing against a gold standard i.e. an isokinetic dynamometer.

P038 - COMPARISONS OF SCAPULAR KINEMATICS BETWEEN CONSERVATIVE AND SURGICAL TREATMENTS FOR MID-THIRD CLAVICLE FRACTURE

[1] **Hsuan-Yu Lu**, [1] Chia-Chen Hu, [1] Yi-Feng Ko, [1] Jia-Da Li, [1,2] Li-Wei Hung and [1] Tung-Wu Lu
[1] Institute of Biomedical Engineering, National Taiwan University

INTRODUCTION

Clavicle fractures have a prevalence from 2.6 % to 10 % in all kinds of fractures in the adult population [1]. According to the anatomical site of the fractures, Allman has classified the injury into three types [2]. Among the clavicle fractures, middle-third clavicle fracture is one of the most frequent in published reports [3]. Generally, clavicle fractures have been managed by either conservative or surgical treatment. However, few studies have documented their efficacy for mid-third clavicle fracture. The purpose of the study aimed to compare between conservative and surgical treatments in terms of the functional kinematics of the shoulder complex, mainly the scapula, after recovering from mid-third clavicle fractures.

METHODS

Eighteen patients with mid-third clavicle fractures participated in the current study with written informed consent as approved by the IRB. Among these subjects, nine underwent surgical treatment (age: 31.4 ± 11 y/o; height:166 ± 6 cm; mass:66.4 ± 15 kg); nine underwent conservative treatment (age: 28.3±7 y/o; height: 170.9±4 cm; mass: 71.5±11 kg). Another twelve healthy young adults with no previous trauma over both shoulders were recruited as control group (age: 23.3±2 y/o; height: 173.8±5 cm; mass: 72.4±7 kg).

Each subject wore four infrared retroreflective markers on the upper arm and four on the trunk while performing arm elevations of 0°, 30°, 60°, 90°, 120°, 150°, and 180° in each of the sagittal, scapular and frontal plane. A scapular locator with 3 markers was used to measure the pose of the scapula via locating the root of spine, acromion angle and inferior angle using a motion capture system (Vicon, OMG, UK). From the measured kinematic data, the angular positions of the scapulothoracic joint was calculated following a y-x-z rotation sequence, corresponding to protraction/retraction, medial/lateral rotation, and anterior/posterior tilt.

All the kinematic assessments were performed after fractured union for both sides. A mixed model repeated measures two-way ANOVA was used to compare the three scapulothoracic angles between the three groups with a significance level set at 0.05.

RESULTS AND DISCUSSION

Similar scapulothoracic kinematics between conservative and surgical treatment were found in most kinematic components for all test positions, but both patient groups showed significant differences from the control in some kinematic components (Figure 1). The surgical group showed reduced anterior/posterior tilt compared to the conservative group, especially at low elevation angles (i.e. less than 90°). Compared to the control (10.07±7.7°), the conservative group (2.83±3.6°) and surgical group (2.85±9.4°) showed significantly reduced anterior/posterior tilt of scapula ($p<0.05$) at 180° elevation angle in all three planes of elevation (Figure 1).

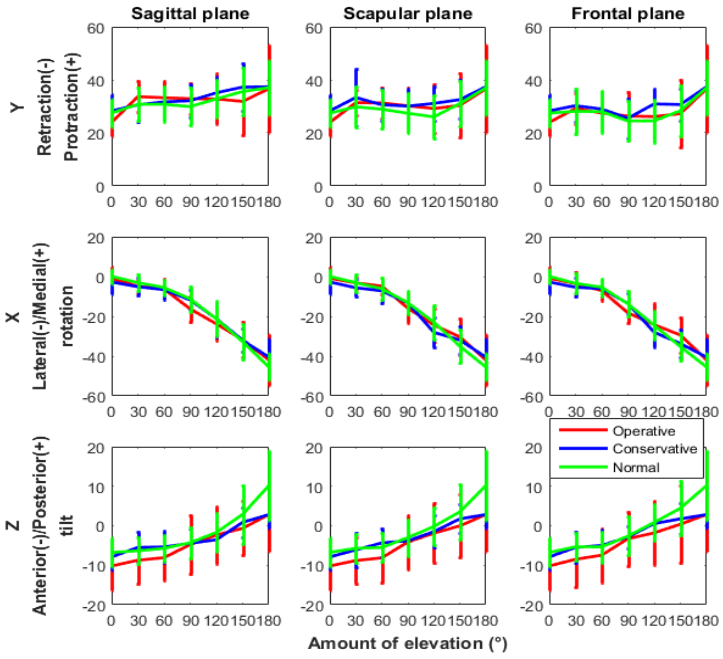

Figure 1: Angular positions of the scapulothoracic joint for healthy controls and for patients with mid-third clavicle fractures with surgical and conservative treatment.

CONCLUSIONS

Patients with mid-third clavicle fractures underwent either conservative or surgical treatment showed similar scapular kinematics after recovery, although different from those of the healthy controls in some kinematic components. The current results suggest that both types of treatment were similar in recovering shoulder kinematics for mid-third clavicle fractures.

P039 - KINEMATIC GAIT VARIATION IN INSTITUTIONALIZED ELDERLY –IMPLICATION TO PRACTICE

[1] **Jerin Mathew**, [1]Teresa Vanlalpeki and [1]Gishnu G Nair
JSS College of Physiotherapy
Rajiv Gandhi University of Health Sciences, Karnataka, India
Corresponding author email: jerinmathew65@gmail.com

INTRODUCTION

Aging is associated by marked by changes in basic kinematics in the lower limbs. The biomechanical and physiological significances of alteration in gait variability in elderly population are potential areas for research. Given the high incidence of mobility disability in older people, it is important to clearly characterize the relationship between ageing and gait variability at the earliest. Early identification of this characteristic particularly in spatiotemporal and kinematic variables can act as a precursor to implementing intervention strategies.

METHODS

This was an observational study conducted in a geriatric home, in India. All the residents of the institution were screened and forty individuals who used gait as the primary mode of ambulation with or without assistive devices were identified. Thereafter a stringent procedure of gait recording was performed.

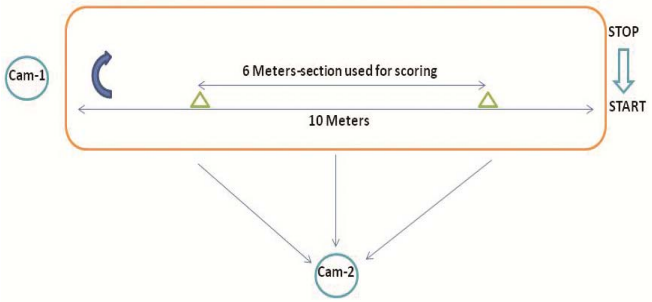

Figure 1: Diagrammatic representation of the walkway with relevant markings

The required parts of the body were exposed and markers were attached on the relevant bony landmarks. The individual was instructed to walk bare foot. A care giver accompanied the participant for safety but did not make contact with the patient. The area selected for the recording was a spacious platform of the study institution (14m×18m). Two web cameras of 'logistics 720 HD' (Patricoski & Ferguson, 2009), connected to two laptops were used for the recording. Both the cameras were mounted on stationary tripods. A tripod with camera was placed at a distance of 3m from the midportion of the walkway to record anterior and posterior views of ambulation (Gupta & Raja, 2012). The videos of each participant comprising of different views were imported to Kinovea 0.2.5 version, a motion analyzing software. Descriptive statistics of the data was done by compiling the ranges of motion at joint during the stance events of the gait cycle.

RESULTS AND DISCUSSION

We screened 20 men and 34 women. Out of this video recording of 19 men and 21 women were included for the analysis. The figures below are graphical representation of maximum angles at different events of the gait cycles.

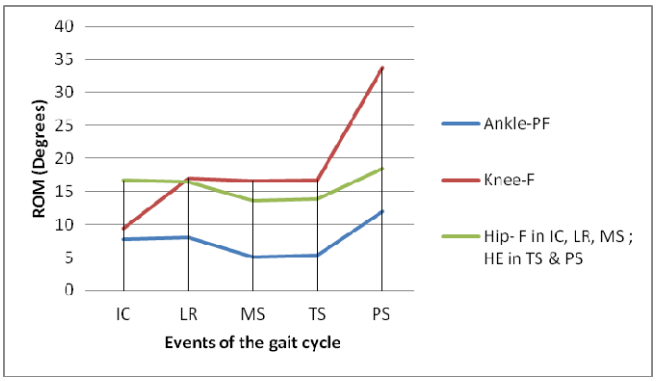

Figure 2: Range of motion in men at different events of gait cycles with the movement observed.

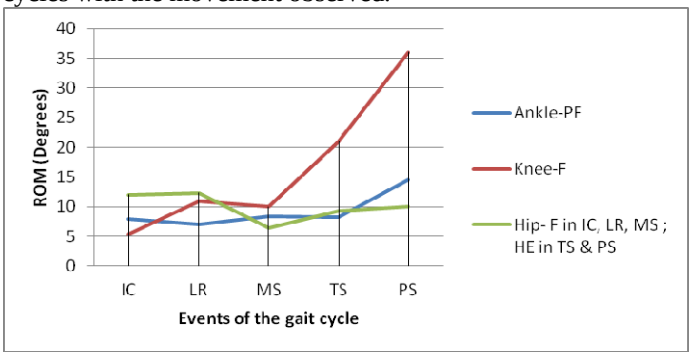

Figure 3: Range of motion in women at different events of gait cycles with the movement observed.

While looking into the spatiotemporal parameters of gait, the result demonstrates that, 36.8% men and 47.6% women have shown a reduction in step length on both the extremities. The gait velocity of all these individuals can be considered as pathological gait velocity (PGV<0.8m/s) (Montero-Odasso & Kaplan, 2016).

CONCLUSIONS

The results of this study show that there is a greater variation from typical, in the kinematic values in older adults. This is an important factor for early identification and management of gait variation in elderly to reduce the risk of fall and to improve the quality of life.

P040 - RELATIONSHIP BETWEEN MECHANICAL STRESS AND INJURY AROUND THE HIP JOINT DUE TO KICKING ACTION IN FOOTBALL

[1] **Kenji Murakami**, [2] Shumpei Miyakawa.

1: Graduate School of Sports Science, Sendai University

2: Graduate School of Comprehensive Human Science, Univ. of Tsukuba. (Tsukuba, Japan)

Corresponding author email:kens.m.lab@gmail.com

INTRODUCTION:

In this study, we therefore analyzed the association between kick-induced mechanical stress (stress distribution) and the clinical findings of injuries around the hip joint that are known to be related to kicking actions in football.

METHODS:

We selected 5 healthy football players, They perform the inside kick, instep kick, and infront kick 3 times each for right-footed. A three-dimensional motion analysis device was used to record their motion and measure the duration between maximum hip extension (MHE) and ball impact (BI). The motion analysis software, SIMM7.0 (Motion analysis, USA) , was used to calculate stress between hip joints and the angle of the hip joint in each kicking motion. In addition, the bone strength analysis software Mechanical Finder7.0 (RCCM, Japan) was used to analyze the computed tomography and magnetic resonance imaging data of each subject to develop a finite-element model consisting of the right ilium, sacrum, and femur. Then, stress between hip joints calculated in dynamics analysis was input as a load value into the finite-element model for the stress analysis.

RESULTS:

At the time of BI, kicking actions produced a high-stress area in the pubic ramus compared with other areas. This value was an equivalent stress value generated in the area of interest (30 mm^3) in the pubic ramus. Stress generated in the superior and inferior rami of the pubic bone was 3.52 and 2.94 MPa for the inside kick, 7.15 and 5.40 MPa for the instep kick, and 4.47 and 3.33 MPa for the infront kick, respectively.

CONCLUSIONS:

The high-stress area on BI was the same area where groin pain syndrome (pubic bone marrow edema) occurs in the clinical examination of football-related hip joint injury and where fatigue fractures occur in pubic bone rami[1),2),3),4)]. Furthermore, in the BI-related area of interest (pubic rami), the values of equivalent stress generated by the inside kick, instep kick, and infront kick in the superior and inferior rami were approximately 3 times, 5 and 4 times, and 3 and 2 times the stress created in the same area by standing by one leg (1.53 and 1.47 MPa in the superior and inferior rami), respectively. The analysis system that integrates motion dynamics into the body structure revealed the relationship between the clinical symptoms of the hip joint and previously reported kick-related injuries around the hip joint.

P041 - FOOT CLEARANCE AND PLACEMENT DURING STEP-OVER-STEP STAIR DESCENT IN PERSONS WITH UNILATERAL TRANSFEMORAL AMPUTATION USING A HYDRAULIC STANCE YIELDING KNEE

Yusuke Okita, Nobuya Yamasaki, Takashi Nakamura, Tomoki Mita, Tsutomu Kubo, Atsuko Mitsumoto and Toru Akune
National Rehabilitation Center for Persons with Disabilities, Tokorozawa, Saitama, Japan
Corresponding author email: okita.yusuke@gmail.com

INTRODUCTION

Persons with a transfemoral amputation (TFA) have difficulty descending stairs in a step-over-step manner because of insufficient control of the prosthetic knee. To overcome this problem, hydraulic stance yielding prosthetic knees have been developed. Those with TFA can achieve step-over-step stair descent wearing this type of prosthetic knee [1, 2]. Instruction in step-over-step stair descent for those with TFA is based on clinician experience, and focuses mainly on positioning of the prosthetic foot [3]. Information on foot placement and clearance, which is currently lacking, would help those with TFA learn how to descend stairs. We investigated how those with TFA with a hydraulic stance yielding knee achieve step-over-step stair descent from the viewpoint of limb kinematics.

METHODS

We evaluated 3 persons with TFA who used a hydraulic stance yielding prosthetic knee. Subject A is a 30-year-old man (5 months after amputation) with 3R80+ knee (Otto Bock, Duderstadt, Germany) and 1D60 foot (Otto Bock), Subject B is a 30-year-old man (6 years after amputation) with Mauch knee (Össur, Reykjavik, Finland) and Elation foot (Össur), Subject C is a 63-year-old man (42 years after amputation) with Mauch knee (Össur) and low-profile Vari-Flex foot (Össur). The protocol of this study was approved by the institutional ethics committee and all subjects gave informed consent. Motion data were collected using a 12-camera motion capture system (MAC3D, Motion Analysis, Natick, MA, USA) with 8 Kistler force plates. Thirty-nine retroreflective markers were placed on the subjects according to a plug-in gait marker set, with 8 additionally placed on the pelvis and feet for better body tracking and to identify foot and sole position. After practice, the subjects performed stair descent on a 4-step custom-made staircase mounted on the force plates. The riser height and the run length of the staircase were 16 cm and 30 cm, respectively. The subjects advanced their prosthetic leg first. Ten trials were collected for each subject.

To evaluate the biomechanics of stair descent, we obtained prosthetic foot and sole positioning and lower limb kinematics. Stick pictures from a sagittal view were derived from one representative trial for each subject. Positions of foot markers at the opposite-side toe-off were projected on the floor to visualize foot placement.

RESULTS AND DISCUSSION

All three subjects showed asymmetric foot placement and clearance, with variation in knee trajectory during prosthetic swing (Figure, A and B). Prosthetic foot clearance was achieved by placing only the mid-rear foot on the step to facilitate foot rolling on the edge of the step, followed by knee extension with little ankle rotation (Figure, A). Contralateral foot clearance was achieved by coordinated knee-ankle motion, making the sole trajectory linear. (Figure, B). Positions of foot markers at the opposite-side toe-off suggested different foot progression angles between the feet, and small loading area of the prosthetic foot (less than half of the plantar surface). This would cause difficulty in weight-bearing on the prosthetic limb.

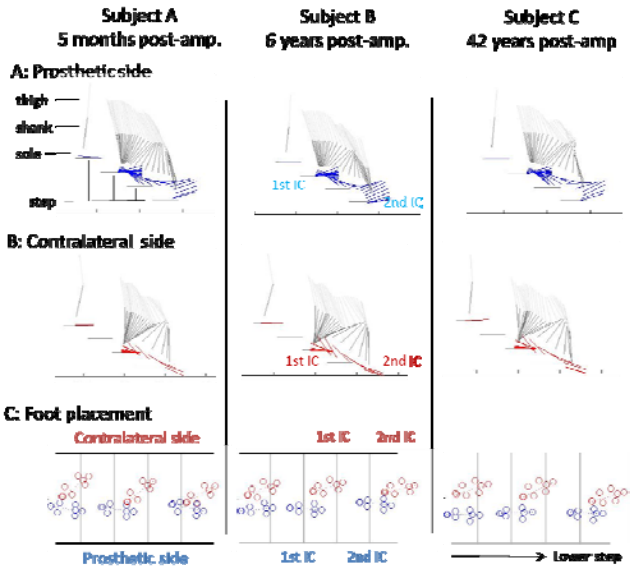

Figure. Sagittal kinematics of step-over-step stair descent is presented with stick pictures (20 Hz, A: prosthetic side, B: contralateral side). Horizontal views of foot placement are shown (C): blue circles indicate prosthetic foot markers and red circles indicate contralateral foot markers at initial position and at the opposite-side toe-off. IC: initial contact; post-amp.: post-amputation

CONCLUSIONS

Kinematic analysis suggested that subjects with TFA could achieve foot clearance in an asymmetric but similar way, possibly associated with limited mobility of the prosthetic foot. In addition to better control of the prosthetic knee, optimizing prosthetic knee-foot coordination should be considered to achieve a stair descent pattern closer to that of healthy people, which emerging powered prosthetic legs (e.g.,[4]) can help achieve.

INTRODUCTION

Electromyography (EMG) signal has been widely explored in different areas such as fatigue process [1], motor control [2] and as diagnosis tool [3]. Conventional EMG devices used in laboratory/experimental studies are complex to use in field research and clinical practice as they require complex protocols, both in their use and in data processing, therefore, preventing widespread use. Recent technological advances have allowed the manufacturing of wearable EMG device that are more practical, user-friendly and portable. In this context, studies that evaluate the reliability of these wearable devices are needed before implementing them in field research and clinical practice. Therefore, the purpose of this study is to investigate the reliability of Mshorts; a wearable EMG device during functional activities in healthy people.

METHODS

Twenty health volunteers wore the Mshorts with EMG sensors (MBody Myontec®). The shorts are made of compression textile and are machine washable. There are 4 EMG channels in each leg (Quadriceps & Hamstrings muscles), with electrode size (M-size) to quadriceps: 160 mm x 33 mm and Hamstrings: 80 x 35 mm that spans over muscle group. The reference electrode is parallel to the lateral face of the femur. The battery is rechargeable Li-ion, 24h or 12h real-time with a single charge, the internal memory of 6 hours of storage has a sample rate of 25 Hz, gain of 1000 and bluetooth v3.0 communication. The output is a time series rectified signal with 25Hz average. The signals were processed off line to extract the quadriceps and hamstrings intensity mean, ratio between intensity of quadriceps and hamstrings and total intensity percentage for both right and left lower limb. The volunteers were instructed to perform two tasks, including 10 repetitions of ascend/descend an eleven-step staircase and squatting at 60º. Reliability data were collected in two different days with an interval of 2 to 7 days between. Test-retest reliability was calculated with the intraclass correlation coefficient ($ICC_{2,k}$) and with the standard error measurement (SEM). The SEM (SEM/mean • 100) was expressed as a % of the mean value of the first day of data collection. ICC values in the range of 0.80 to 1.00 were defined as 'excellent reliability' and ICC values in the range of 0.60 to 0.80 as 'good reliability' while an ICC less than 0.60 reflects 'poor reliability'. A low SEM indicates better reliability of the measurement [1].

RESULTS AND DISCUSSION

Reliability data for wearable EMG parameters during ascend/descend stair and squatting are presented in Table 1. ICC ranged from good to excellent reliability with low SEM for all parameters and activities. Despite no significant differences between activities, the squat activity appears to have higher SEM than stair climbing. This may be related to greater movement of the shorts during squatting activity considering that greater hip flexion angles are required. Based on these results, the Mshorts are a reliable device and it has potential to be implemented in field research and clinical/physical practice.

CONCLUSIONS

Wearable EMG for quadriceps and hamstrings muscles is a reliable device with low error associated to measurement during functional activities.

P043 - EFFECT OF DOWNHILL ANGLES ON PERIODIC MOVEMENT PATTERNS OF THE LOWER EXTREMITIES' FLEXION-EXTENSION DURING WALKING IN THE ELDERLY

INTRODUCTION

One of the major reasons for a decreased quality of life in the elderly in society is falling. It has been reported that 10% to 30% of elderly people have experienced falls at some time while participating in various daily activities [1]. These falls are often caused by unstable posture during walking. In particular, downhill walking challenges the elderly to maintain the stability of the body, which may increase the risk of falls. Therefore, this study was intended to investigate the effect of downhill angles on periodic movement patterns in the lower extremities' flexion-extension during walking in the elderly.

METHODS

Eighteen elderly females (mean age: 66.6±1.4 yrs, mean mass: 56.1±7.5 kg, mean height: 1.57±0.04 m) participated in this study after signing the consent form which was approved by the ethics committee at the University.

The subjects walked on a treadmill at their preferred speed (0.80 ± 0.12 m/sec) in three different downhill angles (0 º, 7.5 º and 15 º).

A system of six high speed cameras (Qualisys, Sweden) was used to collect the position data of the reflective markers attached to the lower extremities of each subject. Hip, knee and ankle flexion-extension angles were calculated using the joint coordinate system from 20 walking strides. Approximate entropy, non-linear time series analysis was then applied to determine periodic movement patterns based on the previous study [2]. Friedman and Wilcoxon signed rank tests were performed if there is any statistical difference between walking conditions with Bonferroni corrections. Significant level was set at $P < 0.05$.

RESULTS AND DISCUSSION

The results indicated an increasing trend of approximate entropy as the downhill angle increased during walking. Significantly smaller approximate entropy for the hip was observed in level walking compared with walking on a 7.5 º and 15º declined downhill slope conditions (Figure 1: left, $P < 0.05$). Significantly larger approximate entropy for the knee was observed in walking on a 15 º declined downhill slope condition compared with walking on a 7.5 º declined downhill slope and level walking conditions (Figure 1: middle, $P < 0.05$). However, no significant differences were found for the ankle (Figure 1: right, $P > 0.05$).

The distinct joint coordination across downhill angles would provide insights on the potential fall mechanism in the elderly. Periodic movement patterns of the lower extremities' flexion-extension may represent "white noise" as well as non-linear signals of movement, showing a dynamic function of the body's neuromuscular skeletal system during walking [3]. It has been suggested that a higher entropy indicates greater complexity or low regularity of human movement. In this study, entropy generally increases with increased downhill angles (i.e. from level to 15 º) for hip and knee joints but no changes for the ankle. Unstable movement patterns in hip and knee joints indicated by high entropy levels may induce constrained motion of the ankle, showing reduced complexity of motion in order to maintain the stability of the whole system during downhill walking.

CONCLUSIONS

The approximate entropy at hip and knee joints in the elderly are sensitive to environmental changes (i.e. downhill walking), showing more complexity or less regularity in periodic movement patterns, while the ankle seems to be less sensitive for terrain adaptation. Downhill walking may increase the risk of falls for the elderly regarding the increased entropy (i.e. degree of stability in the joint) compared with level walking. No changes of entropy in the ankle but increased entropy levels in hip and knee joints in this study may provide insightful information for understanding fall mechanisms and fall-prevention strategy during walking in the elderly.

P044 - RELATIONSHIP BETWEEN BALANCE ABILITY AND THE TIMING OF SIT TO STAND FIVE TIMES TEST

[1] **Jeongwoo Seo**, [1]Taeho Kim, [1]Hyemi Cho, [1]Dongwon Kang, [1]Jinseung Choi, [1]Gyerae Tack,
[1]Konkuk University, Department of Biomedical Engineering
Corresponding author email: grtack@kku.ac.kr

INTRODUCTION

The balance ability usually decreases and the risk of falls increases with aging. The various tests have been applied to the study of balance ability and fall risks. Among them, the sit to stand five times (STS5) test is an established assessment of lower limb strength, balance dysfunction and fall risks [1]. The duration of STS5 was measured using a stopwatch and used an index for the evaluation. Recently, the IMU sensor has been used for balance test. The signals from accelerometer and gyroscope have allowed to extract some significant parameters related to the transition during STS5 and compared them with fall risks [1]. The discriminant analysis using STS5 has been reported to identify 60% of participants over 60 years with balance dysfunction from those without balance problems with an optimal cut-off time of 14.2sec [2]. It is an entire duration for STS5 test. However, the transition period and types of movement can be identified by IMU signal. The purpose of this study was to calculate whole STS5 duration as well as subdivided individual transition periods and to find the relationship between the balance ability by Berg Balance Scale (BBS) & fall experience and subdivided individual transition periods particularly.

METHODS

Eighty-six elderly subjects participated in this experiment (male: 23, female: 63, age: 75.8 ± 5.7years, height: 153.2 ± 9.0cm, weight: 59.2 ± 9.2kg). The subjects were divided by BBS (HO: >52 (N=53), IO: ≤52 (N=33)) and fall experience (Faller: ≥1 (N=27), Non-faller: 0 (N=59)). The subjects performed the STS5 while a wireless inertial measurement unit sensor modules (APDM Inc., USA) on the posterior trunk at the L5 level near the body center of mass and right frontal thigh [2]. The acceleration signal of the sensor was collected with a 128-Hz sampling frequency, and filtered with a 3.5-Hz cutoff zero-phase low-pass Butterworth filter. The transitions were measured using thigh sensor. The time periods included 5 sit to stand to sit time, and total time. The total six time periods were measured by IMU sensor. The independent T-test was performed for statistical analysis (α=.05).

RESULTS AND DISCUSSION

There was not any significant difference between BBS score and fall experience (p=.16). The 5 sit to stand to sit time and total time (no. 1~6 period in Fig.1) were significantly different between HO and IO, between Faller and Non-faller. Results showed that IO and Non-faller groups moved with more restricted and cautious manner than HO and faller did. Published study showed that there was a close relationship between fall risks and total time of STS5 [1]. However, in this study, the times taken STS5 of Non-faller was longer than those of Faller, which is the differences in the characteristics of the subjects. It is believed that the strength of lower extremities is import for the execution of STS5. For further study it is necessary to investigate the characteristics of STS5 as well as the strength of lower extremities of the subjects (Faller and Non-faller).

Table 1: Results of sixth time periods (unit: sec)

	HO	IO	*p*	Faller	Non-Faller	*p*
①1st stand-sit	1.25 ±0.25	1.38 ±0.33	.04*	1.21 ±0.25	1.35 ±0.29	.03*
②2nd stand-sit	1.26 ±0.30	1.45 ±0.38	.01*	1.20 ±0.30	1.39 ±0.35	.02*
③3rd stand-sit	1.30 ±0.36	1.48 ±0.39	.03*	1.23 ±0.35	1.43 ±0.38	.02*
④4th stand-sit	1.32 ±0.37	1.49 ±0.41	.04*	1.21 ±0.38	1.46 ±0.38	.01*
⑤5th stand-sit	1.37 ±0.39	1.54 ±0.47	.04*	1.26 ±0.38	1.52 ±0.43	.01*
⑥Total time	10.67 ±2.36	12.17 ±2.95	.01*	10.11 ±2.42	11.76 ±2.66	.01*

(mean±SD, Independent T-test, *p<.05)

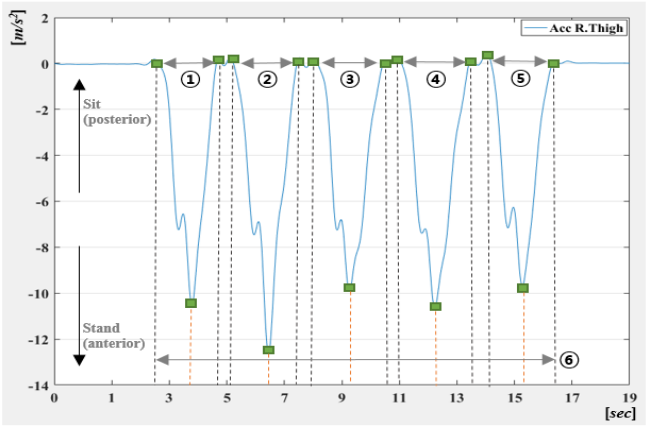

Figure 1: The subdivided time period of STS5

CONCLUSIONS

IO & Non-faller took a longer time than HO & Faller, which indicated that IO and Non-faller groups moved with more restricted and cautious manner than HO and faller did. It is necessary to investigate the correlation of the lower limb strength and fall experience & balance ability.

P045 - THREE-DIMENSIONAL KINEMATICS OF TOTAL KNEE REPLACEMENTS DURING SIT-TO-STAND: COMPARISONS BETWEEN MINIMALLY-INVASIVE AND PATIENT-SPECIFIC INSTRUMENTATION PROCEDURES

INTRODUCTION

Total knee replacements (TKR) have been the main choice of treatment for alleviating pain and restoring physical function in advanced degenerative osteoarthritis of the knee [1]. Recently, there has been a rising interest in minimally invasive surgery TKR (MIS-TKR) but accurate restoration of the knee axis presents a great challenge. Patient-specific-instrumentation for TKR (PSI-TKR) was thus developed to address the issue [2]. However, the efficacy of this new approach has yet to be determined. The purpose of the current study was thus to measure and compare the 3D kinematics and surface kinematics of MIS-TKR and PSI-TKR *in vivo* during sit-to-stand using 3D fluoroscopy technology.

METHODS

Six patients with MIS-TKR (posterior stabilized) and six with PSI-TKR participated in the current study with informed written consent. Each subject performed quiet standing to define joint neutral positions and then sit-to-stand while under the surveillance of a bi-planar fluoroscopy system (ALLURA XPER FD, Philips). For the determination of the 3D TKR kinematics, computer-aided design (CAD) models of the TKR for each subject was obtained from the manufacturer including femoral and tibial components and the plastic insert. At each image frame, the CAD model was registered to the fluoroscopy image via a validated 2D-to-3D registration method [3]. The CAD model of each prosthesis component was embedded with a coordinate system with the origin at the mid-point of the femoral epicondyles, the z-axis directed to the right, the y-axis directed superiorly, and the x-axis directed anteriorly. From the accurately registered poses of the femoral and tibial components, the angles of the TKR were obtained following a z-x-y Cardanic rotation sequence, giving flexion/extension, adduction/abduction, and internal/external rotation [4]. Since the insert was fixed to the tibial component, the contact area was obtained from the kinematics of the femoral and tibial components. Surface kinematics was described in terms of the translations of the contact point (center of the contact area).

RESULTS AND DISCUSSION

During sit-to-stand the patterns and magnitudes of the translations were similar between MIS-TKR and PSI-TKR, with posterior translations ranging from 10-20 mm and proximal translations from 29-31mm. Differences in mediolateral translations existed between the groups but the magnitudes were too small to be clinically significant. For angular kinematics, both groups showed close-to-zero abduction/adduction, but the PSI-TKR group rotated externally from an internally rotated position (10° of internal rotation) to the neutral position, while the MIS-TKR group maintained at an externally rotated position of less than 5° during the movement. The patterns and magnitudes of the translations of contact points were similar between both groups, with anterior translations on medial compartment during knee flexion and posterior translations on lateral compartment during knee flexion (Fig. 1). For surface kinematics, paradoxical anterior translation is observed on medial compartment in both groups.

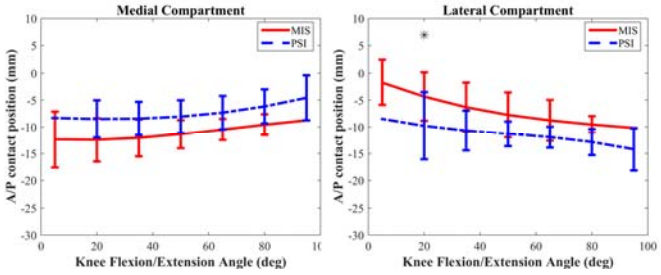

Figure 1: Means and standard deviations of the anterior/posterior contact positions of MIS-TKR and PSI-TKR. * indicates statistical significance.

CONCLUSIONS

The current study was the first attempt to quantify the kinematic differences between PSI and non-PSI MIS for TKR. Compared to MIS-TKR, PSI-TKR showed a pattern similar to the screw home mechanism in a normal knee, which may be related to a more accurate restoration of the knee axis with the patient specific instrumentation during TKR surgery. With close-to-normal rigid-body kinematics, PSI-TKR appeared to be better in maintaining accurate articular contact patterns, which may be helpful for the recovery of normal function of the knee. For the design of TKR, it may help prevent the paradoxical anterior translations.

P046 - ANALYSIS OF PINCH STRENGTH AND HAND FUNCTION IN PERSONS WITH SEVERE CARPAL TUNNEL SYNDROME: PRELIMINARY RESULTS

[1]**Letícia A Silva**, [2]Marcia A Ciol, [1]Maria C Santos, [1]Danielle S Figueiredo and [1]Helga T Tucci
[1]Federal University of São Paulo
[2]University of Washington
Corresponding author email: leticiaaraujos@hotmail.com

INTRODUCTION

Signs and symptoms caused by mechanical compression of the median nerve in the carpal tunnel are called carpal tunnel syndrome (CTS), a neuropathy of high prevalence in the upper extremity. One of the conservative treatments for CTS consists in wearing a neutral custom-molded thermoplastic wrist orthosis nightly in addition to tendon and neural gliding exercises [1,2].

Several objective and subjective measurements are available to evaluate the evolution of CTS treatments. Two of the most used and responsive objective and functional measures are the pulp-to-pulp strength and the tripod pinch strength. The Boston Questionnaire is a common subjective and specific instrument used to evaluate the symptomatology (severity of symptoms and functional status) of patients with CTS [3].

The purpose of this study was to investigate whether a 45-day treatment consisting of wearing a neutral custom-molded thermoplastic wrist orthosis nightly in addition to tendon and neural gliding exercises could improve the pulp-to-pulp and tripod pinch strengths, and reduce the score of Boston Questionnaire is persons with severe CTS. This is a preliminary report of the results of the study.

METHODS

Six volunteers with medical diagnosis of severe CTS in the dominant upper extremity and who had an electrodiagnosis exam to confirm the level of STC were enrolled. Participants wore a custom-molded thermoplastic wrist orthosis in the neutral position during 45 nights. They also performed tendon and neural gliding exercises twice daily for 45 days, with instructions from booklets containing images and written explanations on how to perform the exercises [4].

Before and after the treatment period, three measurements of pulp-to-pulp and tripod pinch strengths of the right hand were measured by the Pinch Gauge© dynamometer. Similarly, the Boston Questionnaire was applied before and after the treatment period. The domains of the Boston Questionnaire were scored separately to evaluate symptom (Symptom Severity Scale - SSS) and Manual Skill (Functional Status Scale – FSS) of CTS. The mean value of the pinch strength obtained for each pinch, and the scores of SSS and FSS domains of the Boston Questionnaire were compared pre- and post-treatment by descriptive analysis. The study was approved by the Research Ethics Committee of UNIFESP, process number 1.683.113.

RESULTS AND DISCUSSION

After 45 days of treatment, patients showed greater values of pulp-to-pulp pinch strength, going from a mean value of 3.86 kgf (standard deviation = 0.60) to 4.30 kgf (0.69), and greater values of tripod pinch strength, going from 4.76 kgf (0.84) to 5.35 kgf (1.0). In the Boston Questionnaire, patients showed lower score in the Symptom Severity Scale domain, from a mean value of 2.52 (0.54) to 1.86 (0.49), and lower score in the Functional Status Scale domain, from a mean value of 2.81 (0.42) to 2.21 (0.80), both of which are interpreted as improvement.

Previous studies have reported that surgery is the most indicated treatment for severe CTS, while conservative treatment can improve pinch strength and symptoms in mild and moderate CTS [5,6]. However, when surgery is not possible or need to be postponed (for example, lack of healthcare coverage or person's comorbidities), the conservative treatment might be a reasonable approach for severe CTS also.

CONCLUSIONS

The results of this study showed that the proposed conservative treatment is potentially effective in persons with severe CTS. The next step is to design a larger study that will allow for confirmation of these results.

P047 - A JOINT COORDINATE SYSTEM FOR BIOMECHANICAL ANALYSIS OF THE SACROILIAC JOINT

[1]**Liesbeth Van Hauwermeiren**, [2]Matthias Verstraete, [3]Dominique Adriaens, [1]Sam Pintelon, and [1]Tom Van Hoof

[3]Ghent University, Department of Vertebrate Morphology

INTRODUCTION

Sacroiliac joint (SIJ) biomechanics have been described in both in vitro as in vivo studies [2]. However, a standardized joint coordinate system for sacroiliac joint motion analysis is lacking, impeding interpretation of research results and communication between research groups. Grood et al [1] proposed a joint coordinate system for the description of knee biomechanics in clinical settings. Up to now, this technique has been applied to set standards for joint motion of most joints in the human body [3]. However, no such standard has been described for the SIJ. This paper proposes a joint coordinate system for the analysis of sacroiliac joint motion, based on the procedure developed by Grood et al. As SIJ motion is reported to be very small, standardization and reproducibility of this procedure is essential for the interpretation of future 3D biomechanical SIJ analysis.

METHODS

The procedure proposed by Grood et al [1] is used to develop a coordinate system for the sacroiliac joint. Firstly, a Cartesian coordinate system (CCS) for both sacrum and coxal bones is established, based on bony landmarks on these two bony segments. Secondly, a Joint Coordinate System (JCS) is developed based on the body fixed axis of each of the CCSs. Finally, movement is described by angles α, β and γ around e_1, e_2 and e_3 axes. Translations q_1, q_2 and q_3 are described by vector H, directed from the origin of the CCS of one bone to the origin of that of the other.

RESULTS AND DISCUSSION

Sacral Cartesian Coordinate System

The center of the auricular joint surface (AJS) is chosen as the origin of the sacral CCS (O_S). The CCS for the sacrum is described by 3 axes: as nutation and counternutation are of interest in the SIJ, a latero-lateral axis is chosen, connecting the AJS center of both left and right joint surfaces. This axis is selected as the sacral body fixed axis (X-axis = e_1). The anteroposterior direction (Z-axis) is defined by the common perpendicular (normalized cross product) of the fixed axis (X-axis) and temporary axis t_S - defined by the central craniocaudal axis through the sacral bodies. The third axis of the CCS, the Y-axis, is placed perpendicular to both X and Z axes (fig 1).

Coxal Cartesian Coordinate System

The center of the AJS of the coxal bone is set as the origin of the coxal CCS (O_C). The first rotation axis (x-axis) is defined by a line perpendicular to the coxal AJS. The craniocaudal axis (y-axis) is defined by the normalized cross product of the x-axis and temporary axis t_C, defined by the line between the hip joint center and the coxal AJS center of mass. This axis is chosen as the body fixed axis e_3. The z-axis is defined as the axis perpendicular to both x and y-axes (fig 1). For both CCSs, the x-axis is positive to the right, the y-axis is positive in the proximal direction, and the z-axis is positive anteriorly.

Joint Coordinate System

Finally, the JCS is described: nutation- counternutation occurs about the sacral fixed axis (e_1) and is described by angle α. Transverse plane rotation is described by angle γ about the coxal fixed axis (e_3) (fig 1). Angle β describes lateral flexion, occurring about the floating axis e_2, as determined by the normalized cross product of both e_1 and e_3 axes. e_2 is not fixed in either segment, but moves in relation to both. Translations q_1, q_2 and q_3 are described by the dot product of the axes e_1, e_2 and e_3 and vector H, connecting O_S to O_C.

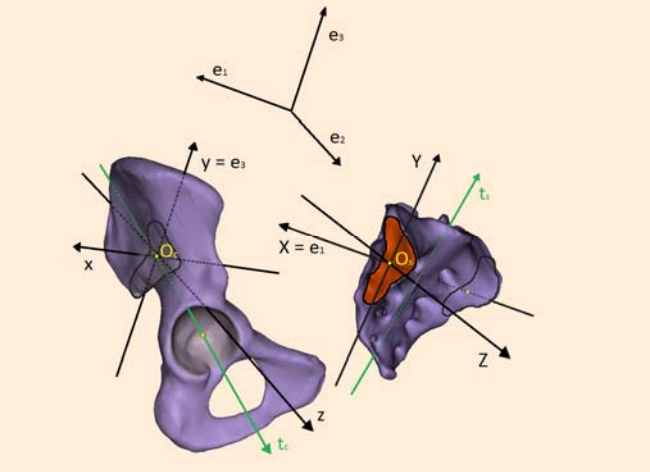

Figure 1: CCS of the sacrum with X, Y, Z axes and t_S axis (green), CCS of the coxal bone with x, y, z axes and t_C axis (green). JCS with body fixed axes e_1 and e_3, and floating axis e_2.

CONCLUSIONS

This paper proposes a joint coordinate system for motion analysis of the SIJ, in order to improve standardization and reproducibility of future biomechanical research.

P048 - EFFECT OF PHOTOBIOMODULATION ON SHOULDER MUSCLE FATIGUE AND SYNERGISM. A PRELIMINARY EMG STUDY USING ACTIVATION RATIOS

INTRODUCTION

Fatigue of serratus anterior can cause shoulder muscular imbalances, compromising the scapular kinematics and predisposing the person to pain and shoulder injuries [1]. Photobiomodulation (PhM) showed been effective in muscle fatigue attenuation due to its action in the muscle bioenergetics [2]. This study aims to investigate the effect of PhM applied to the serratus anterior on the relative contribution of shoulder muscles during arm elevation. We hypothesize that changes on changes on muscles activation ratios were less on subjects who receive PhM (active group) compared with subjects of sham and control groups.

METHODS

Six males [Mean (SD) 23,5(2.0) years; body mass 70.2 (14.0) kg; and height 1.75 (0.03) m] were randomized in three groups: Active, Sham and Control. Surface EMG (Ag/AgCl bipolar electrodes; 20mm inter-electrode distance) was sampled (2kHz) from the upper, and lower trapezius (UT, LT), medial deltoid (MD) and serratus anterior (SA) [4.5]. Upper arm kinematics with respect to trunk kinematic was recorded (Sample frequency: 60 Hz; Software Dvideow©). A trigger was used to synchronize EMG and kinematic. Subjects performed 5 repetitions of a weighted shoulder maximum elevation in scapular plane before and after an induced fatigue task. This task toward SA muscle fatigue and consisted of subjects placing their feet on a step and holding a pushup plus position until exhaustion. PhM was applied over SA, before the task fatigue, using a cluster [7 diodes of 850nm wavelength (GaAlAs), 100mW output power, and 2J per diode totalizing 14J in 20 seconds]. Raw EMG signal was digitally full-wave rectified and filtered (low-pass filter; cutoff = 2.5 Hz). Following, the EMG data were windowed in 3 arc-of-elevation, determined by kinematics: initial (~30°-60°); middle (~60°-90°); and final (~90°-to maximum) and the average value for each one was normalized by the mean value of 3 MVICs of the respective muscle. Finally, for each arc-of-motion on the ascending phase the relative activation ratios between deltoid and trapezius muscles (MD/UT and MD/LT) were calculated, as well as between the upper and lower parts of trapezius (UT/LT); and between the upper trapezius and serratus anterior (UT/SA). An exploratory statistical analysis was done.

RESULTS AND DISCUSSION

Results showed that most part of ratios was greater after fatigue compared to its respective values obtained before fatigue (Table 1). Fatigue of SA can cause alterations on scapulothoracic muscle ratio [5]. Moreover, altered synergic muscle ratios could cause alterations on the scapular biomechanics, leading to shoulder pain and injuries [6]. Thus, complementary treatments or physical resources that could reduce SA fatigue previously to exercises and daily life activities are important for clinical and coaches.

CONCLUSIONS

To use of photobiomulation on SA previously to fatigue was not effective in reducing the alteration in the muscular ratios. Although limited, this preliminary finding suggests that a study with larger sample size should be done to assess the benefits of this resource to reduce SA fatigue.

P049 - A NOVEL APPROACH TO ANALYZING RAPID TETRAPOD LOCOMOTION USING INERTIAL MEASURMENT UNITS

[1] **Hasti Hayati**, [1]David Eager, [1]Ardian Jusufi and [1] Terry Brown
[1]University of Technology, Sydney

INTRODUCTION

Rapid quadrupedal movement on granular media and other irregular terrain is an interesting area of research which is under-explored. Current methods of studying rapid quadrupedal movement involve the measurement of ground reaction forces (GRF) using a force plate and a simultaneous kinematics analysis by a High Frame Rate video (HFR). Although force plates provides highly accurate kinetic data, it is not always practical to deploy in the study of animal locomotion. For instance, it is often not possible to embed force plates in irregular terrains [1] characteristic of most ecologically relevant animals' natural habitats [2]. An alternative method is to utilize an inertial measurement unit (IMU) equipped with a tri-axial accelerometer to analyze accelerations associated with different quadruped gaits. In this study, a tri-axial accelerometer is used to analyze sprinting locomotion dynamics of a greyhound in a simulated racing condition. Kinematics data from videography of the entire race was recorded in each trial for data calibration. In addition, the paw prints of the greyhound on a sandy-loam surface of a race track are also analyzed to sync acceleration data with each individual paw print.

METHODS

Tri-axial accelerometer (GPSports/SPI Pro X) sampling freq 100Hz has been deployed to analyze the sprinting locomotion dynamics of a greyhound in a simulated racing condition. Experiments were conducted at Wentworth Park racetrack, Sydney, NSW. The accelerometer was embedded into a sewn pocket located on the back of the greyhound's racing jacket and positioned between its two forelegs. Paw prints were measured to obtain a track map which then facilitated alignment of each paw print with the acceleration data. The full race video and a HFR video of the run at the second straight of race track were also recorded. The trial started on a straight section (Home Straight) followed by a turn of 52m radius and the second straight (Back Straight). The race was 280m in length with a duration of approximately 26s. Constant velocity running was investigated through analysis of the fore-aft (Y-axis) acceleration data obtained during the greyhound running in the Back Straight.

RESULTS AND DISCUSSION

The fore-aft acceleration as a function of time for the first six strides of a run in the Back Straight as well shown in Figure 1. For each stride we observe three reoccurring local peaks of descending magnitude. These maxima were in the range of ~4.5g to 6.5g and corresponded to a stride each, as aligned foot prints are (Fig.1 C). This result correlates with previous findings that fast quadrupeds have approximately three strides per second in non-acceleration running [2]. The observed three bursts in fore-aft acceleration associated with

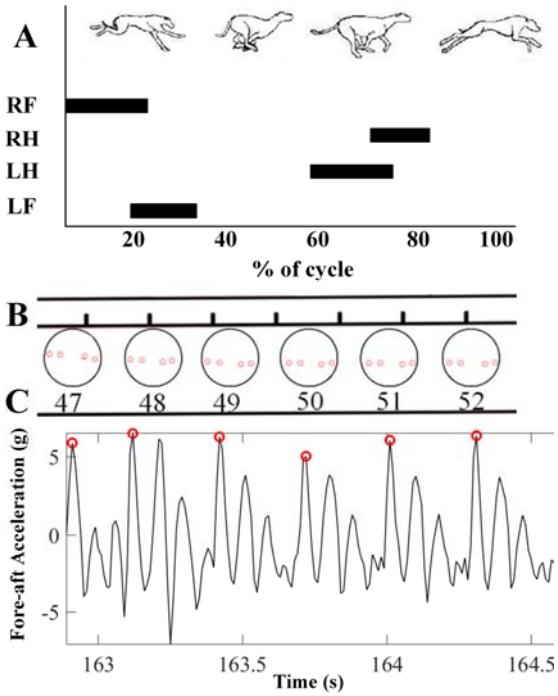

Figure 1: Footfall pattern of a complete cycle of a greyhound running at Back Straight (A) Paw prints during six strides of a greyhound running at Back Straight (B). Fore-aft accelerations as a function of time coinciding with paw prints (C).

the propulsive effort of the hind-legs (Fig. 1 B, C) was also seen in cheetahs [2]. The HFR video of the run in the Back Straight was also analyzed (Fig. 1A) showing that peaks in the forward acceleration were observed when the hind-legs contact the ground. Based on preliminary data from the accelerometer the mean stride frequency in Back Straight (M= 3.4 Hz, SD= 0.2) and Northern turn (M= 3.8 Hz, SD= 0.5) was calculated and did not show a significant difference in an ANOVA [F (1, 20) = 1.6, P= 0.2] and t-test [t (10) = 1.2, P= 0.1]. Comparing this with observed changes in stride length in both conditions allows for an estimate of the speed.

CONCLUSIONS

The conventional methods of gait analysis i.e. using force plates are not always a feasible option mainly on irregular terrains or for animals in their natural habitats. To overcome these difficulties, which exist in studying greyhounds running on real race tracks, in this study a tri-axial accelerometer was used. Results suggest that for a given stride duration greyhounds take greater strides when running straight versus when going around a bend.

P050 - THE ROLE OF INTERSTITIAL FLUID PRESSURE IN SITE-SPECIFIC NEW BONE FORMATION

[1] Rakesh Kumar, [1] Abhishek Kumar Tiwari, [1] Dharmendra Tripathi, [2]Jitendra Prasad and [2] **Subham Badhyal**

INTRODUCTION

In vivo studies have reported that dynamic mechanical loading on bone induces osteogenesis i.e. new bone formation. Recent research efforts have shown that loading induced interstitial fluid flow or pore-fluid-pressure typically governs the site-specificity of new bone formation. For example, Qin *et al.* have noticed that intramedullary pressure distribution positively correlates with sites of new bone formation in an avian ulna loading model [1]. Nevertheless, this relationship has not been substantiated with other *in vivo* studies on bone adaptation. Moreover, *in vivo* loading parameters such as frequency and cycles also affect pore-pressure, fluid flow distribution and magnitude, therefore it may also affect the site-specificity of osteogenesis [2]. Accordingly, this study attempts to investigate and substantiate the role of pore-pressure distribution in site-specific new bone formation reported in an *in vivo* cantilever loading study of Srinivasan *et al.* [3]. In addition, the effect of frequency on pore-pressure distribution is also studied.

METHODS

Present study estimates pore-fluid-pressure distribution at mid-diaphyseal cross-section (1.8 mm proximal to tibia-fibula junction) of a 10-week-old female C57Bl/6J mouse tibia subjected to a continuous cyclic cantilever loading of 0.5 N at 1 Hz. Accordingly, tibia is assumed as a poroelastic cantilever beam subjected to a load of 0.5 N at the distal end (Figure 1(a)). A model based on Biot's theory of poroelasticity is developed to compute pore-fluid-pressure distribution as follows:

$$P_{steady}(y,t) = \frac{M_0 B(1+\nu_u)}{6a^2}\left[\left(1+3\frac{y}{a}\right)\sin\omega t - \mathrm{Im}[\{X+Y\}e^{i\omega t}]\right] \quad (1)$$

where, $X = \dfrac{H\sqrt{i\Omega}\cosh(\sqrt{i\Omega}(y/a)) - \sinh\sqrt{i\Omega}}{H\sqrt{i\Omega}\cosh\sqrt{i\Omega} - \sinh\sqrt{i\Omega}}$

$$Y = \frac{3i\Omega H\sinh(\sqrt{i\Omega}(y/a)) + 3(y/a)(\sinh\sqrt{i\Omega} - \sqrt{i\Omega}\cosh\sqrt{i\Omega})}{i\Omega H\sinh\sqrt{i\Omega} + 3(\sinh\sqrt{i\Omega} - \sqrt{i\Omega}\cosh\sqrt{i\Omega})}$$

and $\Omega = \dfrac{a\omega^2}{c}; H = \dfrac{1-\nu}{\nu_u - \nu}$

where P_{steady} is steady-state component of pore-pressure induced due to a sinusoidal bending moment of magnitude M_o at an angular frequency of ω; B is Skempton coefficient; c is diffusion coefficient; ν and ν_u are Poisson's ratios of solid bone matrix under drained and undrained conditions, respectively; 'i' is the imaginary unit; a is the thickness of the cortex.

Pore-pressure distributions at the cortex are estimated at loading frequencies of 1, 3, 5, 10 Hz which are site-specifically compared with *in vivo* new bone distribution.

RESULTS AND DISCUSSION

A site-specific comparison between locations of *in vivo* new bone formation and pore-pressure distribution indicates that osteogenesis occurs at the sites of elevated/maximum pore-pressure as illustrated with figures 1(b) and (c). It is also evident that pore-fluid-pressure magnitude increases with an increase in loading frequency as shown in figures 1(d) to (f), nevertheless, high frequency loading at 5 and 10 Hz presents localization of pore-pressure at specific sites of the cortex as depicted in figures 1(c) and (d); whereas loading at 1 and 3 Hz (in physiological range) resulted in even pressure distribution at the cortex as shown in figures 1(c) and (d). It indicates that loading frequency may affect the distribution and the magnitude of pore-fluid pressure across the cortex; and hence, it may affect the site-specificity and amount of new bone formation.

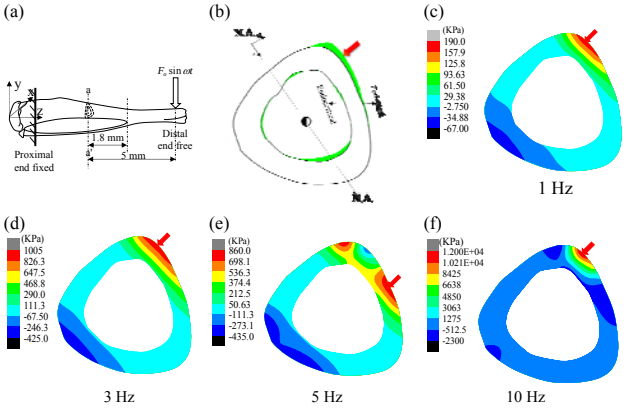

Figure 1: (a) *In vivo* loading configuration of mouse tibia; (b) new bone distribution at mid-diaphyseal section a-a′ (adapted from Srinivasan *et al.* [3]); and pore pressure distribution at: (c) 1, (d) 3, (e) 5, and (f) 10 Hz. Arrow indicates site of the maximum bone formation and the pore-pressure.

CONCLUSIONS

This study substantiates the fact that interstitial fluid pressure positively regulates the site-specificity of loading induced osteogenesis. Moreover, loading parameters such as frequency may affect the pore-pressure distribution and new bone formation.

P051 - THE EFFECT OF BRAIN SIZE ON INDUCING TRAUMATIC BRAIN INJURY

[1]**Melissa A. Boswell**, [1]Kaveh Laksari and [1]David B. Camarillo
[1]Stanford University
Corresponding author email: dcamarillo@stanford.edu

INTRODUCTION

Traumatic brain injury (TBI) is a debilitating public health problem, with an estimated 1.7 million people diagnosed per year in the USA alone [1]. Defining TBI is difficult, particularly in humans, as it relies on subjective symptomology and neurocognitive changes. Animal models can be used as a tool to gain a deeper insight into TBI; however, the utilization of animal models requires a better understanding of the commonalities of TBI across species. Based on the hypothesis that microstructural damage dependent on the magnitude and rate of strain causes TBI [2], it is important to obtain similar strain and strain rate across species to achieve comparable levels of injury. Our goal is to study whether both the strain and strain rate can translate from humans to an exact match in smaller animals.

Scaling laws have been developed to compare TBI across species, with scale factors defined as a function of body mass or brain mass, or defined by a physics-based scaling law [3]. Another scaling method describes strain as a function of the applied loads and radius of the brain [4]. While this method assumes a linear material model for the brain, adding the complexities of a non-linear material can more appropriately evaluate strain and strain rate under varying applied loads and brain sizes, and, thus, help better understand TBI across different species.

METHODS

A finite element (FE) model was created based on a validated continuum model using strain as a function of applied loads and brain radius [4]. The brain was defined as a cylinder with fixed motion along the axis of rotation to replicate the effect of an infinite length, and Ogden rubber material. A rigid outer cylinder surrounded the gel with a no-slip boundary interface to represent the skull. Strain was evaluated at a non-dimensional radius of 0.3, the approximate location of the deep white matter in the corpus callosum where TBI is frequently associated [4]. Animal and human pathology data has shown that the midcoronal plane contains many regions of interest in TBI, and, thus, an angular acceleration load was applied in the representative coronal plane of the FE model. Angular acceleration was represented as a sinusoidal load with a peak magnitude of 12.3 krad/s^2 over an impulse duration of 15 ms, human loss of consciousness injury conditions [5]. Peak strain was then evaluated in the FE model with scaled radii to represent human, pig, and ferret sized brains at 6.8 cm, 3.0 cm, and 1.68 cm, respectively.

RESULTS AND DISCUSSION

Under the described angular acceleration impulse, peak strains for human, pig, and ferret were 0.50, 0.10, and 0.013, respectively. Obtaining similar peak strains of 0.50 required a peak angular acceleration of 74 krad/s^2 for the pig-size brain and 430 krad/s^2 for the ferret-size brain. This showed an exponential increase in peak angular acceleration required to obtain human-level strain values with decreasing brain size. At peak strain of 0.50 across all three species, the peak strain rate values were 380 s^{-1}, 690 s^{-1}, and 1050 s^{-1} for human, pig, and ferret, respectively. A comparison of peak strain rate vs. peak strain across the species was found by adjusting peak angular acceleration as a percentage of the peak acceleration required to obtain peak strain of 0.50 across all species (Figure 1).

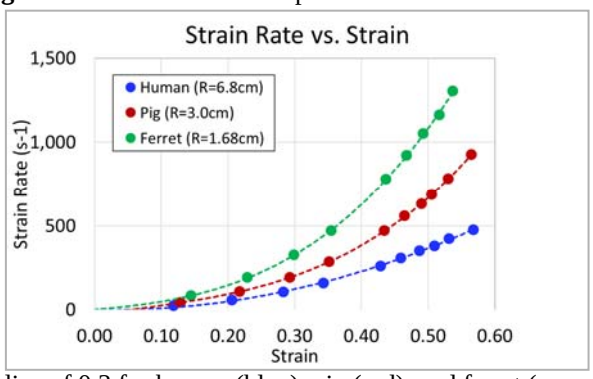

Figure 1: Peak strain rate vs. peak strain at non-dimensional radius of 0.3 for human (blue), pig (red), and ferret (green) brain sizes, with r-squared values of 0.9989, 0.9999, and 0.9997, respectively, fit to a 2nd order polynomial.

There were three main observations found from the FE model: (i) a smaller brain size requires an increase in peak angular acceleration required to induce similar peak strains, (ii) a smaller brain size leads to an increase in peak strain rate for similar peak strains, and (iii) a smaller brain size leads to an increase in the ratio of peak strain rate to peak strain.

CONCLUSIONS

Animal models can help understand mechanisms of concussion if there is an understanding of how to apply animal model results to humans. The developed FE model gives insight into the relationship of strain and strain rate values across species. This information can be used to gauge values required for experimental testing, and, ultimately, better define and understand mechanisms of TBI.

P052 - SIMULATION AND OPTIMIZATION OF THE TAKEOFF ACTION AND PROSTHESIS FOR AMPUTEE LONG JUMP

[1] **Kazunori Hase**, [1] Shiori Murata, and [2] Goro Obinata
[1] Tokyo Metropolitan University
[2] Chubu University
Corresponding author email: kazunori.hase@tmu.ac.jp

INTRODUCTION

Sports prosthesis for lower extremity amputees has a mechanical structure similar to leaf springs, and its elastic energy is expected to improve sports performance. Moreover, it is important to comprehensively optimize the material mechanics of the prosthesis as well as human body movement of the amputee to adapt to the dynamics of the prosthesis. In this study, we focus on a long jump event for track and field, in particular, on the takeoff action because the spring property of the prosthesis is very important in this phase. The purpose of this study is to construct a computer simulation system that derives a comprehensive optimum solution for both the mechanical design parameters of the prosthesis and takeoff action to improve the performance of amputee long jump.

METHODS

The simulation system comprises three parts: the human-body-prosthesis dynamics, motion control, and parameter optimization. In the human-body-prosthesis dynamics system, the mechanical properties of the human body were simply represented by a 2-dimensional model with the following 10 rigid links: the lower and upper torsos, upper arms, forearms, thighs, right calf, and right foot. In our constructed model, it was hypothesized that the left thigh segment was cut in the middle and the lower extremity above the knee was replaced by the prosthesis. The joints of the normal human body model were driven by the joint moments corresponding to the muscle forces, and the prosthetic knee joint of the left lower extremity had a passive viscoelastic element.

The below-knee prosthesis used in sports is similar to leaf springs and calculation formula of a flat spring was employed to represent the elastic properties. The elastic properties of the flat spring model were calculated by combining simple spring elements such as linear and arc elements. The flat spring model only represents the mechanical relationship between deflection and force; therefore, inertia properties, such as mass of the prosthesis, were independently represented by a single rigid body model without deformation. The ground reaction force was calculated as the force synthesized by the deflection of the prosthesis. Moreover, dumping properties were included in the prosthesis-ground contact model to represent the restitution and friction characteristics on the ground.

In the control system, each driving joint moment was generated by proportional-derivative (PD) control. In this case, the input value to the control system corresponds to the joint angle that was parametrically changed using the cubic spline interpolation function and its node points. Therefore, joint moments could be varied by adjusting the node points in the parameter optimization method described later. In this simulation, the takeoff motion during the 0.3-s period was only synthesized by solving the forward dynamics of the human-body-prosthesis model, and the approach run and landing motions were not considered.

In the optimization system, a performance index was represented by a weighted linear combination of various fundamental criteria for the simulated jumping motions. These include the jumping distance calculated via a parabolic motion by assuming the human body as a particle after takeoff, the angular momentum of the entire body at takeoff, and the period of time when the right leg touches the ground.

Parameters for motion control, such as the referred joint angle, and mechanical design of the prosthesis, such as the element lengths and curvatures and the widths of the cross section, were adjusted to maximize the performance index during the optimization process. The genetic algorithms were employed as the optimization method. The initial condition of the parametric referred joint angle was determined by the motion data collected from an actual amputee jumper. An actual sports prosthesis was used as the reference for the initial condition of mechanical design of the prosthesis.

RESULTS AND DISCUSSION

In the initial condition of the optimization process, the model could not synthesize jumping motion and the amputee model fell down, as shown in Figure 1(a). As the optimization proceeded, the model could acquire jumping motion with the distance of over 7 m although the current world record for this is 6.77 m [1]. Figure 1(b) indicates the jumping motion generated after 100,000 searching iterations. As the optimization proceeded further, the cross section of the upper part of the prosthesis became smaller, i.e., the stiffness reduced. The direction of curvature of the lower part of the prosthesis reversed. The obtained mechanical properties were considered to be useful for increasing the vertical ground reaction force during takeoff. However, these properties did not seem suitable for the approach run of a long jump.

P053 - CONSIDERATION OF SENSOR POSITION AND NUMBER BY MULTI-OBJECTIVE STRUCTURAL OPTIMIZATION OF THE MOBILE FORCE PLATE BASED ON BIOMECHANICAL EVIDENCE DURING GAIT

[1] **Yuichiro Hayashi**
[1]Tokyo Metropolitan University
Corresponding author email: hayashiy@tmu.ac.jp

INTRODUCTION

The importance of rehabilitation in the treatment for walking disorders due to such illnesses as strokes continues to increase. When physical therapists instruct a patient during rehabilitation, information about joint moment of lower limb is very useful. Joint moment of lower limb has been calculated by inverse dynamics applied to data obtained from a force plate and three-dimensional motion analysis system and their use conditions and measurable amount of steps are limited because they must be installed at a purpose-built structure. A method to resolve problems can be converting analysis devices into wearable systems. Therefore, the wearable gait motion analysis system using mobile force plate [1] and attitude sensor has been developed. However, structural optimization of the mobile force plate based on the ground reaction force during gait as the experimental evidence consistent with biomechanics has not been investigated yet. In this paper, we showed a new optimum design example of the mobile force plate through the numerical simulation by applying proposed the multiple objective structural optimization technique using finite element analysis, response surface method, desirability function, design of experiments and mathematical programming. Especially, position and number of three-axis force sensor in the mobile force plate are considered.

METHODS

We suggest the method [2, 3] to optimize the design variables of the mobile force plate as shown in Figure 1. We determine the objective function by finite element analysis, response surface method and desirability function as the proposed techniques. We can effectively determine approximate functions by this method if relational expressions between design variables and evaluation indices are unknown. In the proposed techniques, we perform structural optimization of the mobile force plate as follows.
Firstly, we determine approximate values from applied loads as the ground reaction forces during human normal gait. Secondly, we determine objective functions, constraint conditions and design variables. Thirdly, we generate response surfaces of objective functions and constraint conditions. Fourthly, we determine desirability functions by response surfaces. Fifthly, we obtain optimum solution by sequential quadratic programming. Finally, we validate effectiveness of optimum solution by finite element analysis.

Figure 1: Mobile force plate as the wearable sensor system.

RESULTS AND DISCUSSION

We obtain maximum principle strains on the force plate under each load condition by using finite element analysis of the prototype. Then, we perform the initial characteristics evaluation and calculate optimum parameters. Used finite element models are shown in Figure 2 and Figure 3. Moreover, three-axis force sensor position and number are determined by the stress distribution as shown in Figure 4.

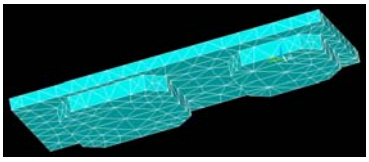

Figure 2: Finite element model of the prototype concerning the mobile force plate.

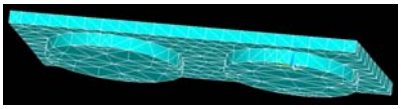

Figure 3: Finite element model of the optimized mobile force plate.

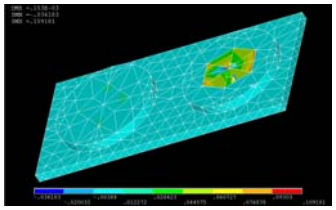

Figure 4: Stress distribution on the mobile force plate.

CONCLUSIONS

As a result of inputting each load condition by using the ground reaction force during gait as the locomotion, we could optimize the structure of the mobile force plate as the minimization of several dimensions based on the maximization of strains to each axis direction of the elements and nodes of maximum principle stresses on the force plate. Furthermore, sensor position and number are approximately determined as the improvement by the distribution of maximum principle stress on the force plate. Finally, we performed characteristics evaluation by applying optimum design variables to the simulation model of finite element analysis and validated the effectiveness of the proposed optimum design example of the mobile force plate concerning each contact condition to the floor.

P054 - FIRST METATARSOPHALANGEAL JOINT STRESS IN PLANUS, RECTUS AND CAVUS FOOT TYPES

INTRODUCTION

Feet are often categorised into three general structures: planus (low-arch), rectus (moderate-arch) and cavus (high-arch). Disorders such as hallux valgus and first metatarsophalangeal (1st MTP) joint osteoarthritis (OA) have been qualitatively associated with a lower arch alignment [1, 2]. Presence of moderate to severe 1st MTP joint OA is reported in 27% and 34% of men and women, respectively, ≥50 years of age [3]. Patients often accommodate with reduced stride length and walking speed, presenting with pain, stiffness, and in more severe cases substantial disability. It is unclear why certain pedal structures are more affected than others.

Despite extensive investigation, physiological structure and joint function in the aetiology of OA have been difficult to assess. Increased joint loading and concomitant stress affecting the articular cartilage are considered to be some of the primary factors in OA onset and progression. The difficulty in studying these mechanisms *in vivo* are the potential risks associated with such invasive measurements. Subject-specific musculoskeletal simulations enable researchers to non-invasively predict individual mechanical behavior that may increase the risk of developing pathological conditions

METHODS

Three-dimensional (3D) subject-specific finite element (FE) models of the 1st MTP joint were created from MRI datasets of two cadaveric first rays (metatarsal, proximal phalanx, sesamoids, and hallux), without OA, and were previously developed and compared with *in vitro* testing to provide experimental validation. Tissues were segmented in Mimics (Materialise, Belgium), assembled in CATIA (Dassault Systèmes, France) and meshed in Abaqus (Dassault Systèmes, France). Bones (E=7.3 GPa, v=0.3) and cartilage (E=25MPa, v=0.4) were modelled as linear elastic parts for this quasi-static analysis. Fourteen ligaments (tension-only 'wires': E=260MPa, v= 0.4) and the plantar fascia (E=350 MPa, v=0.4) were also modeled.

Vertical forces of 28N and 50N were applied to the hallux and sesamoid bones, respectively, to simulate one quarter of the physiological loading conditions experienced during gait, taken from the original forces applied to the model during experimental validation. A horizontal force of 150N~ was applied to the plantar fascia to achieve static equilibrium. The metatarsal declination angle of each FE model was then modified in the sagittal plane to simulate a planus (10°), rectus (20°) and cavus (30°) foot structure.

RESULTS AND DISCUSSION

.

The virtual representations of the planus foot presented peak compressive and shear stress values in the proximal phalanx base cartilage of -8.1MPa and 6.3MPa for specimen 1 and -5.5MPa and 4.7MPa for specimen 2, respectively. Peak minimum principal stress increased in specimen 1 by 32.1% and decreased in specimen 2 by 14.5% between planus and rectus foot structures. Peak shear stress decreased in specimen 1 by 17.4% and increased in specimen 2 by 14.9% between planus and rectus foot structures. A Cavus foot structure resulted in the lowest peak shear stress in both specimens. The highest minimum principal stress was presented in the cavus and planus foot structure for specimen 1 and 2, respectively.

	Specimen1		Specimen 2	
	Tresca	Min. Principal	Tresca	Min. Principal
Planus	6.3	-8.1	4.7	-5.5
Rectus	5.2	-5.5	5.4	-6.3
Cavus	4.2	-4.6	3.6	-6

Figure 1: Peak compressive and shear stress for 1st MTP joint loading for simulated planus, rectus and cavus foot structure for each specimen.

CONCLUSIONS

The ability to calculate internal 1st MTP joint stress can provide insight into the phenomena that may lead to OA in certain pedal structures. This is a step towards understanding the interaction between foot structure and stress in the articular cartilage of the 1st MTP joint on a patient-specific basis.

P055 - MEDIAL KNEE COMPARTMENT STRESS REDUCES AT DIFFERENT STAGES OF THE GAIT CYCLE IN RESPONSE TO ATLAS™ KNEE SYSTEM

[1,3]**Rajshree Hillstrom**, [1]Oliver J. Morgan, [2]David Lowe, [3]Anil Ranawat, [3]Austin T. Fragomen, [3]S. Robert Rozbruch, [3,1]Howard J. Hillstrom

INTRODUCTION

Osteoarthritis (OA), a degenerative joint disease, was reported to account for 1% of total deaths in 2002 worldwide [1]. About 14% of men and 23% of women over 45 years of age in the United States and Europe show radiographic signs of knee OA [2]. Excessive joint pressure is considered the common pathway that damages tissues within the diarthrodial joint. The Atlas™ knee implant, placed subcutaneously alongside the medial aspect of the knee joint, is designed to offload the medial-compartment of the knee. This may halt the debilitating symptoms associated with OA progression. A polycarbonate urethane (PCU) absorber of the implant provides an opposing force to reduce a portion of the total compressive load experienced at the medial-compartment during the weight-bearing phases of gait and posture. The goal of this study is to investigate the effect of the Atlas™ knee implant on knee joint contact stress.

METHODS

A three-dimensional subject-specific validated finite element model (FE) of a left cadaveric knee joint [3] was used in this study. Computer aided design models of the Atlas™ components were meshed, assigned material properties and boundary conditions in Abaqus FE software, and virtually fixed to the medial aspect of the knee model to simulate treatment of medial knee OA. To evaluate the compressive stress distribution within the medial compartment of the knee in response to the Atlas™ implant, the FE knee model was driven by the simulated flexion angle and compressive force experienced during the gait cycle of a healthy 68-kg subject. The femur was fixed and the tibia was rotated in the sagittal plane and free to move in six degrees of freedom in response to the loading conditions. Peak compressive stress was computed in the medial compartment of the knee with and without the Atlas™ implant at 3, 10, 20 and 30 degrees of knee flexion. Compressive force of 408N, 408N and 670N for 10 degrees at 5%, 30% and 50% of stride, respectively. At 20 degrees a compressive force of 811N and 340N was applied at 15% and 55% of stride respectively. For 3 degrees a compressive force of 220N and 670N at 0% and 40% of stride, respectively. Note that the 20 degrees of knee flexion corresponds to the end of weight acceptance.

RESULTS AND DISCUSSION

Peak compressive stress in the medial tibial cartilage with and without the Atlas™ implant at different knee angles are shown in Figure 1.

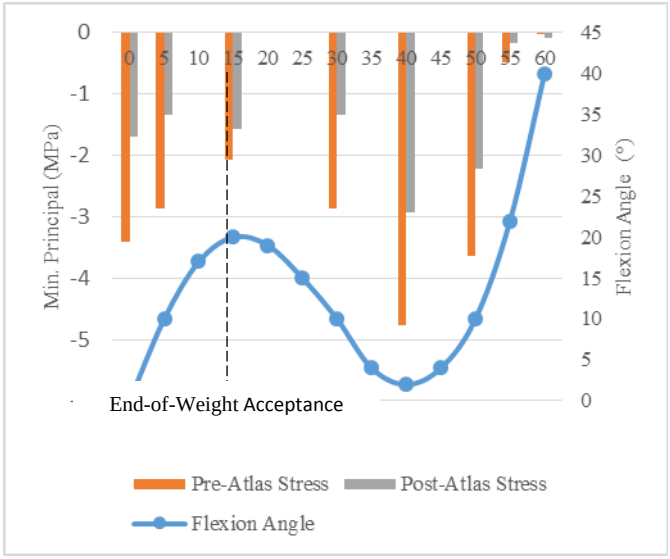

Figure 1: Compressive stress reduction in the medial knee compartment in response to Atlas™ knee system.

CONCLUSIONS

Compressive stress was reduced in the medial knee compartment throughout various stages of stride as a result of the Atlas™ knee system. The findings of this study suggest that this approach for managing varus knee OA may be a viable treatment option.

INTRODUCTION

Epidemiological studies recently have showed that a hand for a long-lasting exposure to high-frequency vibration might cause a complex of vascular, neurological, and musculoskeletal disturbances. These injuries include the peripheral nerve endings of fingertip and capillaries damaged to carpal tunnel syndrome (CTS) associated with musculoskeletal disease, etc. However, the pathophysiological mechanisms behind these effects are not still fully understood in these days. To provide a better understanding of the pathophysiological mechanisms of these vascular and neural diseases, a numerical model of a fingertip can be use serve as a useful tool to simulate the mechanical response of the soft tissue to high-frequency vibration loading. In clinical dental treatment, the dental handpieces are the typical instruments utilized by dentists and dental technicians. Due to the quality of the turbine rotor, the rotor rotating with high-speed process might develop imbalances and generate a dramatic high-frequency vibration. According to research statistics, if they exposed to high-frequency vibration from ultrahigh-speed handpieces all day, they will acquire a deficient vibration perception.. Therefore, this study developed a numerical biomechanical model of a finger based finite element technique to discuss this issue. With simulations of the model by different testing conditions, the response of finger soft tissue due to dental handpiece can be obtained and analyzed to understand this injury described above.

METHODS

The proposed model (Figure 1) is three-dimensional and incorporates the essential anatomical structures of a finger: skin, subcutaneous tissue, bone, and nail. The simulation tests were conducted by using the fingertip model to obtain the responses of a fingertip with/without wearing gloves, suffering different high-frequency vibration loading, and contacting with the different surface property of the handpieces.

Two series of numerical tests were performed. The first series of tests was to verify the response of finite element model with experimental data. The second series of tests were conducted to study the dynamic response of a fingertip. The reaction motion of the handpiece was subjected to triangular wave with peak displacement of 1 and 100um at two frequencies of 1000 and 5000Hz in pure X, Y, and mix X and Y vibration direction. The numerical tests are performed using a constant pressing displacement of 2.5mm in 0.2sec, and then alternating the different types of vibration after 0.2sec. The numerical data is collected and compared with each other in vibration power absorption density (VPAD) and kinetic energy method

RESULTS AND DISCUSSION

The result obtained from the first series of numerical tests shows the force-displacement loop has a good agreement with the experimental data [1]. The second series of numerical tests were performed to investigate the responses of a fingertip under different vibration loading. The results show: (a) After the finger wore gloves in the vibration of amplitude 100um, the soft tissue suffered less kinetic energy than without gloves. But, wearing gloves is not absolute to reduce the kinetic energy. In the vibration of amplitude 1um testing condition, wearing gloves only reduced the soft tissue suffering kinetic energy when the contact surface between the finger/gloves and handpiece had relative sliding. (b) The dental handpiece with textured surface increased the contact friction between finger/gloves and handpiece. The soft tissue suffered more kinetic energy than smooth surface. (c) Comparison with smooth and textured surface series. The dental handpiece with nitrile rubber surface reduced the kinetic energy transmitting to the soft tissue. (d) The kinetic energy of the soft tissue which suffering mixed X and Y direction vibration simultaneously equaled the total kinetic energy of the soft tissue which suffering pure X and pure Y direction vibration. use to the skin layer is close to vibration source, the kinetic energy per volume in skin layer is larger than in subcutaneous layer. And, the simulation results were calculated by VPAD method is similar to the kinetic energy of skin layer. The reason is that both of them were calculated from the velocity and contact force of the contact surface. This result shows the VPAD method cannot predict the vibration energy of the subcutaneous layer accurately.

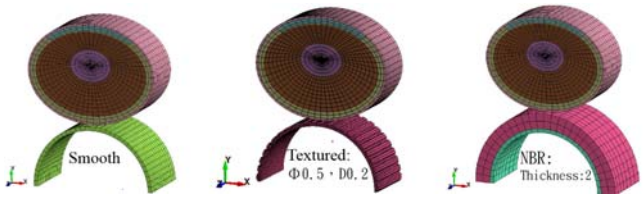

Figure 1: Proposed FE model .

CONCLUSIONS

A numerical model of a fingertip based on finite element method was established successfully in this study. The results show encouraging to understand some injury syndrome due to dental handpiece. Howe ever, some further development and validation is still needed to add to the study.

P057 - COMPARISON OF ECCENTRIC AND CONCENTRIC SCREW PLACEMENT FOR THE SCAPHOID FRACTURE FIXATION

INTRODUCTION

The scaphoid fracture is the most common carpal bone fracture (60% of all carpal fractures) and often occurred from a fall on an outstretched hand. Cast treatment of the scaphoid fracture is conservative but some complications, such as joint stiffness, decreasing of the grip strength and avascular necrosis, might lead to bone nonunion. Internal fixation of the scaphoid fracture is an alternative treatment. The stability of the fixation to the scaphoid fracture was evaluated to find out the optimal placement of the bone screw [2]. However, the placement of the bone screw of the internal fixation to different fracture type is still a biomechanical issue.

Clinically, Russe classification of the scaphoid fracture is commonly used to distinguish among horizontal oblique fracture, transverse fracture and vertical oblique fracture [1]. Nevertheless, the eccentric and concentric placement of the bone screw to the scaphoid was still a debate. Since the scaphoid played an important role in wrist biomechanics for support and force transmission from the hand, this study is to compare the biomechanical effect of eccentric and concentric placement of the bone screw for the scaphoid fracture fixation by finite element analysis.

METHODS

The scaphoid was scanned to obtain the serial CT images for the solid model reconstruction. In addition, the solid model of the bone screw (Headless Multi-Use Compression Screw, 20 mm in length and 3 mm in diameter) was also reconstructed in CAD environment. Both transverse and horizontal oblique fractures were simulated and a 2 mm gap was generated to simulate the fracture site. Concentric placement was to place the bone screw along with the longitudinal axis of the scaphoid. Eccentric placement was to insert the bone screw from the proximal apex to the midpoint of the distal pole. The complete models of the scaphoid fracture with internal fixation were then imported to finite element software for further calculation. Proximal surface was fixed and a 215 N force with 45 degrees inclination to the horizontal surface was applied to the distal end of the scaphoid. The nodal displacement of the fracture surface and the stress distribution of the entire structure were analyzed.

RESULTS AND DISCUSSION

For transverse fracture, the displacement of the fracture surface for concentric and eccentric placement were 0.012 (SD 0.009) and 0.027 (SD 0.019) mm, respectively. The stress concentration was observed in the screw and bone junction. The maximum stress of the concentric placement (322.48 MPa) was lower than that of the eccentric placement (608.40 MPa).

For horizontal oblique fracture, the displacement of the fracture surface for concentric and eccentric placement were 0.012 (SD 0.004) and 0.043 (SD 0.005) mm, respectively. The stress distribution was similar to the results of the transverse fracture. The maximum stress of the concentric placement (299.00 MPa) was lower than that of the eccentric placement (656.46 MPa).

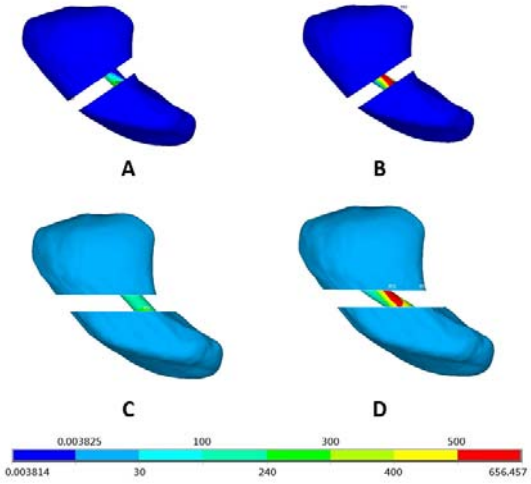

Figure 1: Von Mises Stress distribution of the scaphoid fixation (Unit: MPa). (A: Concentric placement for transverse fracture; B: Eccentric placement for transverse fracture; C: Concentric placement for horizontal oblique fracture; D: Eccentric placement for horizontal oblique fracture)

Although the concentric placement of the bone screw showed good biomechanical performance, it is not easy to be achieved due to interference of the trapezium. Therefore, the surgeon was suggested to place the bone screw along the longitudinal axis of the scaphoid as possible.

CONCLUSIONS

The concentric placement of the bone screw provided better stability than the eccentric placement for both the transverse and horizontal oblique fracture of the scaphoid.

P058 - THREE-DIMENSIONAL NEURO-MUSCULO-SKELETAL MODEL WITH MECHANICAL CHARACTERISTICS OF STRETCH REFLEX

INTRODUCTION

Clarifying the mechanism of motor dysfunctions such as gait disorder is necessary for treatment and rehabilitation. To meet this demand, many types of gait simulators have been developed. Aoi [1] suggested a simulator that considers muscle synergy of the lower limbs and trunk during gait. Ogihara [2] proposed the two-dimentional neuro-musculo-skeletal model with the antagonism of muscles. However, few simulators adequately model the mechanism of neurons and three-dimensional movement. The purpose of this study is to propose a three-dimensional neuro-musculo-skeletal model that considers mechanical characteristics of muscles and neurons such as stretch reflex and reciprocal inhibition and to analyze the relationships between the mechanical characteristics of the human body and gait pattern.

METHODS

The three-dimentional rigid link model created by Hase [3] was applied in our study. The inertial properties of the entire human body were represented by 14-rigid-link system. The interaction between foot and ground was modeled as a combination of springs and dampers. The body dynamic model is driven by 70 muscle models composed of Hill type properties [4] for the entire body. The upper diagram of Figure 1 shows the outline of the neuronal model, where u_n is the state of the nth neuron, x_n is the output of the nth neuron, u_{0n} is the constant input from the cerebral cortex, l_n is the muscle length, s_n is the output from the muscle spindle, U is the signal to control the sensitivity of the muscle spindle, A is the transmission rate of the spinal cord, K is the transmission rate for reciprocal inhibition, and G is the transmission rate for the Golgi tendon organ. Central pattern generators (CPG) are well-known systems that generate basic neural rhythms for locomotion. In this study, the model of CPG proposed by Matsuoka [5] was applied, in which a pair of neural models is used to model each degree of freedom of the joint. Muscle spindle model proposed by Hase [6] was applied to express the stretch reflex. The threshold values of the muscle spindle model parallel to the muscle length are changed and the sensitivity is controlled by the cerebral cortex. The antagonism model of muscle suggested by Ogihara [2] was applied to express the reciprocal inhibition. A model of the Golgi tendon organ, which is a force sensor that is assumed to be inhibitory and to exist only between the corresponding α motor neuron, was also introduced. In this paper, a genetic algorithm (GA) was used for tuning the neural parameters to generate locomotion.

Dietz [7] suggested that the lower limb muscles, especially knee extensor muscles, become stiffer because of spinal cord injury (SCI), so it is likely that the stiffness of the muscle disturbs the gait. Therefore, the stiffness of the knee extensor muscle (vastus) was changed and the relationship between stiffness of the muscle and gait was analyzed in this study.

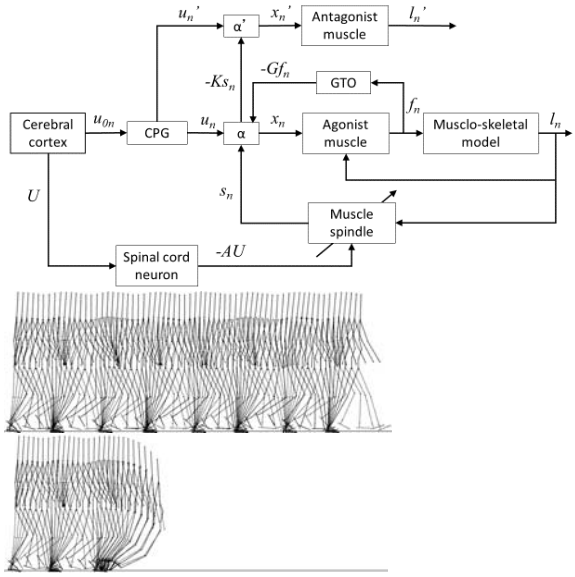

Figure 1: The overview of neuronal model and simulation result

RESULTS AND DISCUSSION

Figure 1 shows the result of the simulation through 50,000 iterative calculations of GA. As the figure shows, the model could walk normally. This gait pattern was considered as the normal gait, and the stiffness of the left vastus was changed to simulate the gait of SCI patients. In this case, as Figure 1 shows, the model stumbled because the stiffer vastus prevented the knee joint from bending. This result shows that this model could express stiff-knee gait, which is a type of typical gait pattern of SCI patients.

CONCLUSIONS

A three-dimensional neuro-musculo-skeletal model was proposed to simulate the relationship between the physical parameters and gait patterns. As per the result of the study, the model walked normally and the gait pattern when the stiffness of the knee extensor muscle was strengthened was simulated.

P059 - EFFECT OF TEMPERATURE AND HYDRATION ON THE MECHANICAL PROPERTIES OF COLLAGEN MOLECULE: A COMPUTATIONAL STUDY USING MOLECULAR DYNAMICS

[1] **Ian Ian Ng**, [2]Shu Wei Chang and [1]Hsiang Ho Chen
[1]Taipei Medical University
[2]National Taiwan University
Corresponding author email: hchen@tmu.edu.tw

INTRODUCTION

Collagen is a structural protein widely distributed throughout the body, providing mechanical properties to different tissues. It is the most prevalent component of the extracellular matrix (ECM), comprising one-third of the body's total protein [1]. Physiological, pathological and psychological conditions, as well as exercise and drugs, can temporarily cause the local temperature of tissues to shift from its set point. Since collagen is such an abundant protein in the body, we are interested in whether or not and in what way will a change in tissue temperature alter the mechanical properties of collagen.

Some groups have studied the temperature effects on the mechanical properties of collagen by directly measuring the mechanical properties using mechanical testing devices, X-ray diffraction and Atomic Force Microscopy [2,3,4], research using Molecular Dynamics(MD) Simulation as an approach is rare. MD Simulation has the following benefits: (1) Experimental results are consistent, they will not be affected by samples or human errors. (2) Collagen at different hierarchical levels can be analyzed easily, despite its scale and complexity. (3) Different parameters can be manipulated at will. (4) Detailed data of intra- and inter-molecular interactions can be obtained. Therefore, the aim of this study is to investigate the effect of tissue temperature on the mechanical properties of collagen using MD Simulation.

METHODS

LAMMPS is Large-scale Atomic/Molecular Massively Parallel Simulations, a free open source code distributed by Sandia National Laboratories for Molecular Dynamics Simulation. VMD is a molecular visualization program for displaying, animating, and analyzing large biomolecular systems using 3-D graphics and built-in scripting. Our tested molecule is a triple helix tropocollagen with 30 residues. First, those molecules were immersed in a water box to mimic the physiological condition. Second, simulation at a certain temperature was calculated until the system reaches equilibrium, where its total energy reached the minimum. Temperatures being tested are 305K, 310K, and 315K, which are 5K below and above normal body temperature (310K) (K: Kelvin). Third, atoms Root-Mean-Square-Deviation (RMSD), hydrogen bonds, end-to-end distance, and other information were collected and investigated from output files. Fourth, we modify parameters like initial velocities, flow and friction at different temperatures to further investigate the effects of temperature. Fifth, Steered Molecular Dynamics which will fix one end of the collagen and pull the other end with a constant force or velocity were applied. Then the persistence length, bending stiffness and Young's Modulus were estimated. Finally, all the information obtained at different temperatures were compared to clarify the effects of temperature on the mechanical properties of collagen.

RESULTS AND DISCUSSION

Equilibration of the molecules was reached for all the temperatures after running the simulation for 5 nanoseconds. Average end-to-end distance, average number of hydrogen bonds and their standard deviations were calculated from 2.5 nanoseconds to 5 nanoseconds (Table 1). We only evaluated data at later time steps to avoid erroneous data derived from non-equilibrated molecules. An inverse relationship between end-to-end distance and temperatures and a direct relationship between the number of hydrogen bonds and temperatures were revealed respectively. Simulation with more different temperatures and different parameters will be conducted to clarify this finding in our further studies.

Table 1. Average distance and the average number of hydrogen bonds of the collagen at three temperatures.

Temp (K)	Average distance ± SD	Average H bonds ± SD
305	85.8 ± 1.0 Å	71.0 ± 10.4
310	85.7 ± 0.9 Å	79.2 ± 7.0
315	85.1 ± 1.1 Å	82.5 ± 8.0

CONCLUSIONS

Medical science studies have long been focusing on the chemical and biological aspects of cells and tissues, but now more and more attentions have been drawn to their physical properties. As in biotechnology and tissue engineering, scientists discovered that physical properties of the extracellular matrix (ECM) or hydrogels can govern stem cells growth and differentiation [5,6]. They want to find ways to accurately modify the physical, especially the mechanical properties, and temperature may be a good approach. If the relationship between temperature and the mechanical properties of collagen can be established, it may save scientists much time and effort in regulating stem cell fate. This is the reason why this study is significant.

P060 - COMPUTATIONAL MODEL OF THE HUMAN CORNEA WITH CONSIDERING ITS MATERIAL PROPERTIES: MECHANICAL ANISOTROPY DUE TO THE FIBER ORIENTATION

[1] **Tomohiro Otani** and [1]Masao Tanaka
[1]Osaka University
Corresponding author email: otani@me.es.osaka-u.ac.jp

INTRODUCTION

The cornea is the transparent anterior part of the eye and acts as the aspherical lens to refract light and focus on the retina. Since the cornea maintains its asphericity under the intraocular pressure (IOP) on its internal surface at the equilibrium state, changes of its mechanical properties and IOP may induce abnormal changes of the corneal geometry resulting in the refractive error such as the irregular astigmatism. The ultimate goal of this study is to develop a computational mechanical model of the human cornea to improve our understandings of the pathogenesis of the refractive error in the mechanical sense. As a first step toward this goal, we introduce the computational cornea model with considering its material properties.

METHODS

Geometrical model of the cornea was represented by using two biconic functions, which expresses the internal and external surface geometries *in vivo*, respectively [1]. A volume mesh was created by using the second-order brick elements (27-node).

In the cornea, there are two collagen fiber families mainly orienting along the nasal-temporal and inferior-superior in the center whereas orienting along the circumferential direction in the limbus of the cornea [2]. To represent these fiber orientations, we modeled the direction of the fiber orientations as the unit vector of the spatial gradient of the scalar variables ϕ_1 and ϕ_2 in each fiber families. The spatial distribution of ϕ_1 and ϕ_2 was determined by solving the Laplace equation by the Galerkin finite element method.

Because the cornea is a soft biological tissue consisted of the collagenous matrices, its mechanical properties should be modeled as a nearly incompressible and anisotropic materials. The strain energy density function of the cornea W is thus, described by following three terms, given by

$$W = W_{iso}\left(\tilde{I}_1\right) + W_{aniso}\left(\tilde{I}_4, \tilde{I}_6\right) + W_{vol}\left(\tilde{I}_3, p\right), \qquad (1)$$

where W_{iso} and W_{ansio} are the chronic parts and expresses the isotropic and anisotropic characteristics, respectively. They are determined by the modified invariant of the right Cauchy-Green strain tensor, in which the volumetric deformation was eliminated. The symbol $\tilde{I}_1$ is the modified first invariant and $\tilde{I}_4$ and $\tilde{I}_6$ are the modified invariants expressing the deformation along the direction corresponding to the orientations of two fiber families. For more details of the mathematical description, one can see [3]. The volumetric part W_{vol} is determined by the third invariant I_3 and the isostatic pressure p being understood as the Lagrange multiplier. The strain energy density function proposed in [4] was adopted to the chronic parts W_{iso} and W_{aniso}. The volumetric part W_{vol} was determined by means of the perturbed Lagrangian method [5].

The corneal geometry at the equilibrium state was obtained by solving the stationary condition of Eq. (1) with respect to the displacement vector **u** and the isostatic pressure p by the Galerkin finite element method. On the boundaries, the fixed displacement condition was set in the edge and the uniform pressure condition on the internal surface with considering the physiological IOP.

RESULTS AND DISCUSSION

Figure 1(A) shows the orientation of the two fiber families. Two fiber families were perpendicular in the center and oriented along the circumferential direction in the limbus, which is consistent with the experimental observation [2]. Figure 1(B) shows the spatial distribution of the anterior displacement at the equilibrium state. The displacement distributed axisymmetrically and its magnitude was in good agreement with the *in vitro* experimental measurements [6].

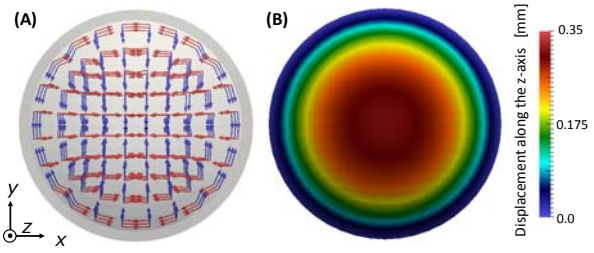

Figure 1: The orientation of the two fiber families (red and blue arrows) (A) and the spatial distribution of the anterior displacement under IOP of 16 mmHg (B).

CONCLUSIONS

We developed the computational model of the cornea considering its material properties. The results successfully exhibited the consistency with the measurement results in terms of both the fiber orientations and the mechanical characteristics under loading. For the further considerations, the corneal geometry at the unloaded state, e.g., without IOP should be estimated to represent the physiologically accurate condition.

ACKNOWLEDGEMENTS

P061 - SUPERVISED LEARNING APPROACH TO MARKERLESS ACQUISITION OF ROWER KINEMATICS

INTRODUCTION

We address the open problem of estimating rower kinematics from monocular images in unconstrained environments. Since 2D intensity images remain the most readily available method for capture of unrestricted motion *in-natura*, feature tracking via direct manual annotation of anatomical landmark locations is the most common form of analysis. Unsatisfactorily, this approach is hindered by tedious, time consuming and highly variable processing. Motivated by these limitations, we present a supervised machine learning approach for markerless estimation of rower kinematics from colour images.

Markerless pose estimation is a challenging computer vision task due to changing scene illumination, background clutter and weak appearance support compounded by deformation, rotation, and occlusions caused by the articulated body. We use a discriminatively learned mixture-of-parts model [1,2] to estimate skeletal kinematics in a given image with one or more rowers. Our technique simultaneously detects and estimates the rower's pose characterised by the joints' spatial locations and limbs' orientations.

METHODS

We construct a probabilistic tree undirected graph representation to model the configuration and appearance of the rower, whose vertices correspond to the body's joints and edges correspond to the body's segments [1]. We model the appearance of each joint by a concatenated Histogram of Oriented Gradients (HOG) feature vector, which we compute over an image patch centred at the joint. Further, we encode a richer family of appearances for each joint by modelling its appearance by a mixture of templates, instead of a single fixed template [2]. We represent the spatial relations between adjacent joints by a quadratic deformation vector from the relative position of the connected joints.

The tree graph structure leads to an efficient and tractable inference such as belief propagation. We produce candidate pose proposals by using a sliding window detection scheme over an image pyramid. We use our models to compute a score for each joint, at every pixel location, and for all appearance mixture components. The optimal match of a model to an image is found by maximizing the score function over all pixel locations and mixture components.

A score associated with a particular pose is a function of the joints' appearance and pose deformation. A unary scalar term measures the appearance discrepancy for each joint with a local template, and is based on convolving the image with a family of underlying linear local templates. Similarly, a pairwise scalar term measures the deformation cost for a given pair of connected joints. A low negative score indicates that a joint's location and orientation with respect to its parent (proximal joint) is close to the learnt prior spatial relations model. We retain the best-scoring candidate rower poses using a threshold and apply non-maxima suppression to prune overlapping proposals.

We learn joints appearance and spatial relations models by training a classifier using a structured support vector machine on 146 manually annotated positive examples of joint locations and 1245 negative examples that are split for model training and cross validation (Fig. 1). Learning is cast as obtaining a weight vector and scalar bias, and is equivalent to solving a quadratic programming optimisation problem. It is underpinned by the notion that a collection of weak classifiers collectively creates a strong class classifier.

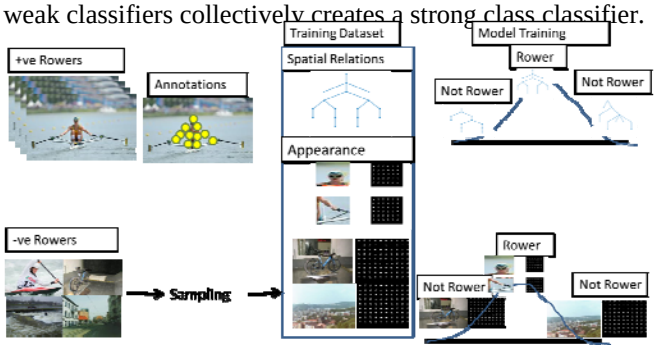

Figure 1: A supervised learning framework of our approach. Appearance and spatial relations features are extracted from both positive and negative images to train an object model.

RESULTS AND DISCUSSION

We evaluate the precision of our method on task-specific datasets using loss functions, and achieve scores of 78.4 and 73.3 on the Probability of Correct Keypoint (PCK) and the mean Average Precision of Keypoints (APK) measures, respectively, which is comparable to the state-of-the-art.

It is impossible to design a discriminative classifier for the general case due to the high variability in the appearance of human motion. The performance of the approach critically relies on the availability of a large quantity of training samples. Therefore, addition of adequate training samples is needed to achieve generalisation of the approach.

CONCLUSIONS

We present a supervised learning method for markerless pose estimation of rowers on-water. Our method simultaneously yields detection and pose estimation for skeletal kinematics extraction. Our technique finds multiple quality hypotheses for the pose.

P062 - RELIABILITY ANALYSIS OF A SOFTWARE ALGORITHM TO PREDICT CENTER OF MASS FROM CENTER OF PRESSURE ON A ZENO WALKWAY DURING GAIT

[1] **Eric D Jenkins**, [1]Brian J Prejean, [2]Christopher T Ray and [1]Mark D Ricard

INTRODUCTION

Calculating center of mass (COM) is a critical component of falls risk analysis in a clinical setting and is observed and calculated both statically and dynamically [1]. When COM goes outside the base of support, the risk of falling is increased [2, 3, 4]. The ability to track these components has been explored using force platforms as well as motion capture technology [4, 5]. In clinical settings, pressure mats are often used to estimate gait parameters. The ProtoKinetics Zeno walkway (PK) (ProtoKinetics, Havertown, PA, USA) utilizes data from thousands of pressure sensors to assess center of pressure (COP) throughout the gait cycle. The center of mass estimated (COMe) is a ProtoKinetics proprietary algorithm which estimates COM based on the changing patterns and values of the pressure sensor activations over time. At least one second of data, both before and after any given point in time, is needed to project the COMe. The purpose of this study was to determine the accuracy of the PK COMe algorithm to predict the body COM in gait.

METHODS

13 college aged males served as participants (height: 1.80±.08 m, mass: 83.43±12.24 kg). A full body 60-marker set using de Leva's segmental inertial parameters was used to define 15 segments: head and neck, trunk, pelvis, upper arms, forearms, hands, thighs, lower legs, and feet [6]. Reflective markers (12.5 mm) were placed over bony landmarks and 4-marker clusters were used for tracking markers on the trunk, arms, and legs. Walking trials were collected using a 16-camera 3D motion analysis system (MX-T40S, Vicon, Oxford, UK) and synced to the Zeno walkway (PK) at 120 Hz. Each participant performed 10 walking trials at a self-selected speed where the participant walked to one end of the mat, turned and returned back to their starting position. The marker data were interpolated and low pass filtered at 6 Hz using a 4th order Butterworth filter. The X, Y coordinates of the body COM were translated into the Zeno walkway coordinate using a custom C# program. The validity of the PK COMe algorithm was determined using linear regression to predict the body COM from the COMe data. The standard error of estimate (SEE), R^2 and RMS errors (RMSE) were computed and then averaged across all subjects and trials.

RESULTS AND DISCUSSION

The PK COMe predicted the X coordinate (mediolateral) of the body COM with an average RMSE of 5.14 ± 0.80 cm (95% CI: 5.00 – 5.28 cm), R^2 = 0.99, SEE = 3.13 cm. Low pass filtering of the PK COMe X coordinates at a cutoff of 0.6 Hz improved prediction of the COM X position with an average RMSE of 3.53 ± 0.37 cm (95% CI: 3.46 – 3.59 cm), R^2 = 0.99, SEE = 2.04 cm. The PK COMe predicted the body COM Y (anteroposterior) coordinates with an average RMSE of 3.40 ± 0.87 cm (95% CI: 3.25 – 3.55 cm), R^2 = 0.99, SEE = 3.31 cm. Low pass filtering of the PK COMe Y coordinates at a cutoff of 0.8 Hz improved prediction of the COMY position with an average RMSE of 1.99 ± 0.37 cm (95% CI: 1.93 – 2.06 cm), R^2 = 0.99, SEE = 2.00 cm. An overview of the PK COMe RMSE is presented in Figure 1.

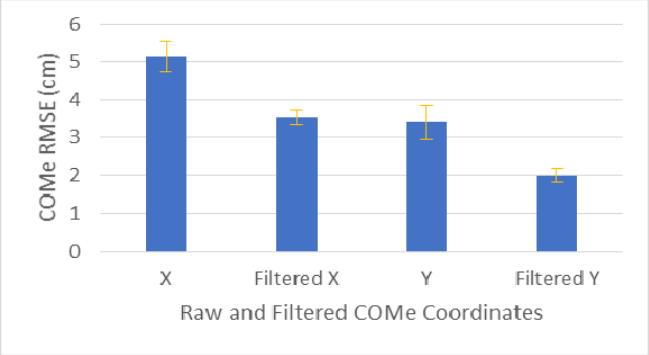

Figure 1: Average RMSE of PK mat COMe X and COMe Y before and after additional filtering.

CONCLUSIONS

The PK COMe algorithm has a prediction error of 5.14 ± 0.80 cm and 3.40 ± 0.87 cm in X, Y, respectively. After additional filtering to remove noise from the PK mat, the error was decreased significantly in both planes. Although the error may remain too large for research purposes, it can serve as a quick reference for clinical applications. The larger PK COMe amplitude could be attributed to the variability seen in the COP transition throughout the footstrike, which resulted in a larger sway amplitude when compared to Vicon COM data.

P063 - MEASUREMENT OF LOCALIZED MUSCLE FATIGUE DURING PROLONGED LOW-LOAD EXPOSURE: A COMPUTER-VISION BASED MUSCLE STIMULATION APPROACH

[1] **Bochen Jia**, [1] Yi Wang, and [1] Hong Zhao
[1]University of Michigan- Dearborn
Corresponding author email: bochenj@umich.edu

INTRODUCTION

Modern living and contemporary work both involve increased sedentary behaviors including more frequent and prolonged sitting, which usually required sustained muscle activity at low-load levels. Measuring muscle fatigue is one important method to quantify the effect of prolonged low-load exposure. Changes of median frequency of muscle Electromyography (EMG) is a common indicator to quantify such muscle fatigue. However, measuring muscle fatigue using EMG-based methods have shown conflicting results under low-load exposure condition. Measuring muscle twitch responses, on the other hand, provides an alternative means for identifying muscle fatigue, which is defined as a reduction in measured twitch responses after muscle fatigued [1]. However, an accurate measurement of evoked twitch response highly relies on the direct measurability of targeted muscles. To avoid such constraints, a computer vision based approach is developed here to quantify the changes of the contractile properties of targeted muscle. Computer-vision can be used as a non-invasive technique for determining muscle contractile properties through measuring the displacement of muscle belly evoked by external muscle stimulation. The changes of such muscle belly displacements can be further used as a measurement of muscle fatigue.

Therefore, the goal of this research was to develop a computer-vision based stimulation method to quantify potential muscle fatigue resulted from prolonged low-load exposure. We hypothesize that muscle fatigue developed during low-load prolonged sustained exposure would be associated with reduced muscle belly displacements evoked by muscle stimulation.

METHODS

Six subjects (gender balanced) were recruited. The right Middle Deltoid muscle were selected to stimulate using a dual-channel, current-controlled muscle stimulator (Grass S88, AstroMed, Inc., West Warwick, RI) in series with a stimulus isolation unit (SIU5, AstroMed, Inc., West Warwick, RI) and a constant current unit (CCU1, AstroMed, Inc., West Warwick, RI). Two pairs of 3.4 x 5.1 cm bipolar stimulating electrodes (PALS® Platinum Model NC89201, Axelgaard Manufacturing Co.Lltd., Fallbrook, CA) were placed over the middle Deltoid muscle belly. To minimize voluntary muscle activity during stimulation, one bipolar wireless surface EMG electrode was placed at the center of middle Deltoid to monitor the voluntary activities of Deltoid muscle. At the beginning of data collection, participants were placed in the customized fixture in a seated posture with the right arm placed in a horizontal position. Participants' skin around Middle Deltoid muscle region was prepared and then stimulated using the protocol developed in our previous study [2]. The sitting posture and arm position were marked to minimize the potential repositioning differences. After completing the first stimulation session, participants were asked to complete a up-to one-hour constant-loading fatiguing trial. Right after the fatiguing trial, participants were required to repeat the stimulation protocol at the marked position. During both stimulation sessions, the twitch responses (i.e., muscle belly displacements) were captured using an action camera at 120 frame per second with 1080P resolution. The OpenCV Lucas Kanade method was applied [3] to identify the displacement of muscle belly and the maximum displacement is identified using the peak detection. Data was filtered with bandpass at [0.5, 5] Hz with 4th order butterworth filter.

RESULTS AND DISCUSSION

As shown in Figure 1, muscle belly displacement was successfully identified using the developed computer-vision based method. The changes in the displacements before and after the fatiguing trial were observed, i.e., muscle fatigue introduced by the fatiguing trial were observed.

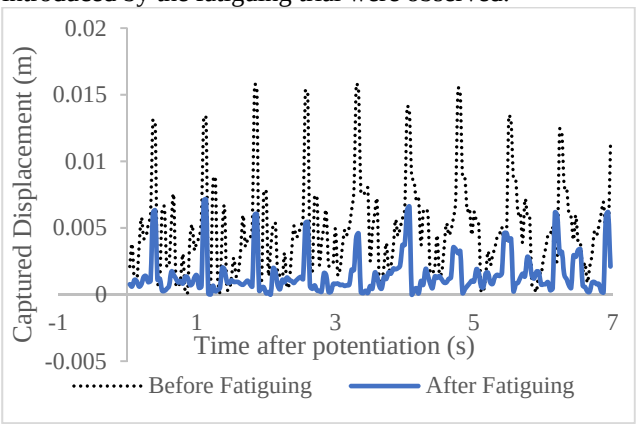

Figure 1: Illustration of detected twitch responses (displacement) before and after fatiguing trial.

Across all 6 subjects, peak detected after fatiguing trial yield a smaller amplitude. No significant gender differences were observed in identified twitch response. Further study is needed to extend current method to account for more inter-subject variabilities, more realistic tasks conditions, such as, prolonged sitting or driving task, and various exposure duration.

CONCLUSIONS

This study demonstrated the ability of a computer-vision based stimulation method on detecting muscle fatigue. Current results will be used as a foundation to develop a sensitive and reliable method to quantify the effects of prolonged automated driving tasks.

P064 - SYSTEMATICAL ASSESSMENT OF ACTIVATION OF LOW BACK MUSCLES DURING PAINFUL ACTIVITIES - INTRODUCTION OF A METHOD TO GUIDE AND TO CONTROLE THE MOVEMENT

[1]**E. Junker**, [1]F.M. Bergamo and [1]C. Disselhorst-Klug

INTRODUCTION

Patients suffering from low back pain report frequently about serious pain when performing activities of daily life. This pain is related to specific movement tasks, can be reduced by coping movements and may even not occur at all under certain circumstances. It is known that low pain is associated with false muscular activation of back and abdominal muscles. However, these findings have mostly obtained in artificial movement conditions, e.g. isometric contractions, which do not reflect the daily life situation and the transfer to daily life might be questionable. Furthermore, information even on the physiological activation of back and abdomen muscles during daily activities is heterogeneous in literature. This might be due to the fact that freely performed movements related to activities of daily life are complex, differ in their execution between different subjects and repetitions and are, therefore, hard to analyze. On the other hand, correct interpretation of the muscular activation pattern needs the information about the performed movement. Additionally, to achieve comparability between different subjects or groups the performed movement has to be reproducible with less tolerance as possible.

Consequently, systematical assessments of the activation of low back muscles during painful activities of daily life needs guidance and control of the performed movement in such a way that reproducibility and comparability is reached.

METHODS

In a first step activities of daily life have been identified, which cause pain and which are most difficult for the patients. For this purpose, 20 patients with specific low back pain have been asked about tasks of daily living causing pain. From that survey movement components have been identified which are common to most of the painful activities. Afterwards, exercises have been defined, which include mainly these pain causing movement components.

In a next step an exercise course of different assistive devices has been developed, in which the exercises can be performed by the subjects in their individual movement rhythm and velocity. These devices are mechanically built in such a way, that coping movements are reduced. In this way, guidance is given to the subjects while performing the exercise. Additionally, die devices are equipped with sensors in such a way that body position, movement speed and direction of movement can be detected. In this way, the performed movement can be controlled and spatio-temporal synchronization between movement and muscular activation becomes possible.

RESULTS AND DISCUSSION

From the survey can be concluded, that those daily activities are difficult for the patients which include movements components related to stabilizing the trunk, flexing and extending the hip or rotating and/or bending the spine. Six exercises have been identified which incorporate these movement components: 1. walking at self-selected speed, 2. climbing stairs up and down, 3. chair-rising without the help of the arms, 4. non-leaning upright standing, 5. holding the upper body in a forward flexed position and 6. bending the trunk to one side with simultaneous rotation.

Figure 1 shows the resulting 5 devices which are needed to guide the movement during each task.

Figure 1: Devices to guide and to control the movement

Switches are included in the steps of the stairs (2), in the seat (3) and in the device controlling non-leaning upright standing (4). 5 magnetic sensors have been embedded in the arc to control the position of hand and trunk (5) and (6). Additionally, one accelerometer has been mounted to the chest of the subject to control movement in those phases in which no physical connection between subject and device was possible (1) and partly (2). Since each of the sensors integrated in the device give binary information (on or off), a string consisting of sequences of “0” and “1” can be defined, which is unique for each combination of exercise and body positon. In this way, spatio-temporal information about individual movement during the task is gained.

Spatio-temporal information about the individual movement in combination with the containment of coping movements is necessary to achieve comparability between different subjects or groups and to analyze muscular activation correctly. In contrast to tracking systems, which would gain spatio-temporal information too, the shown approach reduces the variability in the execution of the movement task. This becomes more pronounced, when additionally the sensor information is used to give feedback to the subjects.

CONCLUSIONS

This paper presents a measurement set-up, which guides and controls movements relevant for patients with low back pain in their daily activities and which enables in this way the systematical assessment of their muscular activation in painful conditions.

P065 - DEVELOPMENT OF A DETECTION ALGORITHM FOR CLASSIFICATION OF LEVEL AND STAIR TRANSITION

[1]**Pankwon Kim**, [1]Jinkyu Lee and [1]Choongsoo S. Shin
[1]Sogang University
Corresponding author email: cshin@sogang.ac.kr

INTRODUCTION

The outdoor environment consists of various terrains. Recognizing and distinguishing those terrains is necessary when using a walking assist device for daily activities. In particular, stair walking transitions were reported to be dangerous compared to level walking [1]. When transitioning from level to stair walking, movements of lower extremity must be modified to adapt to the changed terrain. However, some detecting systems, such as a camera-based motion system and a Kinect, used for human activity recognition are limited to using a wearable device [2]. Using a pressure sensor, which has higher portability and a lower cost than other recognition systems, could be beneficial for classifying level walking and level to stair transition. Thus, the purpose of this study was to develop a new detection algorithm for classification of level walking and level-to-stair transition based on plantar pressure.

METHODS

Fourteen male (age: 24.5±2.7 years, mass: 74.5±10.2 kg, height: 1.76±0.03 m) participated in this study. The subjects were instructed to walk in the following three conditions: level walking, level to stair ascent transition (L-SA) and level to stair descent transition (L-SD). The subjects walked at their self-selected speed and underwent three valid trials. A five step staircase was built and used in this study. The plantar pressure data during stance phase was collected at 100 Hz. The stance time, mediolateral (ML) center of pressure (COP), anteroposterior (AP) COP, ML range of COP, AP range of COP, ML COP excursion and AP COP excursion were calculated. The data was smoothed using a zero-lag fourth-order Butterworth low-pass filter with a cutoff frequency of 6 Hz using Matlab® R2016b. To find the parameters for logistic regression model, independent two-tailed t-tests were performed at significance level of 0.05. Then parameters which were significantly different between each movement were adopted.

To classify the level and level to stair transition walking, the parameters that distinguish the situations were selected based on result of t-test. The polynomial logistic regression method was used to classify the situations. When the polynomial logistic regression model was generated, the regression coefficient can be obtained and the probability was calculated using the regression coefficient. A detection algorithm consists of four tasks (Figure 1). To detect the situation, first task was to classify the test data and the model data to make the model randomly. The 42 trials were randomly selected for prediction test and 92 trials were selected for the model development. Second task was to make a model that used to detect the probabilities of the different possible outcomes using the selected data to make the model. Third task was to carry out a polynomial logistic regression to classify level walking and transition walking from level to stair. The final step was to perform a polynomial logistic regression to classify transition from level walking to stair ascent and descent. In the third and final steps, probabilities of successful detection were calculated respectively. The overall probability calculated by multiplying probability of third and final task.

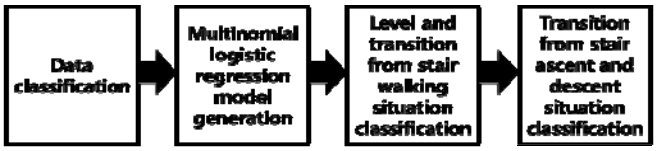

Figure 1: Proposed algorithm flow

RESULTS AND DISCUSSION

The stance time, AP COP at initial contact, AP range of COP and AP COP excursion were significantly different in the comparison among level, L-SA and L-SD walking (all three pairs, $p<0.001$). The ML COP at initial contact, ML range of COP and ML COP excursion were not significantly different among three situations. Therefore, the stance time, AP COP at initial contact and AP range of COP were selected as the classifying parameters between level and transition walking. The AP COP excursion, stance time and AP range of COP were selected as the classifying parameters between L-SA and L-SD.

The probability (sensitivity) of distinguishing between level walking and transition from level to stair walking was 0.952. The probability of distinguishing between L-SA and L-SD was 0.893. Thus the overall probability of successful detection was 0.850. The results indicate that level walking and transition from level to stair walking is easier to be classified than L-SA and L-SD. The overall probability of 0.85 suggests that it is difficult to distinguish between two situations by only the parameters extracted using the plantar pressure. Further study is needed to increase the probability of detection by adding other modalities such as joint kinematics for classifying the transition from level to stair ascent and stair descent.

CONCLUSIONS

The classification of level walking and level-to-stair transition is fundamental to detection algorithms. The main advantage of the proposed approach comes from the fact that the statistical model takes into account the algorithmic changes over the selected parameter through the hidden logistic process. This work gives interesting perspectives in terms of automatic segmentation and characterization of the gait situation detection for the walking assist device.

P066 - BIOMECHANICALLY-ASSISTIVE GARMENT OFFLOADS LOW BACK DURING LEANING AND LIFTING

Erik P. Lamers, Aaron J. Yang and Karl E. Zelik
Vanderbilt University
Corresponding author email: erik.p.lamers@vanderbilt.edu

INTRODUCTION

Low back pain is the leading cause of limited physical activity, affecting 80-85% of adults in their lifetime [1]. Development of low back pain can result from elevated, prolonged and/or repetitive forces on the spine, which commonly occur during daily activities such as leaning and lifting. Wearable assistive devices (e.g., exoskeletons) are emerging as a potential means of mitigating low back injury risks and associated pain, by offloading the lumbar spine. The majority of these exoskeletal devices have bulky form-factors (designed for use in industrial settings), but are impractical for daily use at home or in other business, social or clinical settings. An appealing, low-profile alternative may be to adapt clothing by embedding structures that assist movement biomechanics. These structures could be entirely passive (springs), quasi-passive (clutchable springs), or active (actuated); where both quasi-passive and active might be controlled via feedback from wearable sensors. The purpose of this initial study was to investigate the degree to which a biomechanically-assistive garment could passively offload lumbar muscles and discs during leaning and lifting.

METHODS

We developed a biomechanically-assistive garment prototype that passively assists lumbar extension during leaning and lifting, and is sufficiently low-profile to be worn as (or under) clothing. We then tested 7 healthy subjects performing leaning and lifting tasks with vs. without the prototype to assess its effect on lumbar muscle activity, which was used as an indicator of biological tissue loading. The prototype consists of an upper-body interface (shirt), a lower-body interface (shorts), and elastic bands which run along the back, connecting the upper and lower interfaces (Fig. 1A). As the user leans forward, the elastic bands stretch, providing a lumbar extension moment, which reduces moments required by the muscles. Because the elastic bands act with larger moment arms about the spine (than muscles), they provide equivalent extensor moments with smaller force magnitudes, resulting in reduced compressive forces on the spine. Subjects performed 10 trials: (3 leaning angles + 2 lifting weights) x (2 conditions, i.e., with and without the prototype), while we recorded kinematics, force and electromyography (EMG) data. Each subject gave informed consent prior to participation. Subjects leaned forward to a pre-determined angle (30°, 60°, 90°) for 30 seconds while holding a 4.5 kg weight to their sternum. Subjects then lifted a weight (12.7 or 24 kg) using a squat posture. Mean and peak EMG were the main outcomes for the leaning and lifting trials, respectively. Intersubject means and standard deviations were computed. T-tests were performed to assess significance (alpha = 0.05).

RESULTS AND DISCUSSION

Wearing the prototype during leaning and lifting tasks reduced erector spinae EMG activity (Fig. 1B). Mean EMG was reduced by 15% ± 19% (p=0.07), 27% ± 10% (p=0.001) and 43% ± 33% (p=0.02) for the 30°, 60° and 90° leaning conditions, respectively (Fig. 1C). Peak EMG was reduced by 10% ± 22% (p=0.12) and 11% ± 22% (p=0.07) for the 12.7 kg and 24 kg lifting trials, respectively.

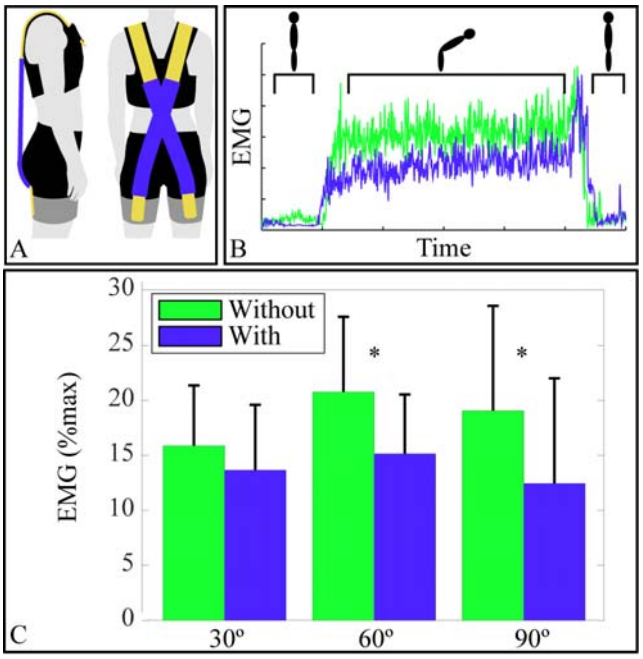

Figure 1: (A) Wearable prototype. (B) Representative EMG vs. time plot for leaning. (C) Mean erector spinae EMG was reduced during leaning With (blue) vs. Without (green) the biomechanically-assistive garment prototype.

These EMG reductions suggest that the prototype reduced lumbar muscle forces. Since these muscle forces constitute the majority of compressive force on the lumbar spine [2], these findings suggest that lumbar disc loading may also be reduced. These results demonstrate the feasibility of biomechanically-assistive garments to reduce lumbar muscle and disc loading, which may help mitigate overuse and/or overloading risks that can lead to low back injury and pain. Future prototypes will integrate quasi-passive structures and wearable sensors in order to control the magnitude and timing of assistance.

CONCLUSIONS

We found that passive, biomechanically-assistive garments are capable of offloading low back muscles, and potentially discs, during leaning and lifting, which may reduce force-induced injury risks.

P067 - MS KINECT A POTENTIAL GAIT ANALYSIS SYSTEM: CLOTHING EFFECT ON THE GAIT KINEMATICS

[1] **Chandu Parimi***, [1]Venkateswaran R, [1]Sanketh V Sai, [1]Vishal B Athreya, [2]Prakash Shrivastava and [1]Tathagata Ray

INTRODUCTION

Quantitative gait analysis (QGA) is rarely used in India as the gait analysis systems currently available are very expensive. Unfortunately, India, the world's second most populous country, is facing the emergence of a hitherto "hidden" epidemic: neurologic disability[1]. This epidemic will potentially add over 3.5 million people to the disabled population annually. Hence, an affordable and accessible QGA tool is need of the hour in India.

Earlier studies have shown Microsoft (MS) Kinect can be a simple affordable robust gait analysis system [2].Unlike marker systems Kinect do not require any external fiducial markers. Kinect tracks skeletal motion of a person. The skeleton is framed by finding the joint positions of the human body inside the field of view of the Kinect sensor. Since the measurement of kinematics is based on this skeleton, the skeleton of a person has to be captured as accurately as possible for robust kinematic measurements. It was observed that the clothing (of a person) affects the skeletal tracking. It should be noted that in a culturally diverse country like India, it is imperative to understand the effect of clothing on the kinematics when using the Kinect system. To our knowledge the effect of clothing on Kinect system for gait analysis has not yet been studied.

METHODS

Microsoft Kinect Xbox 1 (http://www.xbox.com/en-IN/Kinect) was used as a gait analysis system. Figure 1 shows schematic of our gait analysis setup. The distances shown in the schematic i.e. the distance between the camera and walkway, length of the walkway were determined after several experimental trials. In order to capture more accurate gait data the subjects were asked to start walking from a faraway distance such that, when the person reaches the field of view, he/she is in normal gait. This starting point is about 3 to 3.5 meters away from the sensor. With this setup 1- 1.5 gait cycles for each subject was achieved. Since Kinect data also depends on the ambient lighting, tilt angle of the Kinect and the height at which it is placed above the ground, it was ensured that all the above parameters were same throughout our experiments.

Thirteen healthy volunteers 18-21 years of age participated in this study. Subjects were asked to wear different dress codes (dress code 1 Shirt and Jeans Pant, dress code 2 Shirt and Shorts). For each combination of subject and dress code 5 trails of gait data was collected. From the Kinect data information of each joint was obtained in 2.5D frame and converted into real world coordinates. Here only the knee joint flexion/extension angle measured using Kinect are reported.

RESULTS AND DISCUSSION

For each subject average knee flexion /extension angle was calculated using all the five trials. In order to evaluate the consistency of the data across all the trails, the knee angle (y-axis) data for all the trails against frame rates (x-axis) were plotted. Since the frame rate is uniform across all the trails for a subject, at each frame the difference between maximum and minimum values were calculated. This gives us the range of knee angle values for a subject. Similarly range is calculated for all the 13 subjects and for the both the dress codes. To compare the knee angle values for different dress codes across the subjects, the x-axis was converted to percentage of gait cycle. We measured range at each % of the gait cycle to compare the dress codes.

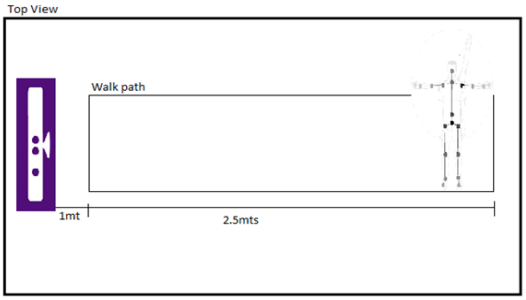

Figure 1: Kinect Experimental Setup.

Standard deviation was also calculated along with the average curve and a 95 % confidence interval was set. For each dress code the number of subjects whose knee angle fell within this 95% interval was found. It was observed that 9 out of 13 subject's knee angle was within the 95% when wearing shorts as opposed to 7 out of 13 with jeans. We also compared the average of all the subject's knee angle for both the dress codes with the normative adult database [3]. Percentage error was calculated across the entire gait cycle and the average value for the entire gait cycle was measured. For jeans the average error is 38% and for shorts it is 27%.

Our observation showed that gait data obtained using shorts seemed to be closer to normative data as opposed to jeans. It was observed that knee angle for a fully clothed subject with a tight fit closely followed normative database values whereas; when the clothing is not tight these values deviated substantially. Since in shorts the knee joint is more visible to the Kinect sensor, the error in knee angle is less.

CONCLUSIONS

Our results show that Kinect an affordable sensor and can be used to acquire knee flexion/extension angles. Our results indicate that the kinematic data obtained by wearing shorts are very consistent across all the trials and among the subjects.

P068 - PRE-IMPACT FALL DETECTION ALGORITHM AND THE DEVELOPMENT OF A HIP PROTECTION AIR BAG SYSTEM

Ahn Soonjae, Choi Eunkyoung, Kim Jongman and Kim Youngho
Department of Biomedical Engineering and Institute of Medical Engineering, Yonsei University
Corresponding author email: younghokim@yonsei.ac.kr

INTRODUCTION

Falling is a major cause of injuries and deaths in elderly adults [1,2]. As for intervention strategies, one of the important problems in preventing or reducing the severity of injury in the elderly is to detect falls before impact [3]. Many studies have been done to prevent from falling by using alarms or airbags. However, there were limitations such as a poor effectiveness of the detection algorithm and the usage of gunpowder for the airbag inflator. A pre-impact fall detection algorithm using an inertial sensor and a spring-trigger type airbag system to protect from fall damages were developed in this study. The effectiveness of the algorithm was also tested in daily activities and simulated falling conditions.

METHODS

Four different simulated falls tests were performed to 20 healthy volunteers (23.4 ± 4.4 years), and six different daily activities were also tested for fourteen elderly subjects (71.8 ± 4.0 years). An inertial sensor unit (MPU-9150, Invensens®, USA), placed at the waist, was used to measure acceleration, angular velocity, and vertical angle during all those activities. Acceleration of 0.9G, the angular velocity of 50º/s, and vertical angle of 25º were set as the threshold of the pre-impact fall algorithm based on the fall data.

The belt-type airbag system with a buckle wearing structure was composed of a polyurethane inner skin and an artificial leather outer shell. A spring-trigger type inflator and a helium gas cartridge were used to inflate the airbag when falls were detected based on the algorithm (Figure 1).

Figure 1: Air bag system and spring-trigger type inflator

RESULTS AND DISCUSSION

For the evaluation of the developed airbag system, a human model dummy and ten healthy adult males (28.5 ± 2.7 years old) were fitted with an airbag system and performed the same activities three times. The simulated fall test results showed that for every fall, the airbag inflated (100% sensitivity) by detecting a fall before 401.97 ± 46.94 ms of impact. In all daily activities, no airbag inflation was noticed (100% specificity).

In the assessment of successful balance recovery from the complete loss of balance in a fall, Thelen et al. [4] found that the maximum lean angle where subjects could recover balance with a single forward step was 32.5° for young men and 23.9° for older men. Our threshold of 25° of trunk inclination is well within the limits of balance recovery during the fall process. In addition, the spring-trigger type inflator is advantageous to be licensed because it is much safer than the gunpowder type inflator.

CONCLUSIONS

In this study, the pre-impact fall detection algorithm with the acceleration of 0.9G, the angular velocity of 50 º/s, and tilt angle of 25º was developed by measuring accelerations and angular velocity signals during fall and daily activities. The developed algorithm was embedded in a belt-type airbag system to protect hip joints before the impact caused by falls. Test results showed both 100% sensitivity and 100% specificity of the developed algorithm for all simulated falls and fully inflated by detecting 402 ± 46.9 ms before the impact. In this study, a spring-trigger type inflator for the airbag system was also successfully developed to overcome the limitation of the gunpowder system.

P069 - EVALUATION OF STATIC AND DYNAMIC EQUILIBRIUM OF OBESE PATIENTS SUBMITTED TO BARIATRIC SURGERY

[1]**Paula S. Anjos**, [1]Raquel de Paula Carvalho, [2]Michel Bastouly and [1]Helga Tucci
[1] Federal University of São Paulo;
[2]Sector of General Surgery – Santa Casa of Santos

INTRODUCTION

According to the World Health Organization [1], more than 1.9 billion adults are overweight and 13% of those adults are obese. Obese has lower base area of support and, consequently, worse postural balance when compared to lean population [2].

The objective of this study was to analyze the effects that the change in the body mass has on the static and dynamic balances of obese who were submitted to bariatric surgery. The hypothesis is that obese patients will improve their static and dynamic balance after surgery.

METHODS

These are preliminary results of a non-probabilistic cross-sectional study. A convenience sample of 5 subjects with class II and class III obesity that were submitted to gastric bypass were enrolled. Subjects were evaluated 30 days before and 30 days after surgery. Static and dynamic balances were evaluated by kinematic and the MiniBESTest, respectively. The marker for kinematic tracking was fixed at the sacral region (S2). The kinematic sampling involved 24 trial of 30s each, with 30 seconds of rest interval between trials, i. e., 6 trials under the following randomized conditions: opened eyes-stable surface (oe_ss); closed eyes-stable surface (ce_ss); opened eyes-unstable surface (oe_us); and closed eyes-unstable surface (ce_us). During kinematic data acquisition, subjects were in orthostatic position, barefoot and with arms at the body sides. The MiniBESTest was performed and scored based on the authors´ recommendations [3]. The reconstruction of the kinematic was done through the software Dvideow© and the data obtained from the marker were used to analyze the CoP oscillations in the anteroposterior (AP) and mediolateral (ML) directions. The calculation of the kinematic variables was done by Matlab© 7.9. Anova with repeated measurement was performed to analyze AP and ML oscillations, and t-Student test was applied for MiniBESTest data. A significance level of 0.05 was set.

RESULTS AND DISCUSSION

There were no significant differences in AP oscillation for time (p=.12), condition (p=.26) and interaction (p=.86). Also, there were no significant differences in ML oscillation for time (p=.35), condition (p=.21) and interaction (p=.47) (Figure 1).

No significant differences were found between MiniBESTest results before (M = 24; SD = 2,56) and after (M = 26; SD = 2,64) surgery.

Moreover, weight loss determines a decrease in CoP velocity resulting in an improvement in postural balance, also due to body mass reduction. (5).

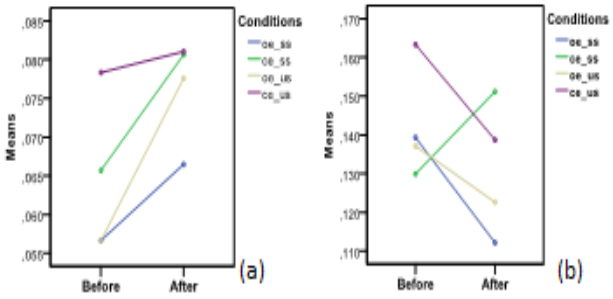

Figure 1: Means values of (a) AP oscillation and (b) ML oscillation in the 4 conditions before and after surgery.

The results of the present study may have been influenced by the short time of reassessment of balance after surgery. Significant changes in postural balance, as demonstrated by previous studies, evaluated patients after 3 and 6 months [4,5]. During this period of time, a greater adaptation involving the somatosensory system associated to weight loss may occur [4].

The sample size of the study is a limiting factor. However, besides results showed no difference in the static and dynamic balance, it is important to emphasize that this is a preliminary study and the data cannot be generalized to the obese population.

CONCLUSIONS

No improvement in static and dynamic balance of obese patients submitted to bariatric surgery was demonstrated one month after gastric bypass surgery by the present study. The short period of time for balance reassessment after surgery may be the main responsible factor.

P070 - MUSCLE SYNERGIES IN PATIENTS WITH PATELLOFEMORAL PAIN DURING WALKING AND STAIR CLIMBING

INTRODUCTION

Patellofemoral pain (PFP) is a common and disabling condition and is believed to have a mechanical aetiology. [1]. Muscle forces play a critical role in distributing loads through the patellofemoral joint and activation strategies are expected to be different in patients who experience patellofemoral pain [2]. Muscle synergies are groups of muscles activated by the same signals from the central nervous system. Synergies in patients with neurological disorder, such as stroke, experience changes in muscle synergies as a result of their condition [3]. Chronic patients who experience PFP might also undergo changes in their control strategies as an adaptation to pain, particularly during tasks such as stair climbing, that exacerbate loading of the joint. We investigated synergies in muscles that cross the knee during walking and stair climbing in PFP patients and pain-free controls.

METHODS

Muscle synergies were extracted from the electromyography (EMG) signals of 7 muscles crossing the knee joint during walking gait (15 healthy subjects and 28 PFP patients) and stair climbing (14 healthy subjects and 26 PFP patients). See Figure 1 for a list of muscles.

Stair climbing and walking EMG data were extracted from the stance phase of the step or gait cycle. EMG data were band pass filtered (30-450 Hz), band stop filtered (49-51 Hz), detrended, rectified, low pass filtered (6 Hz), time normalized (cubic spline) and magnitude normalized to peak value per muscle. The linear envelopes of each muscle were averaged for each subject over three to five trials. Non-negative matrix factorization was used to find the muscle synergies for each subject. Muscle weighting coefficients (W matrix) and activation coefficients (H matrix) were obtained for each subject. The number of synergies needed to reconstruct the input data was found by calculating the R-squared value of the reconstruction (W matrix times H matrix) with a threshold of 0.9.

For each synergy, the mean and standard deviation of the muscle weighting coefficients were calculated. The muscle synergies and the R-squared values of the reconstruction of the PFP patients were compared to pain-free controls in both the walking and stair climbing condition. First, normality of the data was checked using a Shapiro-Wilk test; if the R-squared values were parametric, an unpaired t test was used, and if non-parametric, a Mann-Whitney U test was used. If the synergy weighting coefficients were parametric, an ANOVA was used, if non-parametric a Kruskal-Wallis H test was used. In all statistical tests an alpha value of 0.05 was used.

RESULTS AND DISCUSSION

For walking gait, 34/43 subjects met the condition of requiring three synergies to reconstruct 90% of the EMG signal. As expected, the three synergies presented the three functional muscle groups. Patients with PFP used similar synergies to pain-free controls (p=0.54). The R-squared value did not differ between both groups (0.92 PFP vs 0.94 control).

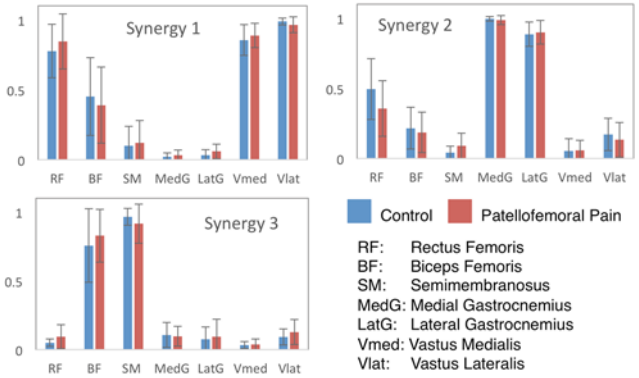

Figure 1. Synergy weighting coefficients of Control and PFP group during the stair climb task. Synergies during walking gait were similar to the stair climb task.

For the stair climbing data, 33/40 subjects required three synergies to reconstruct the EMG data to an R-squared threshold of 0.9. The synergies during stair climbing were similar for Control and PFP groups (p=0.39, Figure 1). The R-squared value of both groups was also similar (0.92 PFP vs 0.93 control). The use of three synergies was adequate to reconstruct the EMG data for most subjects, with ~20% requiring four synergies. This was expected due to the functional grouping of the muscles. Had we included muscles that cross the hip and ankle we would expect a greater number of synergies required to reconstruct the EMG data. The functional knee joint moment demands of walking and stair climbing possibly limit the variability in muscle synergies required to perform the task, even when patients experience pain.

CONCLUSIONS

Synergies of muscles crossing the knee are similar in patients with patellofemoral pain compared to pain-free controls during walking and stair climbing.

P071 - DATA-DRIVEN MODELLING TO REDUCE PEAK KNEE ADDUCTION MOMENTS BY ALTERING FOOT PROGRESSION ANGLE AND STEP WIDTH

[1]Daniel Chen and [1,2]**Thor Besier**
[1]Auckland Bioengineering Institute, University of Auckland, Auckland, New Zealand

Corresponding author email: t.besier@auckland.ac.nz

INTRODUCTION

The knee adduction moment (KAM) has been used as a surrogate measure of the medial compartment knee load and has been associated with the progression of knee osteoarthritis (OA). The reduction of peak KAMs is therefore one strategy to modify gait parameters such as foot progression angle (FPA), trunk sway, tibia angle, foot centre of pressure, and step width (SW) during walking; collectively termed gait retraining.

Despite gait retraining delivering promising results, retraining multiple gait parameters is difficult and cumbersome with current haptic (tactile) retraining systems due to the need for multiple devices [1]. We have designed a wearable haptic ankle bracelet which is capable of retraining multiple gait parameters, namely FPA and SW. FPA and SW were initially chosen due the ease at which these parameters could be modified and has been demonstrated to be easily trained using our ankle bracelet in a previous study [2]. This paper uses a data-driven method of modelling both the first and second KAM peaks of one subject at various FPA and SW in the attempt to find gait recommendations that reduce the peak KAM.

METHODS

One healthy male subject (25 years) walked on a Bertec Instrumented treadmill at 1.2m/s while making random variations to his FPA and SW within what he found to be a comfortable range of motion. Retroreflective markers were placed on the calcaneus, second distal phalanx, medial and lateral epicondyle of the femur, medial and lateral malleoli, with a rigid cluster of four markers on the shank. Using ground reaction forces and marker measurements from a Vicon optical motion capture system, the first and second KAM peaks were calculated, along with the corresponding FPA and SW (Figure 1). A regression model (generalized additive model with smoothing splines) was constructed for both the first and second KAM peaks for the FPA and SW values extending through the range of motion.

The regression model suggested that a toe-in and increased step width gait would reduce first and second KAM peaks. The subject was then asked to walk at three new gaits in addition to his normal gait: **(1)** toe-in (2°) with normal SW (165mm), **(2)** normal FPA (7.4°) with wide SW (500mm), and **(3)** toe-in (2°) with wide SW (500mm). The peak KAMs of these new gaits were then compared with the subject's normal gait to evaluate the predictive capability of the model. A one way ANOVA with a Tukey HSD post hoc test was used to determine differences between the normal and modified gaits ($\alpha = 0.05$).

RESULTS AND DISCUSSION

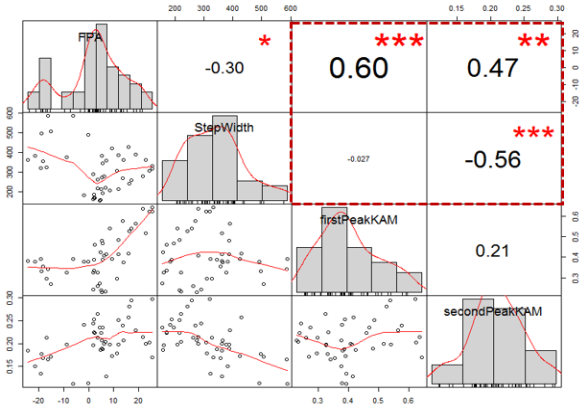

Figure 1. Scatter matrix of subject showing correlations between FPA, SW, first and second KAM peak. Correlation coefficients are shown in the top right triangle of matrix, with *, **, *** denoting statistical significance at the $p < 0.05$, $p < 0.01$, and $p < 0.001$.

The subject had a FPA of 7.4° and a SW of 165mm during normal walking. The first and second peak KAMs for the four different walking gaits were different to the normal gait ($p<0.001$). The toe-in modification alone condition did not reduce either the first or second peak. The wide SW, along with the toe-in with wide SW modifications however, both reduced the second KAM peak from 0.28 ± 0.02 Nm/kgm to 0.23 ± 0.04 Nm/kgm and 0.24 ± 0.03 Nm/kgm, respectively ($p < 0.001$), but increased the first KAM peak from 0.43 ± 0.05 Nm/kgm to 0.57 ± 0.08 Nm/kgm and 0.59 ± 0.10 Nm/kgm, respectively ($p < 0.001$). These results suggest that regression models only gave recommendations suitable for reducing the second KAM peak but not the first. Toeing-in by 5° for this particular subject did not have a noticeable effect, only increasing the SW did. One possible reason for the disparity between the model and experimental values is that the model was constructed from data during random walking, which could inevitably involve abnormal changes in other gait parameters like trunk sway etc. as compared with if the subject was asked to change his gait more systematically.

In summary, our data-driven method was successful in reducing the second KAM peak but adversely increased the first. A systematic method of varying the parameters will be explored to determine whether or not this creates a more suitable regression model.

P072 - THE EFFECT OF AGE ON REACTIONS EVOKED BY SUDDEN BALANCE LOSS: MODULATION OF PERTURBATION-EVOKED ARM REACTIONS FOR BALANCE RECOVERY AND/OR FALL-IMPACT PROTECTION

[1,2] **James R Borrelli**, [2]Jeanie Zabukovec, [2]Simon Jones, [2]Christiane A Junod, and [2,3]Brian E Maki

INTRODUCTION

Falling is a leading cause of serious injury, loss of independence and nursing-home admission in seniors [1]. Arm reactions evoked by sudden loss of balance can play an important role in preventing falls and protecting against serious injury; however, the control of these reactions is very complex and likely to be impaired by aging. Effective arm reactions require the brain to rapidly make several critical decisions which are dependent on situational factors such as the direction and speed of the fall and the proximity of objects that can be touched or grasped for support. A fundamental decision is whether to use the arms to aid in recovering balance or to prepare to protect the head and torso during a pending impact with the ground. This study aimed to probe the capacity to select and execute effective arm reactions based on age, fall speed and direction and availability of handholds. Large perturbations were included to force falling in some trials.

METHODS

The Challenging Environment Assessment Laboratory (CEAL, Fig. 1) was used to deliver unpredictable platform motion to evoke arm reactions. Participants were exposed to small, medium and large, forward and backward platform translations that allowed balance recovery or resulted in a "fall" (safety harness load > 10% body weight). To counter adaptation, analyses were limited to the initial trials (n=6) experienced by each subject. To heighten reliance on arm reactions, stepping movements were prevented by barriers. Thirteen healthy young adults (YA; 20-28 yrs; 6 women; 7 had a handrail present) and twelve older adults (OA; 65-74 yrs; 8 women; 6 had a handrail present) were tested. EMG onset latency was measured bilaterally for tibialis anterior, gastrocnemius, medial deltoid and biceps. Motion-capture markers on the third metacarpal and acromion were used to calculate hand kinematics and timing. Repeated-measures ANOVA was used to test effects of age, perturbation direction/magnitude and handrail (HR) presence/absence on the features of the arm reactions and EMG onset latencies.

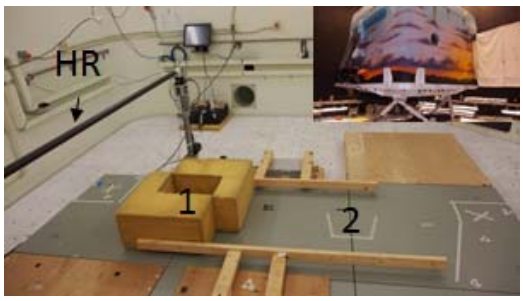

Figure 1: The inset shows the exterior of the CEAL motion platform that we used to deliver forward and backward platform-translation perturbations. The main photo shows the CEAL interior. Subjects stood with a handrail (HR) within reach (position 1) or out of reach (position 2). Foam barriers used to prevent stepping are shown in position 1.

RESULTS AND DISCUSSION

The majority of trials (> 97%) exhibited rapid arm reactions (biceps and/or deltoid latencies <200ms). Preliminary analyses indicate that these reactions were significantly modulated according to perturbation direction/magnitude and handrail presence/absence. Age-related effects were largely limited to onset of EMG activity. Onset of the right upper arm EMG was delayed in OA (157±33ms) compared to YA (143±40ms; p=0.015). These results are consistent with observations that ageing results in slowed activation of muscle responses of the lower [2] and upper limbs [3].

Some direction-related differences in early-onset arm orientation (100 ms after onset of arm movement) that YA exhibited were not exhibited by OA. For example there was a significant interaction between age, HR presence/absence and fall direction (F(1,42)=21.56, p<0.0001) in the early-onset lateral right-hand displacement. Post-hoc comparisons revealed a difference in YA, in the no HR trials, while falling backward versus falling forward (0.0090±0.030 versus 0.032±0.021 m/height). The difference was not found in OA (0.0196±0.0217 versus 0.0247±0.0234 m/height).

In all cases, however, the direction of the early arm movement was consistent with balance recovery, i.e. gravito-inertial 'counter-balancing' or reaching to touch or grasp a handhold. There was no clear evidence of early-onset impact-protection reactions, even though more than 64% (64% for YA and 66% for OA) of trials resulted in a "fall".

As noted above, the analyses that we have completed to date have revealed some modest age-related differences in early-onset arm orientation and a small age-related slowing in the onset of arm-EMG activity. However, these differences apparently were not sufficient to influence whether or not the subject was able to recover balance without falling.

CONCLUSIONS

The preliminary results of this study support the remarkable ability of the CNS to modulate early-onset arm reactions in such a way as to aid in balance recovery. However, we saw no clear evidence of early-onset reactions that served impact protection. These initial results suggest that impact-protection reactions may be "strategies of last resort" that are invoked when initial balance-recovery reactions fail to restore equilibrium. Further investigation is needed, using protocols that allow the body to fall to a larger extent than allowed in the present study.

P073 - RELATIONSHIP BETWEEN PLANTAR SENSATION AND CENTER OF PRESSURE VARIABLES IN POST-STROKE

[1]**Tatiane Caroline Boumer**, [1] Suzane Ketlyn Martello, [1] Gisele Francini Devetak and [1]Elisangela Ferretti Manffra
[1]Pontifícia Universidade Católica do Paraná, Curitiba, Brazil.
Corresponding author email: tatiane_boumer@hotmail.com

INTRODUCTION

Decrease in plantar cutaneous sensation (PCS) is one of the factors that contribute to the deficits in postural control observed after stroke [1]. Asymmetry between paretic limb (PL) and non paretic limb (NPL) may further compromise the maintenance the balance [2]. This study evaluated the correlation between the PSC and center of pressure (COP) variables, since adequate understanding of the balance indicators may be of great importance in the clinic, not only for a correct assessment, but also to design specific rehabilitation programs.

METHODS

This study was approved by the Ethics Committee of the Pontifícia Universidade Católica do Paraná, Curitiba, Brazil (nº 256.523), and informed consent was obtained from all subjects. The sample was composed by 8 stroke patients (5 women and 3 men), with median (Q1-Q3) age of 53 (51 - 53) years old, and time course post stroke of 3 (2 - 8) months. The participants performed three trials of posturography on two force plates (AMTI, OR6-7-1000) during 60 s in a comfortable feet position, and instructed to stay in this position as quiet as possible, looking at a fixed point one meter away. The signals were sampled at 300 Hz and low-pass filtered using a 4ª order dual-pass Butterworth filter with a cut-off frequency of 10 Hz prior to processing. The variables selected to study were root mean square (RMS) of the amplitude of displacement in the anteroposterior (AP) and mediolateral (ML) directions, total mean velocity (TMV) and COP sway area. The average value of the three trials were used in the analysis. The PCS was assessed using the median of 10 points distributed in each foot evaluated by the Semmes-Weinstein monofilaments, calculated according to Mueller (1996) [3]. The higher scores represent reduced sensation. For this population a cut-off score of 4.31 log (mg), was considered as an indicator for sensory retraining [1]. The Wilcoxon test was applied to determine difference between PL and NPL, and Spearman Correlation Coefficient was used to calculate the association between PCS and COP variables ($\alpha = 0.05$).

RESULTS AND DISCUSSION

In the comparison between limbs, statistically significant difference was found for TMV (p=0.012) and for PCS (p=0.018). For the other variables, no statistical significance was found when PL and NPL were compared. Positive correlation was found only between PSC and TMV for the PL (Table 1). In this limb, greater PCS deficits were associated with a larger COP oscillation velocity. However, higher values of TMV were present in NPL, which possibly occurs due to the greater contribution of this member in supporting the body weight and, consequently, in the maintenance of balance [2].

	Variables	Median (Q1-Q3)	Spearman's rho (p values)
Paretic Limb	PSC (log (mg))	5.37 (4.56 - 5.74)	-
	TMV (mm/s)	9.3 (7.9 - 9.9)	0.830 (0.011)*
	Sway area (mm²)	42.7 (28.7 - 73.2)	0.268 (0.520)
	RMS AP (mm)	4.9 (3.9 - 6.1)	0.512 (0.194)
	RMS ML (mm)	1.2 (1.0 - 1.3)	- 0.098 (0.818)
Non paretic limb	PSC (log (mg))	4.30 (4.30 - 4.45)	-
	TMV (mm/s)	15.5 (12.6 - 17.7)	0.103 (0.809)
	Sway area (mm²)	54.8 (45.9 - 72.8)	0.217 (0.606)
	RMS AP (mm)	6.3 (5.2 - 7.1)	0.077 (0.857)
	RMS ML (mm)	1.6 (1.1 - 2.0)	0.358 (0.385)

Table 1: Values of plantar cutaneous sensation (PSC), COP variables and correlations between them.

No significant correlation were found between the PCS and the other COP variables, reasserting the previously published results with the same population but in acute phase [1], where only the RMS AP (eyes closed condition) had a moderate correlation with the sensitivity of the heel.

CONCLUSIONS

As expected, higher PSC values were found in the paretic foot, evidencing the greater impairment of sensitivity in this limb. The positive correlation identified between PSC and TMV in PL may indicate that treatment strategies aimed at stimulating sensitivity, providing symmetry between limbs, may possibly aid in the process of recovery of balance.

INTRODUCTION

Foot morphology and biomechanics are affected by age and gender. As far as the age is concerned, this is consequence of biological alterations of joints and soft tissues which can also be detected by modifications in plantar pressure measurements. While the relationship between some pedobarographic-based parameters - such as the arch-index and the centre of pressure excursion index - and different foot types has been reported in a study involving a large population [1], our current understanding of how specific age groups and gender relate to the main pedobarographic parameters during walking is still limited.

Aim of the study was to characterize plantar pressure data during walking according to gender and age in a population of healthy subjects with normal-arched feet. The pedobarographic-based foot parameters are expected to provide useful information for gender- and age-specific populations.

METHODS

From January to July 2016 more than three hundred subjects were visited by an experienced podiatrist at the Movement Analysis Laboratory of Istituto Ortopedico Rizzoli, and also in other locations: a primary school; a gymnastic training center; a volleyball training center, and a swimming pool 133 subjects (70 M, 63 F) with BMI < 29 presenting asymptomatic feet with normal heel alignment (heel varus < 5 deg) and medial longitudinal arch, and with no previous history of lower limb trauma or surgery, were acquired using a 2304-sensor pressure plate (P-walk, BTS, Italy). 5 steps for each left and right foot were recorded for each subject while walking at comfortable speed.

A custom software was developed and used to determine pedobarographic-based parameters from plantar pressure data [1]: arch-index (AI, %); centre of pressure excursion index (CPEI, %); peak pressure (PP, kPa); pressure-time integral (PTI, kPa*s); foot progression angle (FPA, deg); foot length and foot width (mm).
Subjects' data were pooled according to gender, and to age in four groups: 6-12; 13-20; 21-40; and 41-60 years. For each gender, differences in pedobarographic parameters between age groups were determined via Kruskall-Wallis test with significance at 0.05. Mann-Whitney test was used to determine differences in each parameter between age-matched gender groups. A Bonferroni correction was applied to the significance level to account for the multiple comparisons in each age group (α=0.01).

RESULTS AND DISCUSSION

Differences were found in all parameters across age groups, with the exception of AI and CPEI. The 5-12 years group showed the smallest PP, PTI and foot dimensions for both genders. In general, FPA increased with age: the oldest group showed larger FPA than the youngest group (Figure 1).
With exception of the youngest group, foot dimensions were always larger in males. Differences between males and females in several parameters were found in the 13-20 years group. For example, median PTI in the left foot was 111 kPa*s [94 - 132] in the female group and 142 kPa*s [119 - 171] in the male group (p=0.009).

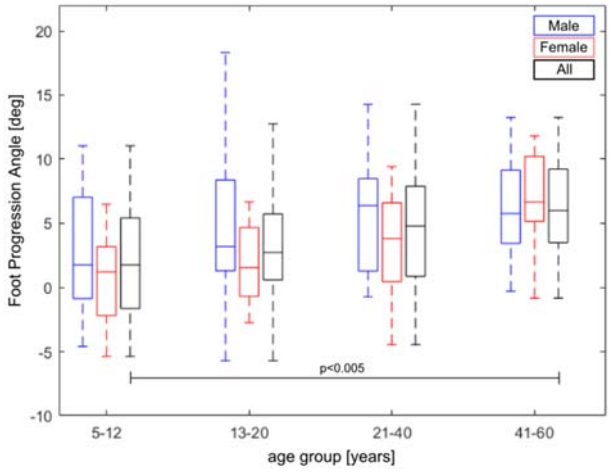

Figure 1: Boxplot of the left FPA [deg] in the male, female, and total male and female sample in the four age groups. Statistically significant differences between age groups are shown in the plot.

CONCLUSIONS

Pressure plates are useful and reasonably priced instrumentation for the analysis of plantar pressure. While this instrumentation is increasingly used by podiatrists to help with the diagnosis of foot ailments, the relevant pedobarographic parameters are often assessed on a qualitative basis only, as gender- and age-specific normative pressure data are missing or incomplete.

According to this study, several pedobarographic-based parameters characterizing foot biomechanics during walking are age- and gender-dependent. Age- and gender-specific normative data are thus recommended when assessing foot biomechanics and in the diagnosis of foot ailments. This data may help assist with the diagnosis of foot pathologies and/or morphological alterations, and with the interpretation of foot biomechanics in healthy subjects.

P075 - SYSTEMIC EVALUATION THE ACCURACY AND REPEATABILITY OF ON-MARKET INERTIA MOTION MEASUREMENT SENSORS FOR BIOMECHANICAL MOTION ANALYSIS

[1] **Sai-Wei YANG**, [2] Ching-Wei CHANG
[1] National Yang-Ming University, TAIWAN

INTRODUCTION

Measurement Unit sensor (IMUs) was first brought out in the 1930s, due to the confidential circuit design, high price, bulk size, and high power consumption, it had limited applications [1]. The recent blossoming of the mobile device promoted the design and fabrication of the sensors to a really attractive feature of affordable price and accuracy. Nevertheless, due to the data drift caused by the integration of acceleration/velocity over time, data latency caused by the transmitting rate, and others. The accuracy and repeatability is the main drawn back off in the Biomechanical motion analysis [2]. The purpose of this study was a systematic review the accuracy and repeatability of several on-market systems.

METHODS

Four commercial products, namely Xsens (Xbus, Xsens, Netherland), APDM (USA), STT (Spain), YOST Labs (USA), and a low cost self-developed IMU (YM) were evaluated by utilizing an industrial robot (Denso, VS6556, Japan), with a figure 8 traction in three different speeds, namely speed 1 (48,48,41 deg/s), speed 2 (24,25,20 deg/s), and speed 3 (12,11,9 deg/s) for yaw (abduction/adduction), pitch (flexion/extension), roll (axial rotation), respectively (Fig. 1). The sensor specifications as shown in Fig 2. The sensor was attached on the end effector of the robot with a wooden extension bar to avoid the metallic interference. Root mean square error (RMSE) and standard deviation (SD) of 10 continue motion were compared with the angular motion of joint actuators.

RESULTS AND DISCUSSION

The results showed that each system has its strength and weakness in different motion directions. The 10 repeated figure 8 showed that the accuracy in Yaw at the speed1 APDM> Xsens> STT> YM> YOST, in Pitch Xsens> APDM> STT> YOST> YM, in Roll, Xsens> YOST> STT> YM> APDM, deYaw Xsens> APDM> STT> YOST> YM; (Fig. 3);at speed 2, in Yaw APDM> Xsens> YOST> YM> STT, in Pitch, Xsens>YOSTI>YM>APDM>STT, in Roll, Xsens> YOST> YM >APDM >STT; deYaw, Xsens> APDM> STT> YOST> YM; at speed 3, in Yaw, APDM> >STT >Xsens >YOST >YM, in Pitch, APDM >Xsens >STT >YOST >YM; in Roll, Xsens >YOST >YM >STT >APDM; deYaw, Xsens> APDM> STT> YM >YOST. The error ranged from 2 to 25 degrees. And SD ranged from 0.01 to 3.68 degrees. Each system has different accuracy and repeatability in three motion directions. Overall, the Xsens provides the best accuracy and repeatability among the tested sensor.

CONCLUSIONS

This systematic comparison provides the first review of the commercial IMU systems, The IMU may be good for a game or animation application, but for a pathologic gait analysis, the markers-video system is preferred.

P076 - MOVEMENT REGISTRATION IN ADOLESCENTS WITH INTELLECTUAL DISABILITY USING A "SMART" SOCCER BALL

[1,2] **Hsin-Yi Kathy Cheng**, [3] Yan-Ying Ju, [1,2]Wann-Yun Shieh, [1]Yu-Chun Yang and [4]Yu-Chun Yu

INTRODUCTION

The physical activity performance of adolescence with intellectual disabilities (ID) is frequently ignored. Development of movement registration and training devices for use in special education settings are relatively overlooked. Different from the regular population, movement performance of this group is relatively unstable and is highly variable [1]. In order to get a complete picture of their sport performance, simple measurement of movement time and distance provides insufficient detail. Our research team has developed and validated a special-designed smart soccer ball based on the movement data of these adolescence. The embedded algorithm is able to register and analyze the movement data, including the reaction time, movement time, and distance travelled of the soccer ball during soccer dribbling. The purpose of this present study was to collect the above-mentioned movement data of the adolescence with ID during soccer dribbling and compared them with those of the typically-developed (TD).

METHODS

The smart soccer ball contained a 3-axis accelerometer, a gyroscope, and a magnetometer. With these sensors and a special-designed algorithm, it was able to measure the time and the distance variables of the movement of the soccer ball, including the reaction time of the participant, the total time and the total distance of the soccer ball motion. This way it can register the motor performance of the adolescents with ID and the TD. The experiment was performed in a special school and a regular school in northern Taiwan. A total of 59 participants aged 15 to 21 years participated in the experiment. Among them, 29 TD students (aged 16.7±1.1years) were recruited from the mainstream senior high school, and 30 students (aged17.6±0.6years) with ID were recruited from the special school. These adolescents with ID were able to follow simple commands and walk without support, and had no serious heart or lung conditions. The test was supervised by a physical therapist and an assistant to ensure the safety of the children. Informed consent forms were signed by the participants and their legal guardians. All participants underwent 2 different tests: the straight-line dribbling test, and the zigzag test. The participants waited at the start line, and they were told to begin dribbling along the straight line / zigzag as soon as they heard the beep. They were encouraged to dribble the soccer ball all the way to the end zone at self-selected speed. Each test was repeated 3 times. The reaction time, the total time and distance of the dribbling, the times of crossing the boundary (OUT) were recorded. Mean and standard deviation (SD) for the variables were calculated from the 3 repetitions. For group comparison, independent t-test was used. The significance level was set as $p = 0.05$.

RESULTS AND DISCUSSION

The descriptive data for each test is presented in Table 1.

The inferential statistics for the straight line test indicated a significant differences between groups for the total time ($p=.000$), the total distance ($p = .000$), and the number of OUTs ($p = .000$), but not in the reaction time ($p=.158$). Similar results were found in the zigzag test with significant between-group differences for total time ($p=.000$), total distance ($p = .000$), and the number of OUTs ($p = .000$), but not in the reaction time ($p=.073$). These findings indicated that adolescents with ID took more time and distance from start to finish, and they also went out of the boundary more than the TDs.

Table 1. Performance variables during dribbling

		Straight line		Zigzag	
	Group	Mean±SD	F	Mean±SD	p
Total distance (cm)	TD	1243.1±80.6	42.1***	1713.8±156.1	21.0***

	ID	1.3±0.7		1.5±1.4	
Out of bounds (number)	TD	0.0±0.1	20.5***	0.3±0.5	28.7***
	ID	0.2±0.3		1.3±0.9	
Cone miss (number)	TD	-	-	0.1±0.3	4.8*
	ID	-		0.4±0.7	
Number of trials	TD	3.0±0.2	8.7**	3.3±0.5	4.1*
	ID	3.5±0.8		3.7±1.0	

CONCLUSIONS

The present study indicated that the motor performance of the ID in soccer dribbling was significantly poorer than their typically developed peers. With this soccer ball assistive device, one can collect and analyze movement data of these children, and design an ID-specific algorithm, sensor module, and application for use in movement evaluation and training for children with ID. In cooperation with the disabled community and special schools, the research team is going to promote the use of this smart assistive device, and to continue collecting and expanding the movement database in the cloud platform. These data can be retrieved for movement evaluation, exercise program design and modification, and also serve as references for future device design and policy modification.

P077 - IMPACT CHARACTERISTIC OF THE SPRING-MODULE FUNCTIONAL SHOE DURING WALKING

[1]Choi E, [1]Jeong J, [1]Kim S, [1]Kim J, [1]Kim Y
[1]Department of Biomedical Engineering and Institute of Medical Engineering, Yonsei University

INTRODUCTION

The shoe plays an important role in the mechanics of human walking. Since the shoe is the only end-effector in the human walking apparatus that interacts with the ground, it has many essential functions such as shock absorption, weight-bearing stability, and push-off [1]. Previous studies have found that changing shoe design can significantly alter the plantar pressure in specific regions of the foot[2]. However, there have been almost no studies which deal with the dynamic contribution of the heel, which are connected with elastic and viscous components of acting force on the spring shoe, to the body propulsion and support based on ground reaction forces(GRFs) and accelerations(ACC). The purpose of this study was to determine the effect of the new spring shoe using a custom-made unit of acceleration sensors and force plates.

METHODS

Twelve healthy male volunteers (age: 26.2 ± 2.6 years; height: 172.8 ± 4.7 cm; weight: 71.9 ± 6.5 kg) with no musculoskeletal diseases participated in this study. The subjects were informed about the purpose of the study and the experimental protocol. Two footwear conditions were used in this study: a general walking shoe(no spring) and a new design(spring inserted) for a walking shoe. Three different stiffness were also applied to the spring module: high, middle, and low. A 3-axis acceleration sensor (LIS311 (STMicroelectronics, USA) and two force platforms (AMTI, USA) were used to measure the kinetic transition from breaking to propulsive phase with the functional shoe during walking at a sampling rate of 1kHz. An ACC sensor was positioned at the heel. x denotes anterior-posterior (AP) direction, y medial-lateral (ML) and z superior-inferior (SI). Statistical analyses were performed using IBM SPSS Statistics (SPSS INC., Version 19, IBM, USA), and the significance level was set by p <0.05.

RESULTS AND DISCUSSION

Significant differences in accelerations of heel transient(at the impact after heel-strike) for AP & SI directions were found. Overall, the heel transient value of the spring module was small. The recovery right after the impact in the acceleration curve appeared to be more gentle in the spring-module functional shoe with the small stiffness than the general one, particularly in SI. Vertical ground reaction forces of the general and functional shoes showed that the impact in the braking phase was significantly different. Interestingly, loading response and mid-stance were significantly elongated in the functional shoe than the general shoe.

CONCLUSIONS

The impact characteristic of a spring-module functional shoe was determined in this study. An acceleration and GRFs were significantly different for AP & SI directions. In functional shoes, the peak value in acceleration and the recovery rate was small showed the gentle slope. Therefore, it was concluded that the shock absorption in the heel of the spring-module shoe in the present study was better than that of the general shoe.

P078 - PENDULAR ENERGY EXCHANGE ON ROUGH AND SMOOTH SUBSTRATES

[1] Alexandra Allen, [1] Robin Huw Crompton and [1] **Kristiaan D'Août**
[1]University of Liverpool
Corresponding author email: kristiaan.daout@liverpool.ac.uk

INTRODUCTION

When walking on a flat terrain, humans exchange potential and kinetic energy with an efficiency of up to 70% by using the so-called *inverted pendulum* mechanism which is a result of our relatively stiff-legged gait (compared to other primates). Is this highly efficient mechanism preserved on complex substrates? Answering this question is relevant from an ultimate perspective (humans evolved on complex terrains) and from a proximate perspective - how efficient are we "in the real world"? We hypothesise that walking on a complex terrain involves changes in gait leading to a more variable and overall smaller pendular exchange.

METHODS

Ten healthy subjects (5/5 male/female, age 27±7 years, height 1.76±0.12 m, mass 67±9 kg) walked at preferred speed over two 14.4 m long walkways: one smooth and one complex with vertical variation up to 27 mm. Subjects were marked using a 67-marker set consisting of anatomical and tracking markers. Kinematics were recorded using a 12 IR-camera system (Qualisys, Oqus-7, 200fps) and analysed in Visual3D 6.0 and MatLab 2016b (Figure 1). Two footwear conditions were tested: the subjects' own walking boots and a standard minimal shoe (Vivobarefoot "The One"). Five trials were analysed per condition (total 200 trials).

Figure 1: A, smooth and B, rough substrate. Width of the substrates is 0.61 m. C, biomechanical model used.

For every trial, we calculated basic spatiotemporal gait parameters (including step width), potential and kinetic energy of the Centre of Mass, CoM (Figure 2), pendular energy Recovery and Congruity [1,3].

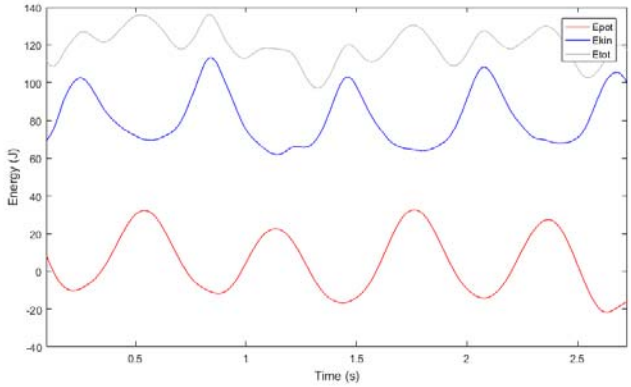

Figure 2: Example plots for potential, kinetic, and total energy of the CoM for four consecutive strides in a trial with minimal footwear on the rough substrate.

Statistics were performed in SPSS 24 using a Generalised Linear Model with Subject as a random factor.

RESULTS AND DISCUSSION

Spatiotemporal gait variables show small differences between conditions and subjects, but variation is higher on the complex substrate. In contrast, we found no significant differences and similar variation between conditions for Recovery or Congruity (Figure 3).

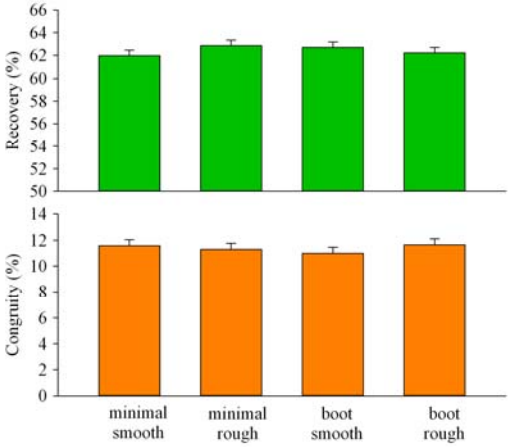

Figure 3: Mean pendular recovery and congruity between the four conditions. Error bars indicate 95% confidence intervals.

This study focused on walking on a moderately complex substrate with vertical variation similar to normal toe clearance. Extending the data set with more subjects and variables will allow for a more fine-grained analysis.

CONCLUSIONS

Based on the data from 10 subjects, we conclude that mechanical efficiency is preserved on a substrate of moderate complexity versus a smooth substrate. This suggests that humans have evolved to be efficient when moving over irregular terrain [3, 4].

P079 - IMPAIRMENT INDUCED COMPENSATORY STRATEGIES RESULT IN CONSTANT ABSOLUTE LIMB WORK

Anahid Ebrahimi, Jill Higginson and Steven Stanhope
University of Delaware
Corresponding author email: anahide@udel.edu

INTRODUCTION

Mechanical work is often used to quantify and describe human movement, because it is a summary measure of energy generated (positive) and absorbed (negative) at the joint and segment levels. Therefore, work done by the limb constituents (hip, knee, ankle, distal foot [2]) can identify the overall strategy used by individuals with impairments to walk. Even in the case of an impairment, the net mechanical work of the limb is theoretically zero over the gait cycle as it is a cyclic task [1]. However, the strategy to maintain net work near zero is unclear when one constituent (e.g. ankle) is restricted such that work at that constituent is significantly decreased. We can investigate work over the entire gait cycle for each constituent as well as the summed constituent work (absolute limb work). We hypothesize that a partial reduction in ankle work will not affect the absolute limb work compared to normal walking. Furthermore, constituent work relative to absolute limb work can identify the work distribution of the limb. The objective of this study is to quantify the compensatory strategies used by lower limbs in the presence of unilateral and bilateral ankle restriction.

METHODS

Nine healthy subjects (34 ± 10 years, 75.6 ± 16.2 kg) were fitted for rigid ankle foot orthotics (AFOs) for each limb. Subjects walked on an instrumented split belt treadmill at 0.8 statures/s for ten minutes while motion and force data were collected. The subjects walked with standard shoes (Shoes), with an AFO on their right limb (RiAFO), and with AFOs on both limbs (BiAFO). Using Visual3D software, 6 DOF powers of each constituent (hip, knee, ankle, distal foot) were calculated bilaterally using methods described elsewhere [2,3]. Work was calculated as the integration of power over the gait cycle and scaled by body mass. Limb work was the sum of the constituent work values. Absolute limb work was the sum of the positive limb work and absolute value of the negative limb work. Relative work was positive or negative constituent work divided by the absolute limb work. Metrics were compared between conditions using repeated measures ANOVAs (overall p=0.05); all post-hoc comparisons were adjusted using Bonferroni corrections.

RESULTS AND DISCUSSION

There was no significant difference in stride length across conditions with individuals walking at a typical normalized speed. The AFO was effective in significantly reducing relative ankle work compared to Shoes by an average of 32% (Table 1). Net limb work remained near zero and absolute limb work did not significantly differ across conditions except between the RiAFO and Shoes conditions on the right limb. Interestingly, the relative constituent work distribution across hip, knee, ankle, and negative distal foot was between 8.2% and 20.4% in Shoes, suggesting load sharing across constituents. However, once the ankle was restricted, positive and negative relative knee work increased compared to Shoes on the ipsilateral limb with the AFO. Right positive relative hip work increased in BiAFO (23.5 ± 2.4%) from Shoes (21.3 ± 1.5%) (p = 0.02). Previously, researchers reported restriction of the ankle joint leads to compensations at the proximal lower limb joints, such as increased bilateral hip power generation with unilateral ankle restriction [4] and increased knee work with bilateral ankle restriction [1]. Our results suggest with a 32% reduction in relative ankle work, the absolute limb work remains constant but there is a shift from ankle to knee in constituent work distribution.

CONCLUSIONS

Overall, absolute limb work does not differ with partial unilateral and bilateral ankle restriction, indicating speed can be maintained without additional mechanical cost. Work by the limb is re-distributed such that the contribution of knee work increases with decreased ankle work. Thus, constituent work is balanced so absolute limb work over a cycle remains constant.

INTRODUCTION

Gait is performed smoothly by various kinetic strategies such as adjustment of center of mass (COM). Thorax includes the upper body COM. The shape and placement of the thorax affects the gait. Thoracic deformation often accompanies with gait deficit in patients with respiration disorder. Here we have made special body wears to induce lateral thorax deviation and investigate effects of the bilateral thorax deviation on the lateral transitions of thorax, COM and ground reaction force (GRF) during stance phases of the gait.

METHODS

Subjects were healthy men (27.7 ± 2.7 years old, 172.1 ± 6.9 cm in height and 68.0 ± 6.6 kg in body mass, n=11) without a history of orthopedic diseases. The tasks were the free walking with or without bilaterally thorax deviated conditions induced by putting on the leftward- or rightward-deviation inducing artificial wears woven by strong wires (termed as “Left-shift” or “Right-shift”); wires-unwoven wear served as control. Each task was repeated 3 times and average value was regarded as the representative value. Transitions of thorax and COM during stance phases of left and right legs were measured using 3-D motion analysis system (VICON-MX, VICON) with 39 markers on the trunk (plug-in-gait full body model). Lateral thorax transition was estimated by measuring the distance of perpendicular line from COM to the vertical line across the xiphoid process on the frontal plane. GRF was measured using the force plates (AMTI Japan) linked to 3-D motion analysis system, and the left/right component (outside/inside) of GRF during the stance phase of each leg was estimated every 10% of each stance phase (a stance phase as 100% time). All obtained parameters were normalized by body mass. Statistics: multiple comparison; repeated one-way analysis of variance for normal distribution, or Friedman-test followed by Tukey-test for non-normal distribution, $p<0.05$ as significance.

RESULTS AND DISCUSSION

Left- or Right-shift of thorax induced by the artificial wear did not significantly alter the lateral transition of COM during either left or right stance phase. In the Left-shift, the lateral transition of thorax was significantly increased at the left stance phase, but not at the right stance phase. Left- and Right-shifts both, when compared with control, significantly reduced the GRF left/right component at 40 and 50% of the right stance phase, but not the left stance phase (Fig. 1).

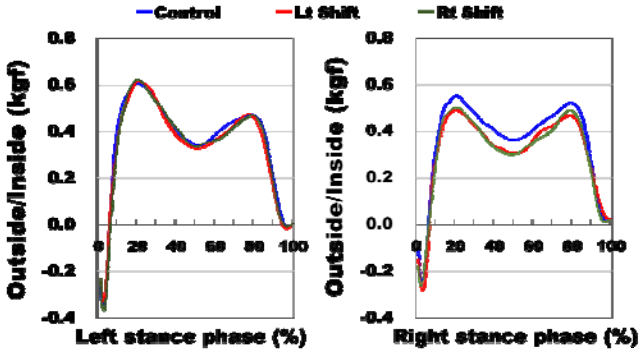

Figure 1: Left/right component (Outside/Inside) of GRF during left and right stance phases (100 % time) with Left-shift, Right-shift and Control of the thorax induced by the special wears.

Forced bilateral thorax deviation-induced reduction in left/right components in the right stance phase suggests that the right leg functions for COM to kinetically keep or retain its location inside the body by reducing the leftward force of the right leg.

CONCLUSIONS

The results suggest that the left stance in the gait is kinetically stable irrespectively with or without thorax transition. In contrast, the right stance phase is relatively instable. The characteristic difference in bilateral stance phases accompanied by the thoracic lateral deviation may provide a hint for treatments of patients having gait deficit.

P081 - POLY-ARTICULED COLLECTIVE SYSTEM: OSCILLATIONS OF THE CENTER OF MASS DURING LOAD TRANSPORT

INTRODUCTION

The inverted pendulum model (IPM) has been proposed to explain, wholly or in part, the cyclical aspect and the energetic performances of walking in human and terrestrial living animals. When this model is associated with the poly-articulated one, it can be shown that every segments of the human body must be considered to study this human-like-pendulum motor behavior [1]. The oscillations of the center of gravity (Cg) in the sagittal plane during walking allow potential energy to be transferred in kinetic energy and *vice versa* on each gait cycle, which explains the mechanical efficiency of walking [2].
The aim of our study is to verify the validity of the IPM in the case of the locomotion of a pair of subjects carrying an object.

METHODS

One pair of healthy subjects (subject 1 (S1): 25 yr, 1.726 m and 76.46 kg; subject 2 (S2): 24 yr, 1.725 m and 70.34 kg) took part in the experiment. The weight of the box the subjects had to carry was 13.41 kg and its size was 0.40x0.40x0.28 m (LxWxH).
Thirteen infrared video cameras (Vicon©) were used to acquire the kinematic data of forty two markers placed on each subject according the anatomical landmarks of De Leva's model. An additional 14 markers were placed on the box. The sampling frequency was set at 200 Hz. The subjects positioned themselves on opposite sides of the box that they carried by grasping a handle fixed on each side. They performed 3 walking trials at self-selected speed on a 12m-long walkway. Verbal or gesture communication between the subjects were prohibited during the test. Four walking cycles per trials were defined between the first left heel strike of S1 and the second right heel strike of S2.
The whole segments and body mass were considered to compute the centers of gravity of S1, S2, the box and the Poly-Articulated Collective System (PACS) that was formed by both subjects and the box.
Data analysis was conducted to investigate the pendulum-like behavior of the PACS and of the 2 subjects and the box separately. In each case, the relationship between the vertical oscillations of the Cg and time was used to determine the sinusoidal function from the average cycle. The amplitude ($A = \frac{(Zmax - Zmin)}{2}$; in meter), the pulsation ($\omega = \frac{2\pi}{T}$, in radian. second^{-1}; with T the period) and the phase shift ($\Delta\varphi = \tau * \frac{2\pi}{T}$, in radian; with τ the time shift) allowed us to determine the function ($Z(t) = A.\sin(\omega t + \varphi)$). The accuracy between the experimental data and the functions was then measured by the linear correlation (r) and the Root Mean Square Deviation (RMSD).

RESULTS AND DISCUSSION

The amplitudes (0.014m, 0.020m, 0.030m, 0.017m), the pulsations (11.28 $rad.s^{-1}$, 11.87 $rad.s^{-1}$, 12.03 $rad.s^{-1}$, 11.61 $rad.s^{-1}$) and the phase shifts (-1.52 rad, -1.60 rad, -1.56 rad, -1.56 rad) were computed from the vertical oscillations of the Cg of S1, S2, box and PACS, respectively (Figure 1).

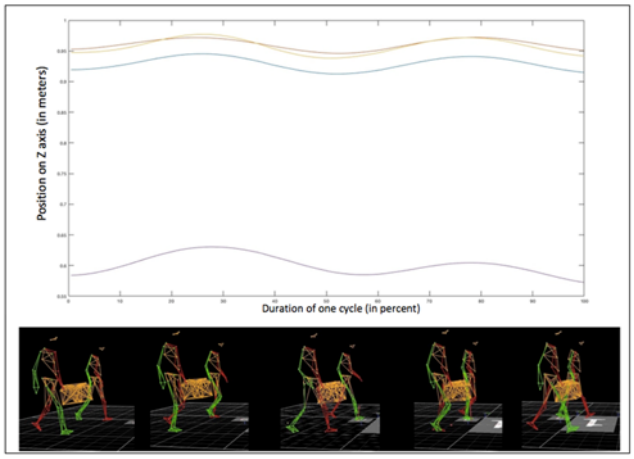

Figure 1: Vertical displacement of the center of gravity of the subject 1 (red), the subject 2 (yellow), the box carried (purple) and the PACS (blue) along with the reconstructed model at 5 times along the cycle.

The correlation coefficient (all with a $P<0.05$) and RMSD [r, RMSD] computed from the equation and experimental data were [0.9635, 0.0027] for S1; [0.9789, 0.0034] for S2; [0.7123, 0.0158] for the box and [0.9761, 0.0028] for the PACS.
We observed a high variation of the amplitude of the box movement along the cycles. The other amplitudes were more stable while a phase shift between the subjects and the box was observed. These results show that the subjects are not coordinated as a mirror movement but for an overall result.

CONCLUSION

The trajectory of the center of gravity of the PACS is a sinusoidal and periodic signal showing that the coordination between the two subjects leads to a pendulum-like trajectory of the Cg of the whole system. This demonstrates the capacity of collaborative behavior to generate an efficient strategy at the level of the whole despite the disturbances of the optimum at the individual level.

INTRODUCTION

Magnetic and inertial measurements unit (MIMUs), due to their limited weight and size represent a recent solution for motion analysis. [1]. In overweight/obese subjects [2], the changes in gait biomechanics, combined with increased joints load, are considered responsible for the development of musculoskeletal pathologies, and particularly knee osteoarthritis. A normal weight subject (NW) and an overwheight (OW) subject were tested during 6 gait trials using H-Gait, a MIMUs based system. The aim was to evaluate the test-retest reliability of the system for joint center trajectory, in the transverse plane, for both knee and ankle. Secondly, to assess differences between the trajectories obtained in the two cases.

METHODS

One NW and one OW young male subjects (BMI 21.2 and 30.4 kg/m^2 respectively), were involved in this pilot study. H-Gait system was used to acquire gait signals. H-Gait consists of 7 MIMUs (TSDN121, ATR Promotions, Japan) [3]. The sensor units were fixed to the subject as described in [4]. Anatomical and static calibration were performed to obtain transformation matrixes between the sensor local reference systems and the global reference system. The subject was requested to walk along a 14 m straight path, at self-selected speed. Gait analysis data were evaluated in all the three planes. The joint center trajectory in the transverse plane was calculated for both knees and ankles. Then, the approximation line [5] of each mean trajectory was estimated. Finally, knee (θ_k) and ankle (θ_a) angles between the left and right approximation lines were calculated. A total of 53 gait cycles for the NW and 54 for the OW.
In addition, conventional gait spatio-temporal parameters (speed, cadence and step length), were also assessed.

RESULTS AND DISCUSSION

Figure 1 shows the knee and ankle joint center trajectories, in the transverse plane. The medial part of the trajectories corresponds to the stance phase, while the lateral part to the swing phase. The approximation lines are also reported.
We found that the standard deviations across the 6 trials, for the knee and ankle angles, were small, for both subjects, and in any case compatible with clinical gait analysis.
We found that the knee angle θ_k is definitely higher in the OW (36.5°±1.8°) with respect to the NW (12.2°±1.0°). For what concerns the ankle angle θ_a values are comparable: 8.5±0.7° for NW and 10.1±0.9° for OW. The area of the knee and ankle joint center trajectories for the OW are greater with respect the NW, especially at the middle of stance and swing phase. These differences joints kinematics could be explained by a higher thigh volume that probably forces OW to establish a different gait biomechanics. Concerning the spatio-temporal parameters, the self-selected

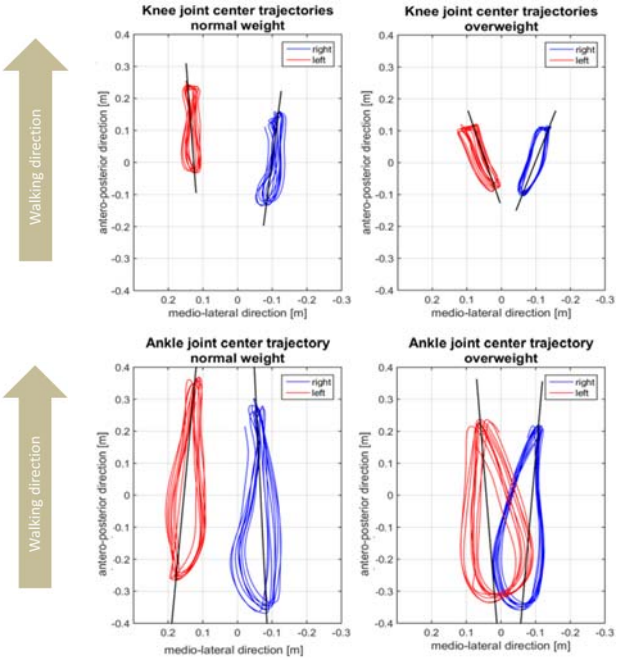

Figure 1: Knee and ankle joint center trajectories for the NW and OW subjects. Approximation lines of the trajectories are drawn in black.

velocities where comparable (NW=0.97±.01 m/s OW=1.03±0.01 m/s). This allows a comparison of the kinematic patterns of the two subjects, not biased by a different walking speed. According to literature, a shorter step length was found for the OW (50.2±2.1 cm) compared to the NW (55.1±8.0 cm). Consequently a higher cadence 55.1±0.3 cycles/min in OW with respect 46.9±0.7 cycles/min in NW was assessed.

CONCLUSIONS

Joint center trajectory in the transversal plane obtained with H-Gait system showed small standard deviation, also in OW, for which it is usually challenging to obtain reliable gait measurements. In addition, the higher knee angle between the left and right joint center trajectories in the OW compared to the NW suggests a difference in gait biomechanics, which could be due to larger tight volume and/or different load distribution in weight-bearing joints.

P083 - RESOLVING THE DEBATE: ANKLE PUSH-OFF DURING HUMAN WALKING CONTRIBUTES TO ACCELERATING BOTH THE SWING LEG AND THE CENTER-OF-MASS

[1]**Karl E Zelik**, [2]Peter G Adamczyk
[1]Vanderbilt University
[2]University of Wisconsin - Madison
Corresponding author email: karl.zelik@vanderbilt.edu

INTRODUCTION

Muscle–tendon units about the ankle joint generate a burst of positive power during the step-to-step transition in human walking, termed ankle push-off. However, the functional role of this push-off has been debated for decades, without scientific consensus. One school of thought has emphasized that this push-off power primarily contributes to accelerating the swing leg, while another school of thought has emphasized the effect on accelerating the body's center-of-mass (COM). There is reasonable empirical evidence to support each perspective, yet these descriptions appear *prima facie* to be in contradiction. The purpose of this work was to unify these seemingly polarized perspectives, and to show that these two possibilities are not mutually exclusive. We demonstrate that both descriptions are valid, and that the principal means by which ankle push-off affects COM mechanics is by a localized action that increases the speed and kinetic energy of the push-off limb. This abstract summarizes findings from our recent JEB Commentary [1].

METHODS

We reanalyzed level-ground walking data from [2], and computed several energy change and work estimates. First, we partitioned Total (whole-body) mechanical energy change into (a) energy changes due to the motion of the body's COM (using individual limbs method), plus (b) energy changes due to motion relative to the body's COM, which we termed Peripheral energy change. Second, we used an alternative way to partition Total mechanical energy change, into contributions from individual body segments and segment groups. For simplicity, we identified three segment groups: (a) push-off limb (trailing limb thigh, shank, and foot), (b) leading limb and (c) head-arms-trunk. Third, we computed how much of the push-off limb segmental energy change also appears as COM energy change during the push-off phase of gait.

RESULTS AND DISCUSSION

We found that under normal walking conditions (1.4 m/s), the vast majority (>85%) of push-off limb energy change contributes directly to COM energy change during push-off (Fig. 1). This observation is consistent across gait speed: >80% at 0.9 m/s , and >90% at 2 m/s. Work provided by ankle push-off manifests principally as increased speed of the push-off limb. The push-off limb increases in segmental kinetic energy with little energy transferred to the torso through the hip. But because the limb is included in body COM computations, this localized segmental acceleration also accelerates the COM, and most of the segmental energy change also appears as COM energy change. Thus, ankle push-off primarily contributes to accelerating both the swing leg and the COM during human walking. It is, in fact, the same energy change in both the push-off limb and the COM, with only a small part of limb energy being purely Peripheral (non-COM). Thus, interpretation of ankle mechanics should abandon an either-or contrast of leg swing vs. COM acceleration. Instead, ankle function should be interpreted in light of both mutually consistent effects. This unified perspective informs our fundamental understanding of the role of ankle push-off, and has implications for the design of clinical interventions (e.g. prostheses, orthoses) that restore function to individuals with disabilities.

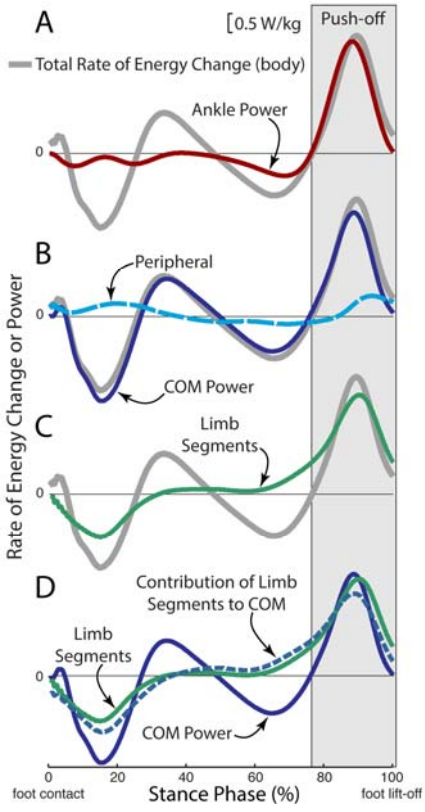

Fig 1. Estimates of the rate of energy change (Ė) and power (work rate) for an individual limb during human walking. (A) Ankle power (red line) overlaid on Total Ė (gray line, due to motion of and about the COM). (B) The majority of Total Ė during Push-off (gray box) is attributable to COM Ė (blue line), and smaller contributions are from Peripheral Ė (due to segmental motion relative to the COM, dashed cyan line). (C) The majority of Total Ė during Push-off is also attributable to segmental Ė from the push-off limb (green line). (D) The contribution of limb segmental Ė (green) to overall COM Ė (solid blue) is shown here in dashed blue. During Push-off, the majority of the limb Ė goes into this contribution (dashed blue), which in turn accounts for the majority of COM Ė. Data depicted are inter-subject means at 1.4 m/s (*N*=9, [1,2]).

CONCLUSIONS

The debate whether push-off from ankles
powers leg swing or COM rankles.
But a unified view
indicates both are true:
two effects inextricably tangled.

P084 - BIOMECHANICAL ANALYSIS IN PATIENTS WITH LUMBAR SPONDYLOSIS DURING FUNCTIONAL ACTIVITIES

[1,2] **Ting-Chun Huang**, [2]Tung-Wu Lu
[1] National Taiwan University Hospital Chu-Tung branch
[2] Institute of Biomedical Engineering College of Medicine and College of Engineering National Taiwan University
Corresponding author email: twlu@ntu.edu.tw

INTRODUCTION

Lumbar Spondylosis is a major health issue in developed country. It affects otherwise healthy individual from a productive life qualities, mainly because functional activities were limited. Activities such as balance, level walking, crossing obstacles [1], and sit-to-stand are essential but are underperformed by lumbar spondylotic patients.

The effect of decompressive surgery [2] has been proved to improved patient's life qualities clinically. However, there has not been qualitative biomechanical research on the effect of decompressive surgery on spondylotic patients.

METHODS

This was a prospective case control study approved by the Institutional Research Board. 20 patients were recruited from the PI's clinic. 10 patients were treated by decompression Surgery (lumbar spondylotic group). 10 age-matched healthy adults were also recruited to serve as controls (Control Group). The inclusion criteria were: (a) Spondylosis on AP and lateral plain film, (b) no previous spine surgery, (c) ability to cross obstacles without assistance, and (d) no excessive pain affecting their gait.

Each participants walk at self-selected pace and cross a height-adjustable obstacles. Motion capture system of 41 infrared retroreflective markers was used to record the motion. The subjects were allowed to familiarize themselves with the walkway before data collection. Before the test, EMG of the maximal voluntary contraction of the muscles will be obtained using manual muscle testing (MMT). Test conditions included level walking, crossing obstacles of three different heights (10, 20 and 30% of leg length) and sit to stand. A cardanic rotation sequence (Z-X-Y) was used to describe the rotational movements of each of the joints of the body. With the measured ground reaction forces (GRF) and kinematic data, intersegmental internal forces and moments were calculated using inverse dynamics. Six successful trials, three for each leg, for each condition will be obtained. Angular displacements were normalized. Angular velocity values were normalized by the maximum absolute velocity. Phase plots of normalized angular velocities (x') against normalized angular displacements (x) for each joint were then generated, and the phase angle (φ) was calculated as $\varphi = \tan^{-1}(x'/x)$. Relative phase angles (RPA) between two adjacent joints were then calculated by subtracting the phase angle of the distal joint from that of the proximal, namely $\varphi_{\text{hip-knee}}$ and $\varphi_{\text{knee-ankle}}$. Deviation phase (DP) was then calculated by averaging the standard deviations of the ensemble RPA curve points for the stance and swing phase for each obstacle height. The statistical methods were non-parametric Mann-Whitney U test and Wilcoxon signed ranks test with $\alpha = 0.05$.

RESULTS AND DISCUSSION

As center of pressure indexes indicated, patients with lumbar spondylosis manifest greater index, suggesting a degradation of balance performance during quiet standing, especially in the medial-lateral direction. During level walking, patients with lumbar spondylosis were unable to maintain normal temporal-spatial parameters with slower walking speed and wider step width. The patients with patients in the current study retain normal swing toe-clearance. However, slower crossing speed and smaller heel-obstacle distance were noted in patients with lumbar spondylosis as this sign was similar to that found during level walking. For the inter-joint coordination, continuous relative phase curves revealed that the two groups had relatively different inter-joint coordination patterns. During the task of sit-to-stand, the hip and knee joint were relatively movable compared to the fixed joint part.

CONCLUSIONS

In conclusion, patient group had altered postural control, joint biomechanics and inter-joint coordination.

P085 - EFFECTS OF VOLUNTARY CONTROL ON THE BODY SWAY DURING QUIET STANDING: MOTION ANALYSIS OF THE CENTER OF PRESSURE, CENTER OF MASS AND BODY SEGMENTAL CENTER OF MASS

[1] **Ryosuke Imai** [1]Tsutomu Fukui
[1] Health Care Science, Graduate School, Bunkyo Gakuin University
Corresponding author email: hybridrainbow0930@gmail.com

INTRODUCTION

This study compared parts of the body sway during quiet standing between relax (RC) and voluntary control (VC). The purpose of this study was to investigate the characteristic of VC by using three dimensional motion capture.

METHODS

Fifteen subjects stood on a force plate to measure the center of pressure (COP) during quiet standing. Subjects were captured by using 3D motion analysis system to create the segment models. Displacement of the center of mass (COM), head, thorax, pelvis and shank were measured to some outcome variables. Mean velocity (MV) and standard deviation (SD) of the amplitude, mean power frequency (MPF) of the displacement of each body parts were calculated.

RESULTS AND DISCUSSION

MV of the COM and each segmental COM of VC were significantly lower in those of RC. The SDs of amplitude of the thorax, COM, pelvis, shank and COP were significantly lower in status of the VC than those of RC. MPF of the COP of the VC was significantly higher than RC. Increased MPF of the COP may indicate higher posture adjustment frequency by ankle strategy during quiet standing [1].

CONCLUSIONS

The characteristic of VC during quiet standing suggested higher posture adjustment frequency by ankle strategy. VC had stabilizing function of body COM and each segmental COM sway.

P086 - SHIFT IN THE LATERAL AXIS OF HIGH-HEELED SHOES ON THE FRONTAL PLANE

[1]**Keio Ishiguro**, [1]Takashi Nakayama [1] Koya Mine, [2] Kaoru Abe
[1] Department of Physical Therapy, School of Health Sciences, Tokyo University of Technology
[2] Graduate School, Major Health and Welfare, Niigata University of Health and Welfare
Corresponding author email: ishigurok@stf.teu.ac.jp

INTRODUCTION

High-heeled shoes are a popular fashion item and are worn by many women and even young girls. Numerous studies have investigated the effects of heel height, but few studies on the lateral movement of the heel axis exist. In this study we investigated and analyzed the angle of inversion and eversion of the foot, adduction and abduction of the hip, joint moment inversion and eversion of the foot, joint moment adduction and abduction of the hip and ground reaction force X, in the hope of gaining a better insight into injuries that may be experienced when wearing high-heeled shoes, such as a sprained ankle.

METHODS

Eleven healthy female students participated in this study. Their mean (standard deviation) age, height, and weight were 19.8 (1.2) years, 158.1 (4.5) cm, and 50.6 (4.3) kg, respectively. Prior to measurements, the purpose and procedure of this study were explained in detail, and informed written consent was obtained from all subjects. The subjects wore two pairs of shoes with a different lateral axis: lateral 3 mm, 0 mm, medial 3 mm and medial mm (Figure 1). Before the measurements were taken, subjects were allowed to practice walking with each pair of shoes to achieve a comfortable gait. A VICON system was used to capture three-dimensional movements. The sampling frequency was 100 Hz. The system was equipped with 6 infrared cameras and 4 force plates, and there were 35 markers (plug-in gait) for each subject. VICON data were recorded while subjects walked, from the time of heel contact to the completion of the walking cycle. Data were recorded throughout the right stance phase of the walking cycle. We defined the stance phase of the walking cycle, ankle joint inversion, as the 'reaction phase'. The latter phase, ankle joint eversion, was defined as the 'recovery phase'. Statistical analyses were conducted using one-factor ANOVA and the Bonferroni correction test.

RESULTS AND DISCUSSION

No significant difference was found in relation to inversion and eversion of the foot and adduction and abduction of the hip. No significant difference was found in joint moment data of inversion and eversion of the foot and adduction and abduction of the hip. One-factor ANOVA with Bonferroni correction revealed a significant increase in ground reaction force X between lateral 3 mm and 0 mm, but not among the other combinations. Therefore, we speculated that a lateral shift in the axis of the heel contributed to hip adduction as a compensatory movement, resulting in an increase in the lateral component of ground reaction force.

Figure 1: Shoes with a different lateral axis

CONCLUSIONS

There are few studies on the lateral movement of the heel axis. We investigated and analyzed the data of joint angles, joint moments and ground reaction forces. One-factor ANOVA with Bonferroni correction revealed a significant increase in ground reaction force X between lateral 3 mm and 0 mm. We speculate that a lateral shift in the axis of the heel contributes to hip adduction as a compensatory movement, resulting in an increase in the lateral component of ground reaction force. However, further research is necessary to investigate these findings in more detail.

P087 - NEUROMUSCULAR RESPONSES TO UNWEIGHTING AT STANDING

[1,2]Naoki Oono, [1]Kanae Sano, [1]Yoko Kunimasa and [1]Akitoshi Makino, [3]Caroline Nicol, [4]Paavo V Komi and [1]Masaki Ishikawa
[1]Osaka University of Health and Sport Sciences, [2]Rinku General Medical Center, [3]Aix-Marseille University, [4]Likes Research Center & University of Jyväskylä

INTRODUCTION

Unweighting treadmill devices with lower body positive pressure (LBPP) technology have been recently used as a tool for the postoperative rehabilitation after lower limb injuries. The advantages of these devices can reduce impact forces, rates of force development and muscle activities during the LBPP running [3,4]. However, the effects of unweighting on neuromuscular system have not been fully investigated during human locomotion. For example, the tendon loading can influence the contributions of afferent feedback to locomotor muscle activities [1] and muscle and tendon behavior can be muscle and intensity specific during human locomotion [e.g. 2]. The question is how unweighing and reloading situations would influence our neural and mechanical systems to our human body.

Therefore, the purpose of the present study was to examine the responses of muscle fascicles of synergistic gastrocnemius and soleus muscles and Achilles tendon as well as background muscle activities in a standing position with different unweighting and reloading conditions.

METHODS

Ten healthy men subjects recruited and they are in a standing position with different low body positive pressure conditions. The low body positive pressure was set from 10% body mass (10%BM) to 80% body mass (80%BM) with each 10%. During the LBPP conditions, ankle and knee joint angles with kinematics and the vertical ground reaction force (Fz) with the shoe-mounted potable force plates was measured to calculate Achilles tendon force (ATF). Simultaneously, the background muscle activities with surface electromyogram (EMG) as well as muscle fascicle and Achilles tendon length of medial gastrocnemius (MG) with ultrasonography were measured during standing.

Values are presented as means and standard deviations. A repeated one-way analysis of variance was used with a post hoc Tukey's test to compare the parameters between conditions. Relationships between variables were investigated using Pearson's product-moment correlation coefficient. A criterion alpha level of $p < 0.05$ was used to determine statistical significance for all data.

RESULTS AND DISCUSSION

The reliability test for the setting of the LBPP device was performed by the relationship with Fz and ATF. The significant linear relationship was observed between the setting values of the LBPP device and the changes of Fz (also ATF) with LBPP ($r=-0.99$, $p<0.001$). However, the setting values of the LBPP device was undervalued by 5%BM relative to Fz at the standing conditions.

The muscle fascicles of MG and soleus muscles are getting longer (7.5% and 8.0% at the 20%BM, respectively) and Achilles tendon are shorter (2.0%, at the 20%BM) with unweighting. The background muscle activities of MG and soleus muscles were decreased with unweighting. However, those reduction patterns with unweighting were different between muscles. The MG showed the rapid reduction during the early unweighting conditions. However, there were not any significant differences between in the following 50-20%BM conditions. In SOL, the reduction of EMG was significantly related to the lower body positive pressure conditions (Figure 1).

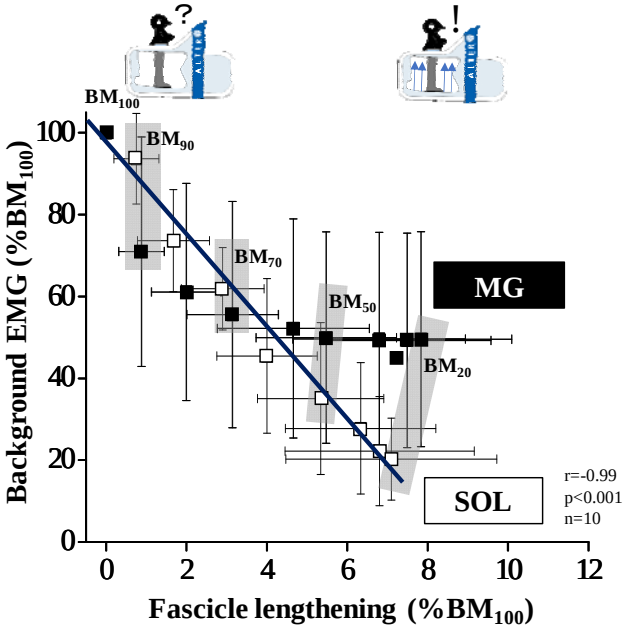

Figure 1: The relationship between the background EMG reduction and muscle fascicle lengthening of medial gastrocnemius and soleus muscles.

In the initial 90%BM condition, MG muscles were modulated dominantly. In the following 80-60%BM conditions, MG and SOL muscles were regulated differently to each condition. Further 50%BM conditions, the MG lengthening was occurred without the EMG reduction due to the increased dorsiflexion with the TA muscle activation.

CONCLUSIONS

These results clearly showed the muscle specific to unweighting responses in a standing condition. This muscle specificity to LBPP cannot be explain by the modulation of Ib afferent activities to changes of Achilles tendon forces and points out the need for future detailed investigation

INTRODUCTION

Recent advances in technology have prompted the use of robotic devices to assist walking, and the developments in microprocessor technologies have attempted to optimize the walking change [1]. From the viewpoint of the control system of assistive walking devices, the walking intention provides a real-time reference trajectory for the motion controller [2]. Therefore, it is important to study the walking intention to identify gait characteristics based on kinematic data to cope with the walking change such as stair-climbing. Stairs are frequently encountered obstacles in daily life and studying the kinematics of lower limbs during stair-climbing has shown to be useful to understand the walking intention and the gait rehabilitation [3]. The objective of this study was to measure the walking intention using the inertial measurement unit (IMU) and to identify stair-climbing in advance before foot contact on the first stair.

METHODS

Twenty healthy volunteers (age: 24.8 ± 2.3years; height: 171.56 ± 2.96cm; weight: 67.66 ± 7.3kg) participated in the walking experiment. Before starting the experiment, subjects took sufficient time to get used to the experimental procedure. According to the national construction standards, the 3-floor stairs were made with a height of 18cm and a width of 30cm. The last stair was made with a width of 50cm for the subject's safety. Two IMUs were attached to the right thigh and the right tibia of the subject and the x, y, and z axes were directed to the anterior-posterior (AP), superior-inferior (SI), and medial-lateral (ML) directions, respectively. The acceleration data were collected at 100Hz and analyzed by using Matlab. The 3D motion analysis system (VICON Motion System, UK) was also used to measure the timing of the gait event with a sampling frequency of 200Hz. For each subject, the walking from the level to the stair was performed five times respectively. The level walking (LW) was performed from the initial contact (IC) of the right leg to the next contact of the right leg on the ground and the stair-up walking (SW) was performed from IC of the right leg on the ground to the next contact of the right leg on the first stair. Student's t-test was conducted for the statistical analysis on the peak acceleration in each direction under the LW and SW to compare gait characteristics with $p < 0.05$.

RESULTS AND DISCUSSION

The peak acceleration in each direction was observed between 50% and 70% of the gait cycle. No significant differences were found between LW and SW conditions in both the peak AP acceleration and the peak ML acceleration in the thigh. However, the peak SI acceleration in the thigh was significantly larger in SW than that in LW for all subjects during the initial swing phase. No significant differences were also found between LW and SW conditions in both the peak AP acceleration and the peak ML acceleration in the tibia. However, the peak SI acceleration in the tibia was significantly larger in SW than that in LW for all subjects during the preswing phase (Table 1). The peak SI acceleration was observed earlier in the tibia than in the thigh, and the vertical acceleration in SW was significantly larger than that in LW.

Table 1. Peak accelerations for LW and SW conditions

		condition	peak acceleration(g)	time(%)	p-value
Thigh	AP	LW	0.99 ± 0.26	56.56 ± 1.26	0.1932
		SW	1.11 ± 0.15	55.08 ± 3.29	
	SI	LW	-2.03 ± 0.27	65.28 ± 1.62	0.0065*
		SW	-2.54 ± 0.25	63.20 ± 3.96	
	ML	LW	0.14 ± 0.16	58.75 ± 2.19	0.1476
		SW	0.24 ± 0.08	57.50 ± 4.57	
Tibia	AP	LW	0.89 ± 0.37	59.75 ± 2.64	0.1793
		SW	1.09 ± 0.17	58.30 ± 4.43	
	SI	LW	-2.11 ± 0.29	56.92 ± 0.94	0.0190*
		SW	-2.61 ± 0.34	55.80 ± 2.60	
	ML	LW	-0.64 ± 0.04	66.60 ± 1.19	0.0555
		SW	-0.84 ± 0.24	64.04 ± 3.33	

(* : $p < 0.05$)

CONCLUSIONS

We analyzed gait characteristics to identify the transition from the level walking to the stair-up walking by using IMU. For all subjects, peak SI accelerations in both the right thigh and the right tibia were larger in SW than in LW. In addition, they were observed just before toe-off or very early in swing before contacting the first stair. The present experimental results would be used as an indicator to identify stair-climbing in advance before climbing the first stair.

P089 - GAIT ANALYSIS IN TRANSFEMORAL AMPUTEES DURING SLOPE AND UNEVEN SURFACE WALKING

INTRODUCTION

Human walking plays important role in daily activities, and has been studied widely in normal subjects during level walking. However, since our surroundings are not always same level, it is important to be able to various types of surface [1]. Unlike normal subjects, trans-femoral amputees (TF) may have experience functional limitations when walking in slope and uneven surface. There are asymmetry between prosthetic limb and non-affected limb during walking, which may cause loss of balance. Consequently, TF need adjustment strategies during slope and uneven surface walking. Nevertheless, to date, walking in lower limb amputees during slope and uneven surface has not been studied variously. The purpose of this study was to determine the gait characteristic of TF during slope and uneven surface walking and finally, determine the adjustment strategy in TF during slope and uneven surface walking.

METHODS

Three trans-femoral amputees (all males, age: 51 ± 13yrs, height: 176.9 ± 1.4cm, and weight: 80.8 ± 11.7kg) participated in this study. Before the gait analysis, the helen-hayes full body marker set was applied to the subject. Static trial was performed with 29 markers, and then 4-medial markers were removed before dynamic trials. Throughout experiment, all subjects wore their won habitual shoes. All subjects were asked to walk at a self-selected velocity on level, slope and uneven surface. Walking surface order was randomized for each person. The procedure was:

1) Level walking: Walk at self-selected velocity on a 10m walkway
2) Slope walking: Walk at self-selected velocity on 6m slope of 7° (up and down)
3) Simulated uneven surface: Walk at self-selected velocity on bumpy mat.

During walking, a three-dimensional motion capture system (Eagle4, Motion Analysis, USA) with 11-infrared cameras was used to record marker trajectories at a sampling rate of 120Hz.

RESULTS AND DISCUSSION

During upslope walking, gait velocity was decreased compared to level walking in both non-affected limb and prosthetic limb. The hip flexion angle was increased during initial contact in prosthetic limb. The knee flexion angle at terminal swing phase was reduced in prosthetic limb. The hip extension angle at initial contact was decreased in non-affected limb. However, the knee flexion angle at toe-off was increased in non-affected limb.

During downslope walking, the hip joint angle showed reduced progressively extension compare with level walking in prosthetic limb. Furthermore, maximum flexion angle was founded slightly early mid swing phase in prosthetic limb. The knee flexion angle reduced in non-affected limb during stance phase. And maximum knee flexion angle during swing phase in prosthetic limb was remarkably reduced.

During simulated uneven surface walking (bumpy mat), the gait velocity was reduced in both non-affected limb and prosthetic limb. Since the uneven surface was irregular and different with general indoor environment, the TF felt functional limitations to walk.

Since TF were not able to control prosthetic knee flexion or extension during slope and uneven surface walking, gait velocity was remarkably decreased. It might be an adjustment strategy to minimize their unbalanced and asymmetry. Furthermore, TF are required other adjustment strategy to adapt slope and uneven surface. For example, hip joint on prosthetic limb at initial contact was increased in upslope walking while hip extension angle at initial contact was decreased in non-affected limb. It provides safe foot clearance and foot positioning in upslope walking.

Table 1: Walking velocity on each surface.

	TF (non-affected limb)	TF (prosthetic limb)
	Mean ± SD	Mean ± SD
Level	123.1 ± 18.5	123.1 ± 19.2
Upslope	101.3 ± 20.8	100.3 ± 18.3
Downslope	90.4 ± 30	92.7 ± 31.5
Bumpy	56.9 ± 20.9	57.5 ± 16.3

CONCLUSIONS

In this study, we determined gait characteristics of TF during level, slope, and uneven surface walking. The results show that several adjustment strategies during multiple surface walking. Due to the small number of sample, couldn't determine the influence of the diverse prosthetic devices. Despite of this limitation, our results could be useful information in prosthetic design and lower limb amputee's rehabilitation training.

P090 - GAIT RECOVERY IS ASSOCIATED WITH IMPROVEMENT OF WEIGHT-SHIFTING ABILITY IN POST-STROKE HEMIPLEGIC PATIENTS

[1, 2] **Arinori Kamono** and [1] Naomichi Ogihara

INTRODUCTION

Hemiplegia is one of the most common impairments after stroke, and gait recovery is a major objective in the rehabilitation program. To restore walking ability of stroke patients in gait rehabilitation, it is anticipated that load applied to the paretic leg should be increased so that the contralateral unaffected leg can be lifted from the floor to move forward. However, no studies have actually investigated whether restoration of gait function is associated with weight-bearing ability of the paretic leg [1]. In the present study, we longitudinally investigated the possible relationship between gait performance and the lateral weight-shifting ability in hemiplegic stroke inpatients towards development of better rehabilitative interventions.

METHODS

Six male rehabilitation inpatients with stroke (mean age: 60 years; range: 44-75 years) participated in the present study. Four patients had left hemiplegia, whereas remaining two patients had right hemiplegia. Measurements started from 74.7 days in average after stroke onset, ranged from 39 to 107 days. Participants were included in the experiment if they could (1) stand independently for 30 seconds without a mobility aid and (2) walk 10 m without physical assistance. However, those who had (1) lower limb orthopedic surgeries; (2) history of other neurological conditions that would influence gait; (3) bilateral strokes of bilateral sensorimotor impairment; (4) severe forms of aphasia or other cognitive problems that could hinder communication or operation; (5) severe affective or psychiatric impairments; and (6) visuospatial neglect, were excluded. All patients received between 40 and 60 minutes of physical therapy and occupational therapy per day. All patients had moderate hemiplegia because of the first episode of stroke (Brunnstrom Recovery Stage: IV-V). All participants gave their written informed consent before study entry. This study was approved by the Ethics Committee of the School of Nursing and Rehabilitation Sciences, Showa University, and Nakaizu Rehabilitation Center.

Walking gait was measured longitudinally every month using an array of six force plates (AMTI, Advanced Mechanical Technology, Inc., USA) set in a wooden walkway and an eight-camera motion capture system (Vicon Motion Systems Ltd., UK). Participants were asked to walk at self-selected speed and permitted to use walking aids (e.g. T-cane) and customary braces (e.g. angle-foot orthosis). Gait speed (horizontal speed of the center of body mass), duty factor (stance period of the paretic leg as a percentage of stride duration) and trajectory of the center of pressure (COP) were quantified. At least 10 walking cycles were measured and analyzed for each subject and experiment.

The ability to shift the body weight to the paretic leg during quiet standing, i.e., lateral weight-shifting ability, was also quantified using two force plates. Each foot was placed on separate force plates, so that the change in the ground reaction force and the COP of each foot were measured. The participants were asked to apply a load on the paretic leg as much as possible and the maximum vertical ground reaction force on the paretic leg was measured. The measurements were repeated five times and the mean value was taken. The value was normalized by body weight for comparisons. Furthermore, the lateral displacement of the COP toward the paretic side was calculated.

RESULTS AND DISCUSSION

Gait speed significantly increased in five out of six participants with an increase in post onset duration. Duty factor decreased in all participants toward 0.6, the value similar to that of normal walking gait in healthy subjects. The normalized maximum load applied to the paretic leg significantly increased in four out of six participants. Combining all six participants, the gait speed was found to be significantly correlated with the maximum load on the paretic leg ($p < 0.05$). These results indicate that the walking ability was associated with the lateral weight-shifting ability.

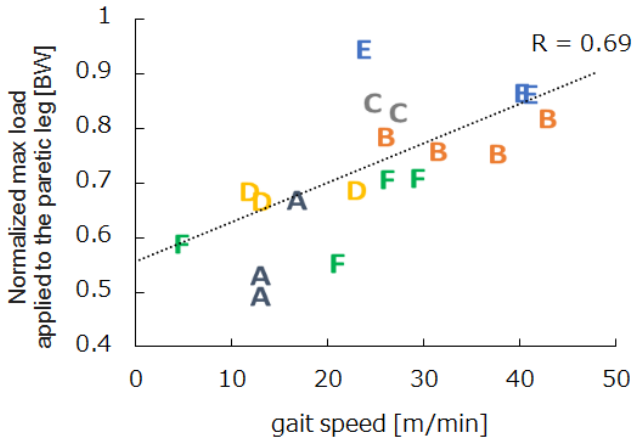

Figure 1: Relationship between gait speed and the maximum load on the paretic leg. A-F indicates each of six participants.

CONCLUSIONS

Improvement of the gait performance is linked to the weight-shifting ability on the paretic leg. Improvement of lateral balance is important for restoration of gait ability in hemiplegic patients.

INTRODUCTION

Biomechanics is the application of Newtonian mechanics to the study of the neuromuscular skeletal system. Human gait is a complex process to adjust the balance of energy using the motion of body segment. In order to move the body from one point to another, both legs alternately move in stance and swing phase. The flexion momentum of locomotion changes at each joint, and the equilibrium of the body takes place alternately via loss and recovery [1]. This paper proposes a gait stability evaluation technique based on the linear inverted pendulum model and moving support foot ZMP. With this, gait improvement can be made for the walking.

METHODS

In this study, a biped is modeled as a 3D inverted pendulum of which the body mass concentrates on the point C (the CoG), as shown in Figure 1. OXYZ is the global coordinate system, where X and Y axes are the anterior-posterior and midial-lateral directions respectively. XZ and YZ planes refer to the sagittal and frontal planes respectively; and OXYZ is the local coordinate system fixed to the center of the support polygon.

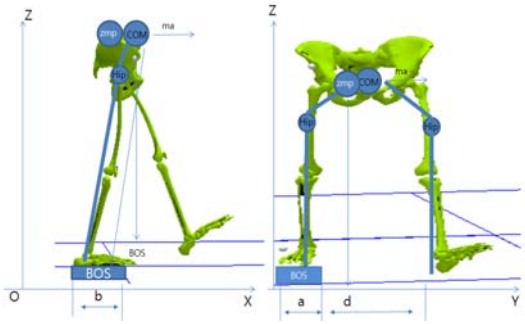

Figure 1: 3D inverted pendulum model

RESULTS AND DISCUSSION

The CoG trajectory of the normal gait is shown in Figure 2. During the double limb support period, CoG is located at the midpoint between the two supporting feet. At right heel contact, the CoG is first shifted from the point A to B. Here the distances between the point A and the point B in X and Y direction are t_i and x_i respectively. From the point A the left leg steps forward while the right leg supports the body, and CoG moves forward along the curve AB. When the left leg lands off the floor, CoG moves to the point B. When the ground reaction force is acting to the vertical direction, CoG reaches to the point C. As the body moves forward, the CoG moves to the point D, where the opposite heel contact is made. When the right toe is off the floor, CoG reaches to point E. During the stance period of the left limb, CoG follows the mirror trajectory of the stance period of the right limb. The ZMP is located within the support polygon during the single limb support period. ZMP(sagital plane) change pattern of normal gait is shown Figure 3, and ZMP(frontal plane) change pattern of normal gait is shown Figure 4.

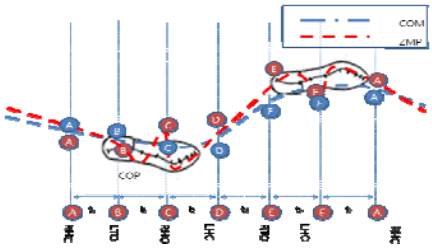

Figure 2: Trajectories of COG and ZMP in walking

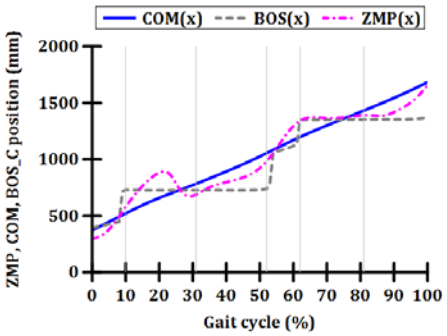

Figure 3: Sagittal plane ZMP trajectory on the sagittal plane

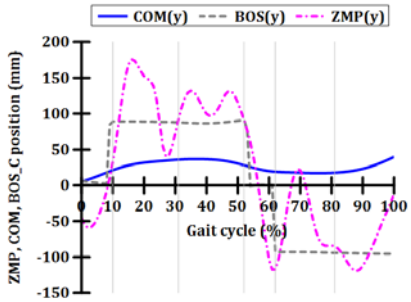

Figure 4: Frontal ZMP trajectory on the frontal

CONCLUSIONS

In human walking, dynamic stability is achived by the automatic control using the body segments to prevent the falling. In this study, the dynamic stability for gait was determined by using a ZMP method.

P092 - THE EFFECT OF TASK PRIORITIZATION DURING DUAL TASK WALKING

[1] **Jongman Kim**, [1]Seongjung Kim, [1]Eunkyoung Choi, [1]Min Jo, [1]Youngjae Jeong and [1,2]Youngho Kim
[1]Department of Biomedical Engineering, Yonsei University

INTRODUCTION

Cognitive-motor dual-task is common in daily living, for example when listening to music or talking on a mobile phone during walking. Walking is a automatized task, and walking patterns change under dual task [1]. Several recent studies have shown that safety risks increased according to increased difficulty level of dual task during walking [2]. But little has been known about the effect of task prioritization during dual task walking. The aim of this study was to quantify and compare the effects of two different task prioritization on dual task walking in healthy adults, using 3D motion capture system.

METHODS

In this study, fifteen healthy male subjects participated (27.3±1.3 years, 174.0±7.6cm, 65.3±8.3kg). All subjects were free of muscular-skeletal and cognitive injuries or limitations. After providing written informed consent, the subjects performed counting backward from the number during walking in laboratory. Three different task conditions were performed: (1) normal gait at self-selected walking speed (single-task), (2) walking with counting backward by 7 from the number in counting priority, and (3) walking with counting backward by 7 from the number in gait priority. Experiments were conducted in a random order to prevent the training effect, and the random numbers were given among 100s.

3D motion capture system (VICON MX system, UK) with 6 near infrared cameras and Helen Hayes marker set with 14 mm diameter retro-reflective markers were used to measure hip range of motion(RoM), knee range of motion, ankle range of motion, walking speed, K1 and A1. K1 represents knee flexion angle in stance phase. A1 represents ankle plantarflexion angle in loading response. All data were analyzed using Mann-Whitney and ANOVA in SPSS statics 19 (SPSS 19, IBM, USA).

RESULTS AND DISCUSSION

The graphs in Figure 1 show the gait kinematics and walking speed according to the dual task prioritization. The range of motion(RoM) in normal gait was 43.85±2.95°, 58.14 ±3.00° and 33.09 ±4.15° at hip, knee and ankle joint, respectively. In gait priority, the range of motion was 42.25±3.24°, 57.73±3.67° and 31.86±4.38° at hip, knee and ankle joint, respectively. In counting priority, the range of motion was 39.61±3.69°, 55.23±3.50° and 28.79 ±3.80° at hip, knee and ankle joint, respectively. Walking speed was 1.29±0.16m/s, 1.21 ±0.17m/s and 0.99±0.18m/s in normal gait, gait priority and counting priority, respectively. K1 was 11.81±3.29° in normal gait, 9.99±4.82° in gait priority and 7.31±4.20° in counting priority. A1 was -7.84±1.82° in normal gait, -8.85 ±2.11° in gait priority and -9.36±2.57° in counting priority.

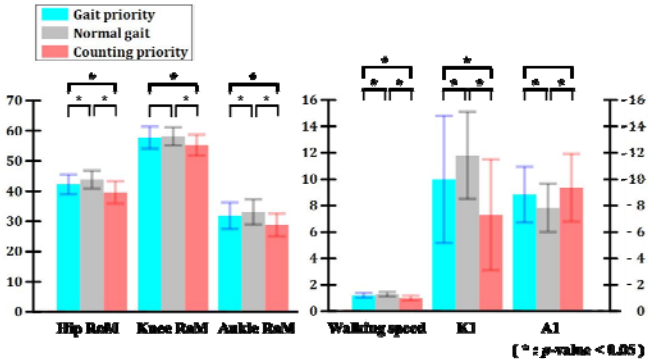

Figure 1: Gait kinematics and walking speed according to the dual task prioritization

In dual task condition, most of gait kinematics and walking speed significantly decreased than in normal gait. Also in counting priority, most of gait kinematics and walking speed significantly decreased than in gait priority. These results show that even though difficulty level of dual task was the same, there were significant differences according to dual task prioritization. There were no significant differences in knee range of motion between normal gait and gait priority, and A1 between gait priority and counting priority. These results show that gait kinematic parameters affected by dual task were different, depending on dual task prioritization. Based on these findings, we recommend that researchers pay attention not only to the difficulty level of dual task but also to consider the task prioritization during dual task walking.

CONCLUSIONS

This study compared the difference between gait kinematics and walking speed according to dual task condition, and determined the effects of task prioritization during dual task walking. There were no significant differences in knee range of motion and ankle plantarflexion angle in loading response according to task prioritization. These results indicate that dual task prioritization have different effects from difficulty level of dual task in walking. These results may have important implications for the research applications of the counting backward test for dual task training or dual task experiments.

P093 - VALIDITY OF APDM INERTIAL SENSOR SYSTEM FOR STRIDE TIME AND STRIDE LENGTH DURING TREADMILL WALKING

[1]Jinseung Choi, [1]Jeongwoo Seo, **[1]Taeho Kim,** [1]Hyemi Cho, [1]Dongwon Kang, [1]Gyerae Tack

INTRODUCTION

Gait analysis is an important method for orthopedic approach and neuro-musculo-skeletal rehabilitation in a laboratory, daily health, care and clinics. In general, gait analysis has been utilized 3D motion capture system based on multiple high-speed infrared cameras. The advantage of this equipment is that it allows relatively precise measurement of motion. Moreover, due to the widespread availability of commercial equipment, it is easy to synchronize and share measurement data with various other equipment. However, the price of such equipment is very expensive and has limitations on the number of cameras and the space of the experiment.

Recently, gait analysis using an inertial sensor, which is low cost and has good portability without space limitation, has been increasing. Among these inertial sensor devices, MobilityLab system (APDM Inc., Portland, OR, USA) is widely used for gait and balance evaluation [1].

And treadmill is the most commonly used equipment for gait research. The treadmill makes it easy to control the experimental conditions such as duration, space, and speed in walking experiment. The purpose of this study is to verify the accuracy of stride time and stride length data using the MobilityLab system when treadmill walking, and to apply the error correction method using linear regression.

METHODS

Three healthy young male subjects participated in this experiment (age: 27.7 ± 0.6 years, height: 177.3 ± 8.1 cm, weight: 89.0 ± 13.9 kg). Subjects walked on the treadmill for 3 minutes at the preferred walking speed, and only the middle 50 steps were used for the analysis.

3D motion capture system (MotionAnalysis Corp., Santa Rosa, CA, USA) and MobilityLab system were used simultaneously to compare stride and stride length data. Two variables compared the mean difference and RMS difference. In order to correct the stride length error obtained from the APDM, the error value was extracted using the linear regression method with a range of motion in shank and arm, and this value was added to the stride length obtained from the APDM [2]. The range of motion in shank (ROMshank) and arm (ROMarm) were applied to calculate the regression equation.

RESULTS AND DISCUSSION

Figure 1 shows an example of the stride length and stride length of one subject extracted from 3D motion and APDM. Table 1 shows the mean and RMS differences of the two variables. Stride time showed very high agreement (0.0000 sec and 0.0081 sec, respectively), but the stride length showed a slight difference (-0.1017 m and 0.1149 m, respectively). However, after correcting the error using the regression equation (eq.1), the mean and RMS differences were significantly reduced (-0.0209m and 0.0430m, respectively).

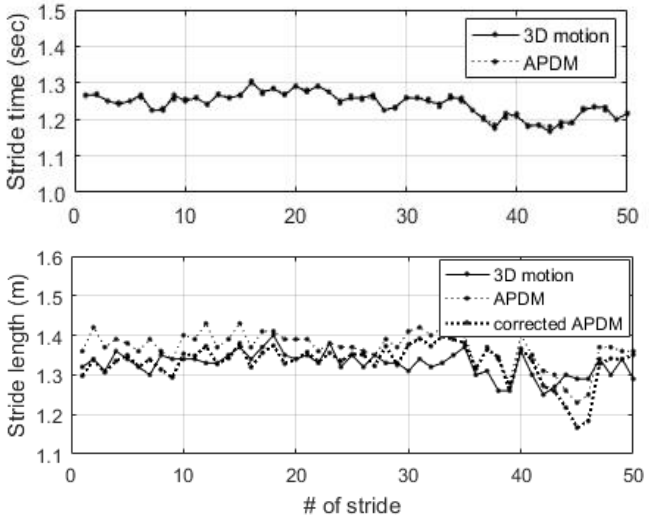

Figure 1: Example of stride time, stride length and the corrected stride length data for one subject

Stride length error=B_0+B_1×ROMshank+B_2×ROMarm [eq.1]

where B0 =0.067, B1=-0.003, and B2=0.005.

Table 1: Mean and RMS differences between measurements due to 3D motion and APDM sensor

	Original data		After correction	
	Mean difference	RMS difference	Mean difference	RMS difference
Stride time(sec)	0.0000	0.0081	-	-
Stride length(m)	-0.1017	0.1149	-0.0209	0.0430

(RMS: root mean square)

CONCLUSIONS

The stride time provided by the APDM in the treadmill walking was very high, but the stride length was slightly different. However, this difference could be reduced significantly through correction using regression equations. Although additional supplementation is needed, it is considered that APDM variables can be used in treadmill walking study.

P094 - DEFORMATION OF FOOT ARCH IN LONG DISTANCE RUNNING ON A TREADMILL

[1] **Kensaku Kimura**, [2]Norihisa Fujii
[1]Graduate school of Comprehensive Human Sciences, University of Tsukuba, Japan
[2]Faculty of Health and Sport Sciences, University of Tsukuba, Tsukuba, Japan
Corresponding author email: kimura@lasbim.taiiku.tsukuba.ac.jp

INTRODUCTION

The foot has three arch structures. Decreasing the height of the medial longitudinal arch leads to a decrease in the shock absorbing function during walking and running. In the previous studies[1-2], the medial longitudinal arch height, which is the height from the ground to the navicular bone, is considered to decrease after a long distance running and to increase to the original height after a sufficient rest. However, it is not clear what kind of change is occurring in the medial longitudinal arch during long-distance running. In this research, we aimed to clarify the characteristics of the change of the medial longitudinal arch which is occurring inside the shoe during long distance running.

METHODS

Subjects were seven male college students who had experience of running 10km and running habits. Shoes (IGNITE-XT, PUMA) that were processed so that reflective markers could be affixed directly to the feet, and socks worn by subjects. The trial was done in order of (1) static standing posture, (2) 15m running on the flat road, (3) 10km running on the treadmill (ORK-5000SE, OHTAKE), (4) 15m running on the flat road, (5) static standing posture. For data collection, 3D coordinates of 51 reflective markers on a body were recorded with a motion analysis system (VICON MX+, Vicon Motion Systems), operating at 250Hz. In running on flat road, ground reaction force of the left support phase was obtained with a force platform (9287, Kistler), operating at 1000Hz. Determination of running speed was set to be a "somewhat hard" load on the Borg scale by running on the treadmill on another day (running speed 12 ± 3km/h). The running speed during flat road running was measured with a laser speedometer (LDM301S, JENOPTIK) at the same speed as running on the treadmill. For the shoes used in this study, the shape of the insole was flat. A special flat insole with no irregularities was inserted it in the shoes. A virtual foot sole was defined based on the reflection marker directly attached to the foot. The length of the perpendicular line drawn from the navicular bone to the virtual foot sole was calculated to be the navicular bone height. The distance between the inner side of the calcaneus bone and the ball of the foot was defined as the arch length. The navicular bone height was divided by the arch length to calculate the arch height rate.

RESULTS AND DISCUSSION

The medial longitudinal arch during running was deformed gradually. The arch length increased when the vertical component of the ground reaction force showed the maximum value, then the arch height rate was the lowest when the ankle joint had the maximum dorsiflexion. Figure 1 shows that the arch length was maximal (55% time) after the left heel contact (50% time). The arch height rate reached a minimum value (around 78% time). In the static standing posture before and after long distance running, the arch height rate decreased for 6 of 7 subjects. This result seems to support the report of the previous study[1]. However, the minimum value of the arch height rate in the support phase (50% time to 89% time) of 3 in 7 subjects increased at 5km point and 10km point compared with 0km point. Figure 1 shows a data of typical subject. These subjects combined the pronation of the rear foot and the further supination of the forefoot during the support phase. Due to this movement, taking off toward the little toe was continued from 0km to 10km. As a result, it was considered that the minimum value of the arch height rate increased because the amount of load in the inward direction of the foot during the support phase decreased and the deflection of the bones constituting the foot arch was also reduced.

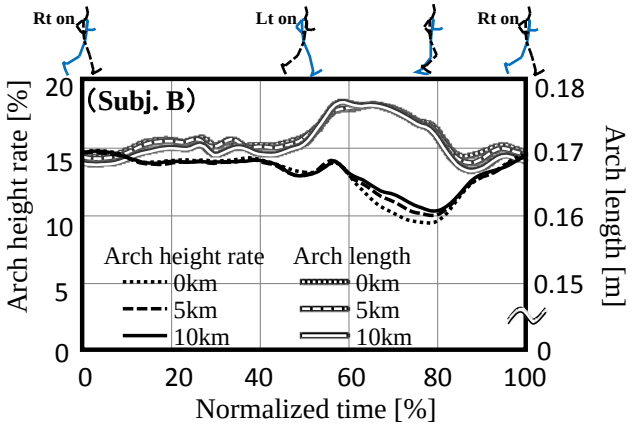

Figure 1: Arch height rate and arch length while running of 0km, 5km, and 10km points on the treadmill of the subject B.

CONCLUSIONS

The important results of this study are as follow: (1) The medial longitudinal arch during running was deformed gradually. (2) In the static standing posture before and after long distance running, the arch height rate decreased. (3) Comparing the 0km point and the 10km point, the minimum value of the arch height rate of some of subjects increased.

INTRODUCTION

It is well-known that locomotor characteristics might be the result of the neurological/musculoskeletal degenerative processes typical of advanced age. Gait variability would be associated with risk of falling in elderly people. Recently, Hamacher et al. (2016) reported that dance training could increase local dynamic stability of the trunk during normal walking in elderly people. However, little is known about the effect of dance training on gait stability in healthy young adults. So, the purpose of this study was to investigate the effect of dance training on gait stability during treadmil walking at different speed.

METHODS

Subjects were 18 healthy young females. Nine of them were dancers who had dance experience more than ten years and nine of them were controls with no dance or regular training experiences. Head and trunk acceleration were measured during a 40-sec treadmill walking using a 3D accelerometer. Walking speed was set at three different speeds such as natural walking speed (NWS), 1.5 times of NWS (HIGH) and 0.5 times of NWS (LOW) in each subject. Subjects were asked to walk on a treadmill at three above-mentioned speeds by two different manners, such as natural walking and conscious stable walking. For conscious stable walking, subjects were asked to walk to minimize the fluctuation of their head. The following dependent variables were assessed: the time of one step and the acceleration variability (root mean square [RMS]) of the head and the trunk.

RESULTS AND DISCUSSION

There was no significant difference in the speed of walking in two different manners between dancers and controls. For natural walking, no significant difference was obtained in RMS of the head and the trunk acceleration. Therefore, it is indicated that dance training would not induce gait stability during treadmill walking at natural speed for young subjects..

On the other hands, for conscious stable walking, only dancers showed significant smaller lateral RMS of their head and the hip acceleration compared with natural walking at LOW. At HIGH, dancers also showed significant smaller vertical RMS of their head acceleration during conscious stable walking compared with natural walking. Significant smaller sagittal RMS of their hip acceleration during conscious stable walking compared with natural walking for both groups at NWS. From the results of this study, it is indicated that dance training would induce higher gait stability when they consciously change gait patterns to minimize the fluctuation of their head on a treadmill.

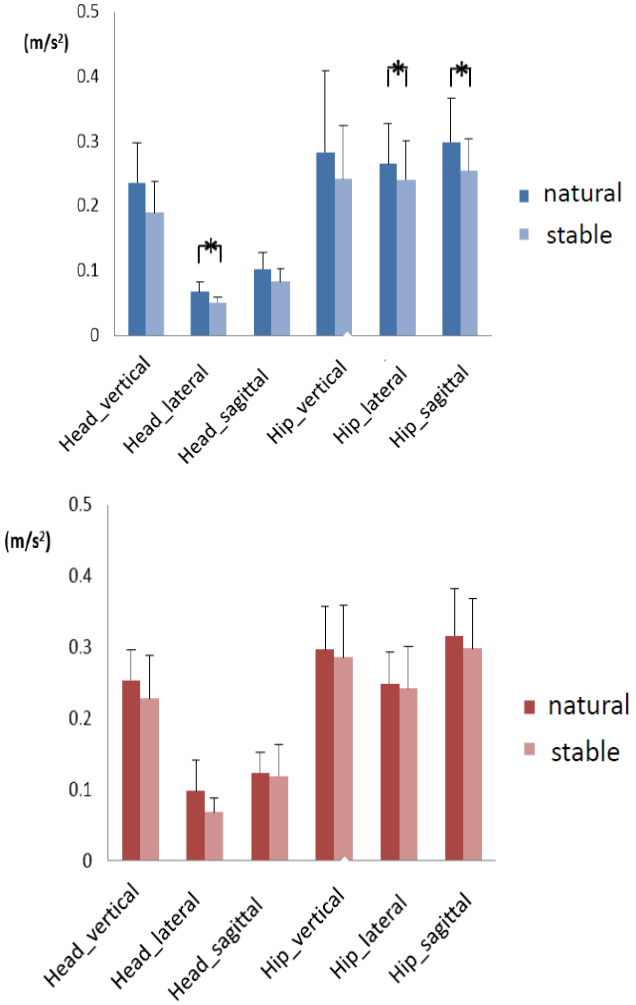

Figure 1: Tri-axial acceleration during natural walking and conscious stabile walking at slow speed
(Upper figure: dancers, Lower figure : controls)

CONCLUSIONS

These findings indicate that dance training would induce to change gait stability during conscious walking to minimize the fluctuation during treadmill walking either at slow and fast speeds.

P096 - WALKING STRATEGIES FOR THE TRANSITION FROM UPHILL TO DOWNHILL WALKING

[1] **Jinkyu Lee**, [1]Yoon No Gregory Hong and [1]Choongsoo S. Shin
[1]Sogang University
Corresponding author email: cshin@sogang.ac.kr

INTRODUCTION

An effect of walking environment such as continuous slope walking on lower extremities movements has been studied [1,2]. However, an actual walking environment often consists of combination of uphill and downhill slopes. Further, to the best of our knowledge, no study has yet reported an effect of transition between uphill and downhill on the locomotion mechanics. Previous study suggested that during transition of walking from a level surface onto different inclined surfaces, lower extremity movement must be modified to ensure safely movement as the elevation and orientation of the support surface [3]. Thus, one can expect that lower extremity movement biomechanics during a transition between uphill and downhill walking would also be altered in comparison to those during continuous slope walking. The aim of the present study was to identify the mechanism of alteration of the walking strategy during up-down transition walking in comparison to those during continuous uphill walking. The following hypotheses were made in this study. The ankle dorsiflexion angle, the percentage of the stance phase at the time of the COP passing the foot COM and at the time of heel-off are different between the up-down transition walking on a triangular slope and the continuous uphill walking.

METHODS

Twelve male students (age: 24.5±2.7, mass: 74.5±10.2 kg, height: 1.76±0.03 m, BMI: 24.1±3.2 kg/m^2) participated in this study. The subjects were instructed to walk in the following two situations: continuous uphill walkway and triangular walkway. Two sets of experiments were performed. In one experiment, for the up-down transition walking, a force plate was embedded into the inclined walkway, which was the uphill walkway of the triangular slope. In the other experiment, for continuous uphill walking, an uphill walkway was constructed with an inclination angle of 15°. A 3D motion capture system equipped with 8 infrared cameras (5 Eagle, 2 Hawk, and 1 Raptor, Motion Analysis Corp., Santa Rosa, CA, USA) was used to record the motion of lower extremity joints at a sampling rate of 200 Hz. The measured kinematic and kinetic data were filtered using a zero-lag, fourth-order Butterworth low-pass filter with a cutoff frequency of 10 Hz. To calculate the joint kinematics, the coordinate systems for each body segment were defined by following previous methods[4]. Paired two-tailed t-tests were performed in order to determine significant differences between up-down transition walking and continuous uphill walking at a significance level of 0.05.

RESULTS AND DISCUSSION

One notable difference between the two walking conditions is that during the up-down transition walking, ankle dorsiflexion was significantly greater after 68.2% of the stance phase in comparison to that during the continuous uphill walking (Figure 1). The movement of the body COM in anterior direction may have caused this alteration. A previous study suggested that a greater ankle dorsiflexion contributed to the movement of the body COM in the anterior direction during walking [5]. It would also be supported by the fact that the percentage of the stance phase at the time of the COP passing the foot COM (up: 52.7(10.5)%, up-down: 44.8(11.4)%, P*=0.034) and at the time of heel-off (up: 74.0(3.4)%, up-down: 70.3(6.8)%, P*=0.031) were significantly lower during the up-down transition walking on the triangular slope. These results suggest that a participant walking on a triangular slope would need to actively control a faster moving body COM by performing ankle dorsiflexion. Although the stance time was not different (up: 0.87(0.13)s, up-down: 0.91(0.11)s, P=0.183), the percentage of some gait events within the stance time could be modified by adopting a different strategy during the up-down transition walking.

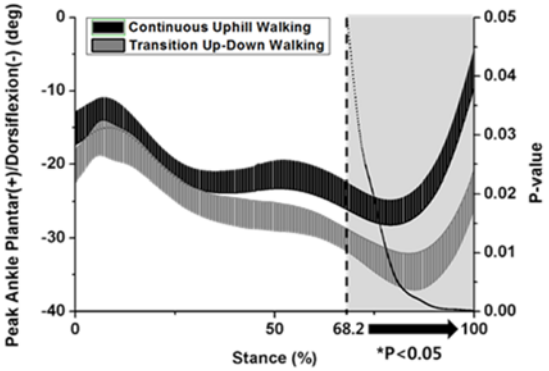

Figure 1: Ensemble curves for the ankle joint angle. The stance phase is presented from initial contact (0%) to toe off (100%). The shaded grey and dark grey areas represent the mean ± one standard deviation.

CONCLUSIONS

To conclude, differences in the times of gait events and in the ankle dorsiflexion angle between up-down transition walking on a triangular slope and continuous uphill walking suggest that a modified strategy was used during the up-down transition walking condition.

P097 - EFFECTIVENESS OF CUSTOM-FIT INSOLE IN TERMS OF FOOT ARCH HEIGHT, FOOT EVERSION, AND KNEE ROTATION DURING GAIT

[1] **Jung-Min Lee**, [2]Wenming Chen, [1]Sang-Won Woo, [1]Emmanuel Eghan-Acquah and [1]Sung-Jae Lee

INTRODUCTION

Studies have shown that excessive reduction of the arch height at the plantar surface of the foot may cause abnormal foot eversion which is linked to excessive internal rotation of the knee joint, that subsequently results in knee cartilage and anterior cruciate ligament injuries [1,2,3,4]. Although custom orthotics with conforming arch support is one of the conservative treatments available in maintaining the arch height [5], its fabrication process can be quite complex as it requires professional skills and techniques. The recently introduced heated-molding method for custom-fit insole is drawing a lot of attention because of its quick fabrication process and greater conformity between the plantar surface and the insole [6]. In this study, biomechanical effectiveness of maintaing arch height, foot eversion and knee rotation of a custom-fit insole made using the heated-molding method was investigated.

METHODS

Seven subjects (6 males, 1 female; age=23.43 ± 1.51 years) without injuries and trauma of lower limbs were recruited for gait analysis. The subjects were tasked to walk at their own gait velocity on a 7m walk way [7], twice with: bare-foot (Case 1), shod with ordinary insole (Canvas shoe, EONIA, Korea; Case 2), custom-fit insole (Footbalance System Ltd., Finland; Case 3). Gait analysis was conducted using a 3D motion capture system (CORTEX 6.0, Motion analysis Corporation, USA), which includes 8 infrared cameras set at 120Hz. 12 reflective markers were placed on the lower limbs of the subjects according to the 'Helen Hayes marker set' [8]. At the mid stance of gait cycle (about 55% of stance phase) [9], foot eversion and knee rotation were measured: changes in foot arch angle and particularly resulting arch height were evaluated from 3 reflective markers on the medial first-metatarsal head, the navicular and the medial calcaneus (Figure 1-a). It should be noted that changes in arch height was represented in relation to changes in arch angle: arch angle closer to 180 degrees suggests flatter plantar surface, thus, less arch angle suggests greater arch height. In addition, the arch height at the static standing posture before the gait was measured to assess the changes in arch height due to dynamic nature of the gait.

RESULTS AND DISCUSSION

Compared to the static standing posture, relative reduction of foot arch angle during gait was 1.1%, 4.4%, 5.4%, for Case 1, Case 2 and Case 3 respectively (Figure 1-b). This suggests that Case 3 maintains arch height better than Case 1 and Case 2. The foot eversion results showed that Case 3 (0.5±2.3°) was lower than Case 1 (1.6±4.1°) and Case 2 (1.1±2.3°), suggesting that the customized insole is most effective against eversion (Figure 1-c).
However, in knee rotation, Case 3 (9.5±13.1°) exhibited the greatest knee external rotation as compared to Case 1(6.9±13.5°) and Case 2(6.1±12.5°) (Figure 1-d).

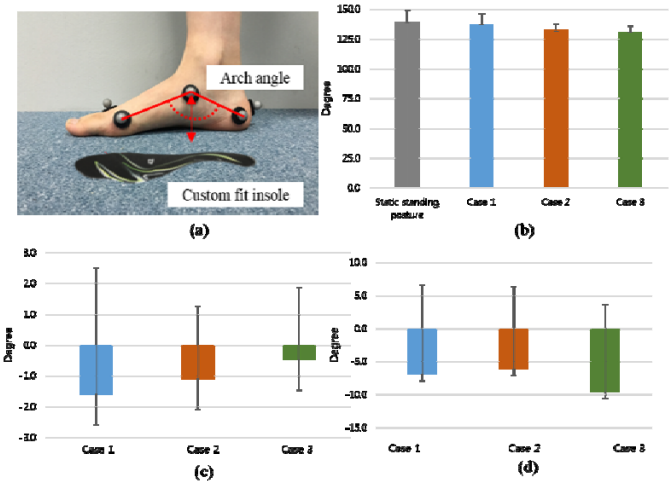

Figure 1. (a)Definition of arch angle (b)Foot arch angle (c)Ankle eversion and (d)Knee external rotation at mid stance.

CONCLUSIONS

Our study results established that custom-fit insoles made using the heated-molding method can be effective in maintaining arch height and reducing unwanted foot eversion. However, its effectiveness against knee external rotation remains lacking. Further studies are recommended to better understand the comprehensive biomechanical effectiveness of the custom-fit insole.

INTRODUCTION

Walking is a fundamental function for people's daily activities, but most of stroke patients have difficulties in recovery of normal gait [1, 2]. Patients after stroke with the nerve injury which impair descending motor pathways cannot complete the flexion and extension of knee joint during walking independently by contracting muscles in lower-extremity [3]. The intensity of the surface electromyography (sEMG) reflects information of neurological control and muscle contraction [4]. Few study reported the knee angle range (KAR) symmetry and muscle contractions during knee flexion and extension, the exact reasons of abnormal gait in stroke patients are still unknown.

The purpose of this study was to investigate the pathological patterns of the relationship between muscle contractions and the knee flexion and extension in stroke patients during walking. We hypothesized that the symmetry of knee joint in stroke group is lower than that in control group during flexion and extension. We also hypothesized that muscle contractions of healthy subjects are greater than those of stroke patients and the paretic side of patients is more weakened in sEMG than non-paretic side, and the abnormity of muscle contractions generate the asymmetry gait.

METHODS

Ten stroke patients and 10 gender- and age-matched healthy subjects participated in this experiment. The data of reflective markers attached on lower-extremity, and sEMG signals of rectus femoris (RF), femoris (BF) and gastrocnemius (GAS) were collected during walking. Each subject performed 10 trials in the experiment. The KAR was calculated as the difference between the biggest knee joint angle and the smallest angle during flexion and extension.

The KAR Symmetry ratio (λ) was calculated as the ratio of the paretic side and the non-paretic. The RMSE of sEMG was defined as the root mean square value of the difference between the actual amplitude and the average amplitude. Mean comparison was used to test for differences of λ and the RMSE of sEMG between groups and within group ($p < 0.05$).

RESULTS AND DISCUSSION

Most patients were found significantly lower than the controls in the λ of knee flexion ($p < 0.05$) and knee extension ($p < 0.01$). Stroke patients showed higher RMSE value of RF muscle than healthy subjects during knee extension on non-paretic side ($p < 0.05$, Figure 1 (a)). Differences were found in both paretic and non-paretic sides between two groups in RMSE of GAS during knee flexion ($p < 0.05$), also differences were observed in GAS between two limbs for both stroke ($p < 0.01$) and control ($p < 0.05$) (Figure 1 (c)).

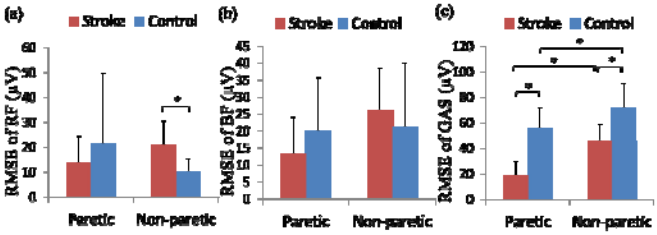

Figure 1: RMSEs of sEMG in (a) RF, (b) BF and (c) GAS muscles on paretic and non-paretic sides of two groups. *$p < 0.05$.

The weak knee joint flexibility in paretic side of stroke patient shows the KAR asymmetry, which led to lose stability and balance during gait. Patients need stronger muscle contraction of RF to complete the non-paretic knee extension, which may be the compensation for the weaker paretic side. The ability of GAS muscle contractions was weakened after stroke, especially in paretic side. A potential reason of the KAR asymmetry would be the decreased contraction strength of the GAS on paretic side during flexion and the increased contraction of RF on non-paretic side during extension.

CONCLUSIONS

This study demonstrated that the effect of muscle contraction on knee during flexion and extension after stroke. Stroke causes remarkable symmetry of knee joints for gait. Increasing the GAS contraction on paretic side and easing the RF contraction on non-paretic side will be beneficial to the recovery and rehabilitation of the gait for stroke patients.

P099 - EVALUATION OF POSTURAL INSTABILITY IN STROKE PATIENT DURING QUIET STANDING

[1]Wei Wang, [1]**Ke Li**, [2]Na Wei, [3]Cuiping Yin, [3]Shouwei Yue
[1]Department of Biomedical Engineering, School of Control Science and Engineering, Shandong University
[2]Department of Geriatrics, Qilu Hospital, Shandong University
[3]Department of Physical Medicine and Rehabilitation, Qilu Hospital, Shandong University
Corresponding author email: kli@sdu.edu.cn

INTRODUCTION

The center of pressure (COP) signal has been used for assessing postural stability during standing in stroke patients. The fluctuation of COP in anteroposterior (AP) and mediolateral (ML) directions increased after stroke during quiet standing, reflecting an increase in postural sway [1]. The correlation between COP series from bilateral planta reflected the inter-limb coordination [2]. Removing the vision aggrandized the COP sway and weakened inter-limb coupling during stance [3]. It was still unknown that the influence of stroke on COP fluctuation on paretic and non-paretic sides and the alteration of inter-limb coupling in stroke patients under non-vision condition during standing.

The purpose of this study was to evaluate the effects of stroke on postural sway and inter-limb coupling during quiet standing. We hypothesized that patients with stroke performed greater COP fluctuation on two limbs in AP and ML directions and lower inter-limb coordination compared to healthy subjects. We also hypothesized that EC condition increased COP sway on both sides in two directions, but decreased coordination between limbs in two groups.

METHODS

Eleven subjects with stroke and 11 gender- and age-matched healthy volunteers took part in the study. The COP signals of both limbs were recorded during quiet standing on two adjacent force platforms for 30 s with vision (EO) and 30 s with non-vision (EC). Each subject performed four trails.

The fluctuation and inter-limb coordination of COP were quantified by the standard deviation (SD) and the cross correlation-coefficient (CC):

$$SD = \sqrt{\frac{1}{n}\sum_{i=1}^{n}(x(i)-\bar{x})^2} \quad (1)$$

$$CC = \frac{\sum_{i=1}^{n}(x(i)-\bar{x})(y(i)-\bar{y})}{\sqrt{\sum_{i=1}^{n}(x(i)-\bar{x})^2\sum_{i=1}^{n}(y(i)-\bar{y})^2}} \quad (2)$$

The repeated ANOVA and *t*-test were used for statistical analysis ($p < 0.05$).

RESULTS AND DISCUSSION

The non-paretic side of patients showed significantly higher SD of AP-COP than the paretic side under the EO ($p < 0.05$) and EC ($p < 0.001$) conditions. The SD of ML-COP on non-paretic side of patients was higher than that of controls under EC ($p < 0.05$). Lower CC values of AP-COP was found in patients versus controls under two vision condition ($p < 0.05$), and the values under the EC was increased after removing vision information in stroke and control ($p < 0.05$).

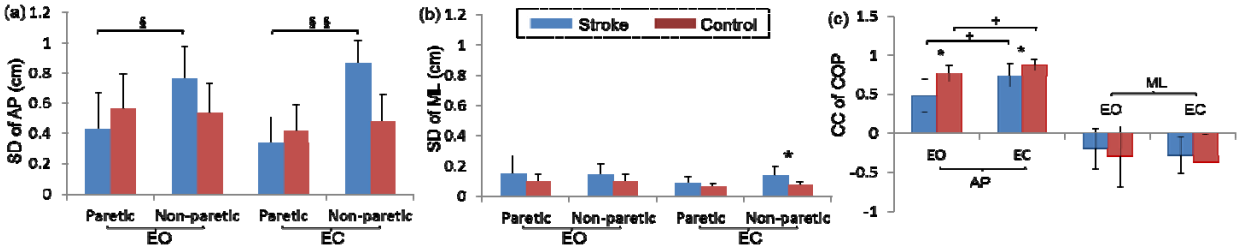

Figure 1: The SD of COP in (a) AP and (b) ML directions, and (c) the CC of COP in AP and ML directions under the EO and EC conditions in stroke and control. *$p < 0.05$. $^{+}p < 0.05$. $^{\$}p < 0.05$. $^{\$\$}p < 0.001$.

The non-paretic limb was relied upon to adjust the COP for maintaining COM stability for stroke patients during quiet stance. The postural instability after hemiplegia may be related to the inter-limb incongruity, which could be on account of asymmetrical weight distribution and excessive relying on the non-paretic limb during quiet stance. Healthy person and patients with stroke performed similar adaptive mechanism during quiet stance that increased inter-limb coupling compensated for the absence of vision feedback.

CONCLUSIONS

Stroke patients exhibited decreased postural stability during quiet stance, especially under non-vision condition. Increasing the contribution of paretic limb and enhancing coupling between limbs may improve standing stability for patients post-stroke.

P100 - BIOMECHANICAL COMPARISONS OF THE LOCOMOTOR SYSTEM DURING LEVEL WALKING BEWTEEN USING ANTERIOR AND POSTERIOR ROLLATORS IN THE ELDERLY

[1]**Song-Ying Li**, [1]Pei-An Li, [1]Hsing-Po Huang, [1,2*]Tung-Wu Lu
[1] Institute of Biomedical Engineering, National Taiwan University, Taiwan, R.O.C.
[2] Department of Orthopaedic Surgery, School of Medicine, National Taiwan University, Taipei, Taiwan

INTRODUCTION

Anterior and posterior rollators are popular walking aids for the elderly. Comparisons of the gait characteristics between anterior and posterior rollators have been reported for children [1], but those for the elderly have not been available in the literature. Differences in gait patterns in the elderly when using anterior and posterior rollators remain unclear. Hence, the purpose of this study was to compare the biomechanical differences of the lower extremities in the elderly when walking without aids, with an anterior rollator, and with a posterior rollator.

METHODS

Twelve healthy older adults (8 males and 4 females; age: 76.6 ± 8.1 years; height: 160.8 ± 10.0 cm; mass: 65.9 ± 11.9 kg) walked at a self-selected pace on a 12-meter walkway without walking aid (IW), with an anterior rollator (AR), and with a posterior rollator (PR). Each subject wore thirty-nine skin markers placed on specific anatomical landmarks, three-dimensional trajectories of which were measured using an 8-camera motion capture system (Vicon T-40S, Oxford Metrics Group, UK) at a sampling rate of 200 Hz. The ground reaction forces (GRF) were also measured simultaneously using three forceplates (AMTI, U.S.A.). A custom-made, height-adjustable four-wheeled rollator was used in the study. The rollator could be used as an anterior or a posterior one by a simple conversion mechanism. The joint kinematics and kinetics were calculated using inverse dynamics analysis. The values of the joint angles and moments at toe-off, heel-strike, contralateral toe-off, contralateral heel-strike, the next heel-strike were extracted for subsequent statistical analysis.

For each of the calculated variables, including joint angles, joint moments, and temporal-spatial parameters were compared with one-way repeated measure ANOVA between the three walking conditions. All significance levels were set at $\alpha = 0.05$ and all the statistical analyses were performed using SPSS version 20.0 (SPSS Inc., Chicago, IL, USA).

RESULTS AND DISCUSSION

Compared to independent walking, the posterior condition significantly decreased the gait speed (IW: 830.95±58.07; PR: 751.35±103.34mm/s) and cadence (IW: 98.05±6.29; PR: 91.13±12.61steps/min) ($p<0.05$). There was no significant difference in temporal-spatial parameters between the anterior and posterior conditions. Compared to the anterior condition, the posterior showed significantly decreased hip flexion at heel-strike (AR: 28.3±3.87; PR:25.84±3.45°), contralateral toe-off (AR: 21.07±3.43; PR:19.27±3.03°), toe-off (AR: 2.15±3.5; PR:0.3±3.21°), and the next heel-strike (AR: 26.83±3.35; PR:25.1±3°) ($p<0.05$). Compared to independent walking, both rollator conditions showed significantly decreased knee flexion angles (IW: 16.79±3.49; AR: 10.75±3.99; PR: 10.02±3.64°) and increased ankle plantar flexion angles (IW: 0.59±2.22; AR: 3.77±2.8; PR: 4.93±2°) at contralateral toe-off ($p<0.05$) (Fig. 1). In addition, the anterior condition showed significantly decreased knee moment (AR: 0.52±1.74N*m) while the posterior condition showed significantly decreased ankle moment during contralateral toe-off (PR: 0.21±0.96N*m) ($p<0.05$) (Fig. 1).

The healthy older adults were found to have reduced gait speed when using PR. Compared to the posterior rollator, the anterior one showed significantly increased hip flexion angles at most gait events, possibly related to the fact that the elderly tended to lean forward while pushing the rollator. Compared with independent walking, the anterior and posterior conditions showed significantly reduced knee and ankle extensor moments, respectively, at contralateral toe-off, presumably as a result of the support provided by the rollators.

Both anterior and posterior rollators are used to provide support to the user with increased gait stability. In the current study, both types of rollators were also found to be helpful for the elderly during walking with reduced mechanical demands to some of the lower limb joints.

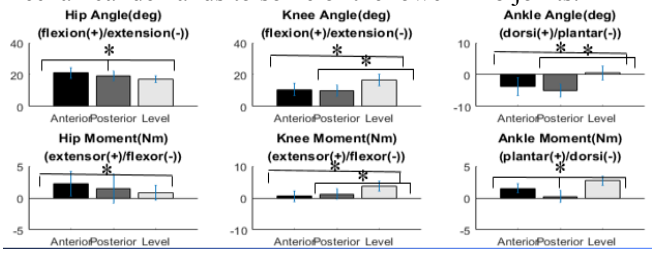

Figure 1: Means (standard deviations) of joint angles (above) and moments (below) of the hip, knee and ankle in the sagittal plane at contralateral toe-off for independent walking (white), and anterior (black) and posterior conditions (grey). * indicates statistical significance.

CONCLUSIONS

The current study was the first attempt to compare the gait characteristics of healthy older people while ambulating with an anterior or posterior rollator. The current findings suggest that both anterior and posterior rollators produce beneficial biomechanical effects to the lower extremities apart from gait balance, and may provide a guideline for selecting rollators for the elderly or patients.

INTRODUCTION

Measurement of the movements of skeletons is essential for a better understanding of the functions and/or etiology of normal, pathological and post-treatment joints. Model-based tracking (MBT) methods using x-ray imaging systems have been developed to quantify non-invasively the three-dimensional (3-D) kinematics of various joints [1-2]. While some used purpose-built synchronized biplane imaging systems, others failed to take into account of the non-synchronizing, alternating nature of clinical x-ray imaging systems, leading to errors in the 3-D measurements. The current study solved the problem by developing and experimentally validating a new model-based tracking technique, which will be useful for measuring 3-D joint kinematics using alternating biplane x-ray imaging systems available in clinical settings.

METHODS

The study employed a clinical biplane x-ray imaging system (Allura Xper FD20/20, Philips Medical Systems, Netherlands), two detectors of which enabled the acquisition of a pair of fluoroscopic images with a time offset of 1/2 image frame. Each of the two detectors acquired 30 frames/s, so the system has a frame rate of up to 60 frames/s. The biplane imaging system was calibrated for intrinsic and extrinsic parameters through a calibration procedure [2]. Computed tomography (CT) of the joint under test would be collected and used to reconstruct the volumetric and surface models of the individual bones. The proposed new MBT algorithm consisted of two stages of 2-D/3-D image registration. At the 1st stage, an existing single-plane MBT [3] was used to determine the initial six degrees-of-freedom (6-dof) of the bone models for each imaging frame. At the *N*th frame, the 6-dof of the (*N*-1)th and (*N*+1)th frames, determined using the single-plane MBT from images of the detector different from the detector used for the *N*th frame, were used to produce a set of trajectories of model points at *N*th frame. At the 2nd stage, a new method, called "trajectory interpolation and degree-of-freedom decomposition (TIDD)", employed a two-level numerical optimization scheme with which the less accurate components (i.e., z-translation & x-rotation) were refined by solving an optimization sub-problem (i.e., inner level) according to the obtained trajectory profiles. The outer level optimization searched for the remaining 4-dof such that the final 6-dof best-fitted the bone models to the corresponding fluoroscopic images.

An *in vitro* validation experiment using ovine knee and human ankle specimens were conducted to assess the errors of the proposed MBT method in measuring dynamic motions of the bones. The MBT-determined 6-dof of the bones were compared with those obtained from an 8-camera infrared motion capture system (VICON, Oxford Metrics, UK) with markers attached to bone pins, giving the measurement errors in 6-dof for each bone.

RESULTS AND DISCUSSION

The root-mean-squared errors (RMSE) of the 6-dof of the femur and tibia of the tibiofemoral joint were less than 0.58 mm in translations and 0.87° in rotations (Table 1). The RMSE for the tibia, talus and calcaneus of the AJC were all less than 0.24 mm for translations and 0.95° for rotations. The results showed that the proposed MBT method successfully reduced the translation errors along the projection axis (T_z component), which were the biggest error in conventional single-plane MBT methods [2-3]. The rationale behind the current TIDD strategy was that the relatively accurate kinematic components of adjacent frames were utilized to help correct the less accurate kinematic components of the current frame.

Table 1: The root-mean-squared errors of each kinematic component of the bones of tibiofemoral and ankle joints.

	T_x(mm)	T_y(mm)	T_z(mm)	R_x(°)	R_y(°)	R_z(°)
Tibiofemoral Joint						
femur	0.58 ±0.01	0.33±0.02	0.25 ±0.03	0.50 ±0.03	0.87±0.04	0.33 ±0.02
tibia	0.50 ±0.00	0.26±0.02	0.26 ±0.02	0.44 ±0.02	0.47±0.02	0.31 ±0.02
Ankle Joint Complex						
tibia	0.19 ±0.13	0.24±0.13	0.22 ±0.11	0.25 ±0.11	0.95±0.08	0.22 ±0.19

calca. = calcaneus

CONCLUSIONS

The study successfully developed and validated a new model-based tracking method to solve the synchronization problem with clinical alternating x-ray imaging systems. Since biplane x-ray imaging systems use alternating image detections in most clinical settings, the proposed approach provided an effective way to quantify *in vivo*, 3-D kinematics of joints in sub-millimeter and sub-degree accuracy at higher sampling frequencies for clinical applications.

INTRODUCTION

Accurate quantification of *in vivo* kinematics of the ankle joint complex (AJC) is crucial for numerous orthopedic research and clinical applications. In recent years, model-based tracking (MBT) techniques have been developed and applied for assessing 3-D kinematics of the talocrural and subtalar joints during functional activities using either single-plane fluoroscopy [1] or biplane radiographic systems. Although some studies used purpose-built synchronized biplane imaging systems to quantify joint dynamics, others failed to take into account of the non-synchronizing, alternating nature of clinical x-ray imaging systems, leading to errors in the 3-D measurements. To address the issue, our group has developed a new MBT algorithm to solve the synchronization problem with clinical alternating x-ray imaging systems and validated it *in vitro*. However, the approach has yet to be evaluated for its applicability in living subjects. Therefore, the purpose of the study was to demonstrate the feasibility of the new MBT method in measuring *in vivo* 3-D kinematics of the AJC and to evaluate the inter-operator repeatability of the method.

METHODS

One healthy subject without any neuromusculoskeletal disorders at the AJC participated in the current study with written inform consent approved by IRB. The subject's right ankle was scanned using computed tomography (CT). Dynamic ankle dorsi/plantar flexion on a purpose-built ankle testing platform were recorded using an alternating biplane x-ray imaging system (Allura Xper FD20/20, Philips Medical Systems, The Netherlands).

Two operators were asked to perform independently the image segmentation of the bones and model reconstruction, as well as give the initial poses of the tibia, talus and calcaneus on the first image frame for the new MBT program. The MBT algorithm was then applied to search for the 6 degrees-of-freedom (6-dof) of the bones for the subsequent image frames. The registered 6-dof of bones over all frames were then used to calculate the 3-D rigid-body kinematics of the talocrural and subtalar joints.

To evaluate the inter-operator repeatability of the MBT algorithm in conjunction with alternating biplane imaging system, the coefficients of multiple correlations (CMC) [2] and root-mean-squared deviations (rms-D) between two kinematic waveforms derived from the two operators were computed to quantify the waveform similarities for each kinematic component.

RESULTS AND DISCUSSION

The kinematic waveforms of the talocrural and subtalar motions averaged from the data of the two operators are shown in Fig. 1.

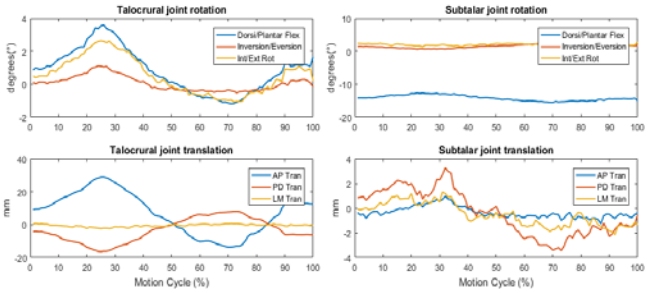

Figure 1: Waveforms of talocrural and subtalar joint motions.

The CMC of translations along the x-, y- and z-axis of the talocrural joint were 0.99, 0.99 and 0.98, respectively. The corresponding values for rotations were 1.00, 1.00 and 0.78. The rms-D for the talocrural joint were less than 0.32 mm for translation and 0.77° for rotations. The CMC of translations along the x-, y- and z-axis of the subtalar joint were 0.95, 0.98 and 0.66 respectively. The corresponding values for rotations were 0.63, 0.92 and 0.84. The rms-D for the subtalar joint were less than 0.37 mm for translations and 1.05° for rotations. In general, the new MBT for alternating biplane x-ray imaging systems was shown to be capable of producing highly repeatable kinematics of the AJC except for the medial/lateral translation and inversion/eversion of the subtalar joint. The relatively lower CMC for these two components may be explained by the fact that the ranges of secondary motions were smaller compared to the ranges of the primary motion components. Although the CMC values for the talocrural joint motion were generally higher than those in subtalar joint motions, the rms-D showed similar results between the two joints.

CONCLUSIONS

The new MBT technique has been applied to the measurement of the AJC kinematics of a living subject using a clinical alternating x-ray imaging system. The results suggest that the method is capable of measuring accurately the talocrural and subtalar joint kinematics with a moderate to high inter-operator repeatability in a clinical setting.

P103 - CHANGES IN STEPPING STRATEGIES FOR UNPREDICTABLE SLIPS AND TRIPS

INTRODUCTION

Recent studies of responses to repeated postural perturbations have suggested dramatic improvement of balance recovery response in young and older adults during a single session [1]. However, because most previous studies used systems that induce a single type of perturbation (e.g. only slips) at a fixed location, it is possible that these changes were somewhat due to changes in approach gait with expectation of subsequent perturbations. Adaptation strategies based on prediction may not be useful in real life fall situations, which can be unpredictable. Therefore, we have developed an unpredictable perturbation system which could generate both trips and slips in various locations. The purpose of this study was to examine the adaptation to unpredictable slips and trips.

METHODS

Ten healthy young adults (5 female and 5 male) aged 20 to 40 years participated in this study. The trip and slip perturbation system was built on an 11-m walkway with wooden decking tiles. A slip was generated by a movable tile on two hidden low-friction rails with leaner bearings that could slide up to 70cm upon foot contact. A trip was induced using a 14-cm height tripping board that flipped up from the walkway at mid-swing using a wireless controller. The tripping board and the slipping tile were concealed and could be moved to various locations along the walkway. To maintain usual walking velocity, participants were asked to walk the length of the walkway while striking each stepping tile, adjusted according to the individual's usual step length and cadence was guided by a metronome.

The experiment consisted of 3 fixed sets of 8 mixed trials: 1) 4 slips and 4 trips on the right leg at a fixed middle position, 2); 4 slips and 4 trips on the left leg at a fixed middle position; and 3) 4 slips and 4 trips on random legs and in random positions. A total of 6 unperturbed- trials were randomly presented throughout the trials.

Strategies for recovery from slips were classified as (1) backward stepping: the first recovery step landed posterior to the slipping leg and (2) forward stepping: the first recovery step landed anterior to the slipping leg. Strategies for recovery from trips were classified as: (1) hit and lower, where the obstructed limb was lowered to the ground and the contralateral limb executed the recovery step; (2) hit and cross, where the obstructed limb executed a recovery step after obstacle-hit; and (3) clear and cross, where the participant was able to avoid hitting the obstacle while stepping over it. Kinematic data were collected at 100Hz with an 8-camera VICON system (Plug-in-Gait, Nexus 1.8.3) which was used to calculate the first recovery step length and extrapolated centre of mass (XCOM).

To examine changes in the strategy for recovery from slips and trips, the generalized linear mixed model (multinomial and binomial distribution, with logit link function) was used.

RESULTS AND DISCUSSION

Walking velocity, cadence and step length across trials were consistent with no significant changes ($p > 0.05$).

In the first slip trial (S1), backward stepping was the most prevalent strategy (90%), with repeated slips showing reduced backward stepping (50%) and more forward stepping (40%) at S8 (Figure 1). However, introduction of a different slip location caused all participants (100%) to revert to backward stepping (S9) ($p > 0.05$) indicating a jagged pattern (Figure 1 A). This jagged pattern was also observed in changes in XCOM ($p = 0.016$) and step length ($p = 0.072$) at the first recovery step (S1 to S12).

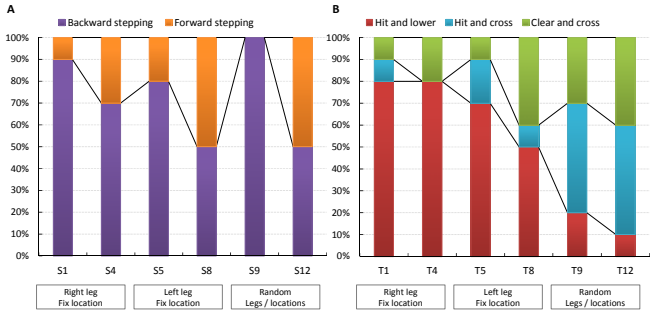

Figure 1: Strategies for recovery after slips (A) and trips (B)

The most prevalent strategy in response to the first trip was hit and lower (80% at T1). With repeated trip trials, this response was significantly reduced (10% at T12) with most participants employing the hit and cross (50%) and clear and cross (40%) at T12 ($p < 0.01$). This linear pattern was also observed in the more forward XCOM ($p = 0.020$) and larger step length ($p = 0.005$) at the first recovery step (T1 to T12).

CONCLUSIONS

These results demonstrate learning effects with reapeated slip and trip trials with changes in recovery strategies employed. This learning effect was lost with a new slip location, while the learning effect persisted with new leg and location for tripping. These learning effects were supported by matching changes in the step length and XCOM at the first recovery step.

P104 - NORMALISATION OF MUSCLE ACTIVITY DURING GAIT IN HEALTHY ADULTS

[1,2] **Pornsuree Onmanee**, [1] Kristen Hollands, [1] Richard Jones and [1]Richard Baker
[1]University of Salford
[2]Sirindhorn National Medical Rehabilitation Institute

INTRODUCTION

Different methods of normalisation to reduce variability of electromyography (EMG) are available with no particular consensus on which technique to use or how to evaluate techniques [1]. If normalisation is successful it should reduce the variability of measurements both between participants and within participants when measured on different occasions.

This study thus aims to compare the effects of normalising EMG signals captured during walking to peak and mean values across the gait cycle and to maximum voluntary isometric contraction (MVIC) on inter-participant variability (standard deviation (SD)) and inter-session standard error of the measurement (SEM)) of the EMG profiles recorded using surface and fine-wire sensors on selected lower limb muscles.

METHODS

Nine healthy adults (age 35±6 years, 4 females, height 1.67±0.10 m, weight 71±12 kg) consented to participate. Fine-wire EMG of tibialis posterior, tibialis anterior and medial gastrocnemius and surface EMG of tibialis anterior and medial gastrocnemius were recorded simultaneously during a MVIC task on a dynamometer for two sessions and during walking at a self-selected speed following published guidelines [2,3]. SD and SEM were calculated between participants and between-sessions. All data were scaled to their means to allow direct comparison.

RESULTS

Mean and peak techniques consistently reduced both SD and SEM (see Figure 1) from non-normalised signals by an average of 40% (mean) and 35% (peak). Normalisation by MVIC gave less consistent results but performed less well than mean and peak normalization on all measures. It actually increased the variability of measurements for made with surface sensors.

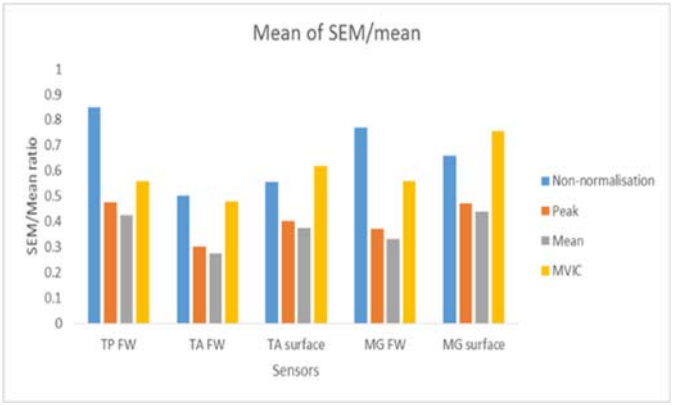

Figure 1: Intra-partcipantt, inter-session variability. FW = fine-wire. TP = tibialis posterior, TA = tibialis anterior, MG = medial gastrocnemius.

DISCUSSION AND CONCLUSIONS

Mean and peak values were effective normalisation techniques which substantially reduced inter-participant and inter-session variability. MVIC was not as effective (as mean and peak) and in surface EMG it increased variability. Therefore, it would be recommended to use peak or mean for normalisation to compare patterns of EMG activity in clinical gait analysis and intervention studies. However, normalisation may not work well for some pathological groups where the magnitude of the signal is one of its important features.

P105 - COMPARISONS OF TIBIOFEMORAL CONTACT PATTERNS DURING CYCLING ESTIMATED WITH AND WITHOUT CONSIDERING CARTILAGE

INTRODUCTION

Measurement of *in vivo*, three-dimensional (3-D) arthrokinematics of the knee joint is crucial and technically difficult during functional activities. Accurate quantification of the position and area of contact regions between the articular surfaces can provide insightful understandings of joint mechanics, contributing to relevant clinical applications. A simple approach for estimating articular contact patterns has been proposed by using 3-D CT-derived bone models, assuming that the thickness of cartilage is uniform [1]. To better reproduce the articular contact patterns of the knee, recent studies would include MRI-derived subject-specific cartilage geometry into the estimation of the contact patterns. However, no study has documented the potential differences between contact estimation with and without considering the articular cartilage. Therefore, the study aimed to bridge the gap by comparing the contact patterns of the tibiofemoral joint during cycling estimated using the two approaches with CT-derived bone models and MR-derived cartilage models.

METHODS

Eight healthy young adults participated in the current study with written informed consent as approved by the IRB. Each subject received a computed tomography (CT) and a magnetic resonance (MR) scan of the tested knee joint. After the necessary segmentation and reconstruction process (Amira, Visage Imaging Inc., Germany), the subject-specific CT-derived bone models and MR-derived bone and cartilage models were obtained. For each subject, a spatial registration between CT-derived and MR-derived bone models was carried out to synchronize two different coordinate systems by using iterated closest points (ICP) algorithm, which provided a fixed transformation matrix that attach the MR-derived cartilage models onto the CT-derived bone models. The subjects performed pedaling movement while sitting on a stationary bike under the surveillance of a biplane x-ray imaging system (Allura Xper FD20/20, Philips Medical Systems, The Netherlands) to collect fluoroscopic images of the knee at a sampling rate of 30 frames/s. Three cycles of the pedaling movement were collected and a model-based tracking procedure [2] was used to determine the spatial poses of the CT-derived bone models during movement.

Without considering the cartilage, the contact area of the CT-derived tibia and femur was defined by the points that were within the distance of 2.5 mm between the two bone surfaces [1]. With the MR-derived cartilage model, the contact area was defined by the model points that were penetrated to the opposite cartilage model. For both methods, contact points on the bone/articular surface were estimated as the weighted centroid of the contact area.

RESULTS AND DISCUSSION

For the anterior-posterior component of the contact positions, no statistically significant differences in the medial and lateral compartments were found between the two methods. However, compared with CT-derived contact positions, MR-derived contacts were displaced medially in the medial compartment for flexion positions greater than 30° and in the lateral compartment for flexion positions greater than 65°. Although the CT-derived model neglected the non-uniformity of the cartilage thickness, the estimated anterior-posterior contact positions were not significantly different from those obtained by the MR-based method. The primary differences between two methods occurred mainly in the medial-lateral components of the contact positions.

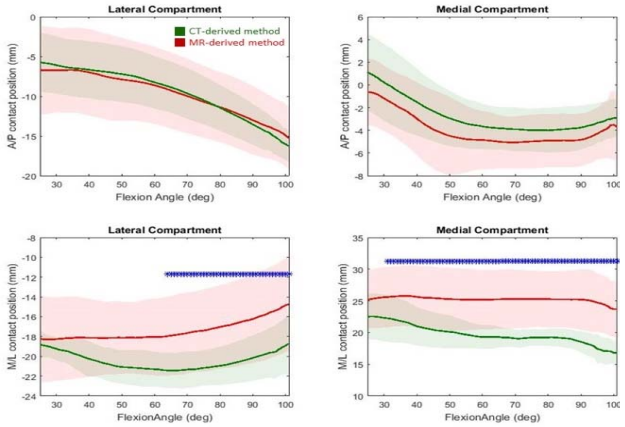

Figure 1: The means ± standard deviations of the contact point positions on the tibial plateau by using CT-derived bone and MR-derived cartilage model at intervals of 25° to 100° knee flexion.

CONCLUSIONS

The CT-derived bone models were capable of producing the anterior-posterior contact positions of the tibiofemoral joint similar to those obtained using the MR-derived articular models. However, the estimated medial-lateral contact patterns were different between methods. This suggests that MR-derived articular models should be used if accurate medial-lateral contact patterns are essential in the intended application.

P106 - SIT-TO-WALK FLUIDITY IS IMPAIRED IN THE POSTURAL INSTABILITY AND GAIT DIFFICULTY PARKINSON'S DISEASE SUBTYPE

[1,2]**Paulo H S Pelicioni**, [3]Marcelo P Pereira, [3]Juliana Lahr, [3]Mariana M L Rodrigues, [3]Lilian T B Gobbi
[1]Falls, Balance and Injury Research Centre, Neuroscience Research Australia, Sydney, NSW, Australia

INTRODUCTION

Postural instability and gait difficulties (PIGD) are marked symptoms in Parkinson's disease (PD). Hence, people who exhibit more deficits on these clinical characteristics are allocated into a PD subtype, named PIGD [1] Another PD subtype is marked by tremor dominance (TD). Higher PIGD score have been related with lower harmonic ratio, during normal walking at a self-selected pace [2], demonstrating an unstable gait pattern. However, no previous data have reported the behavior differences between PD subtypes in a more postural demanding and daily task, such as STW task.

STW key measurements have proved to be effective in investigate PD's motor behavior: (i) difficulty to start walking before standing up; (ii) poorer fluidity to perform STW, which reflects a behavior adopted to minimize postural instability [3]. As long as the PIGD is a subtype which is also marked by greater bradykinesia, weaker lower limbs strength and higher frequency of falling at home and balance related falls, it is believed that performing a daily task such STW under time constraint would be risky and challenging to this group. Thus, the aim of this study was to compare the PIGD and TD subtypes' performance across STW task.

METHODS

Twenty four people with PD were assigned to two groups: PIGD group (n=10) and TD group (n=14). STW performance was analysed considering: duration of STW phases, time to complete STW (sum of phases) and fluidity index (FI). The first phase is defined as the time between the movement onset (first change on vertical ground reaction force (GRF)) and seat-off (first peak on anteroposterior GRF). Phase 2 starts from the end of Phase 1 and continues until the center-of-mass (COM) peak vertical velocity. The third phase is marked by an overlapping. It begins on the swing heel off and continues until toe off, analyzed by kinematic. In this phase, negative values mean a gait start prior to the first vertical COM peak velocity and, positive values mean that the participant started walking after full standing. Finally, Phase 4 is considered as the time between the end of Phase 3 until the swing limb heel contact, analyzed by kinematic. Fluidity Index (FI) was considered as the maximal percentage drop in the COM forward momentum. This drop is presented as a percentage of the first peak of COM vertical velocity. Higher FI values mean greater movement fluency.

STW measures were contrasted between the TD and the PIGD groups with Student t-tests for independent samples. Significance levels were set at 0.05.

RESULTS AND DISCUSSION

The PIGD group exhibited longer Phase 3 duration, longer STW Total time and lower FI (Table 1). According to these results, we observed that the PIGD group started to walk after reaching the full standing position. The PIGD group also spent more time to complete STW, as well as lower FI. This last result could reflect the motor strategy adopted by PIGD group in which lower anteroposterior momentum is generated, characterized by split the STW in two tasks (standing up and gait initiation). In summary, lower IF reflects deficits in motor planning. This poorer overall performance in STW exhibited by the PIGD subtype can be explained by two different reasons: neurological damages and a more cautious behaviour adopted to perform this task.

PIGD exhibit the following neurological damages: (i) hypo-connectivity striato-pallidal pathway; (ii) lower putamen activation; (iii) white matter lesions in the pathways which connect frontal lobe and basal ganglia; (iv) lesions in the superior longitudinal fasciculus, which disrupt the cortico-pontine-cerebellar circuits. Those neurological damages affect: balance, motor preparation, sequential movements, sensorimotor integration and gait, all components necessary to perform STW [4-7].

Thus, the PIGD subtype adopted a cautious behaviour, being less fluid in order to prioritize stability over mobility, since they present postural instability and gait impairments.

	TD	PIGD	p
Phase 1 (s)	0.63 (0.06)	0.68 (0.14)	0.223
Phase 2 (s)	0.2 (0.16)	0.18 (0.1)	0.674
Phase 3 (s)	-0.05 (0.13)	0.08 (0.11)	**0.009**
Phase 4 (s)	0.39 (0.04)	0.41 (0.04)	0.315
Total time (s)	1.17 (0.11)	1.36 (0.24)	**0.018**
FI (%)	63.59 (11.27)	50.74 (16.45)	**0.049**

Table 1: STW performance data for the TD and PIGD groups. Data are mean (SD)

CONCLUSIONS

The PIGD subtype exhibits poorer fluidity and consequently, more cautious behavior to perform STW, possibly due to more neurological damages and more frailty.

P107 - A COMPARISON OF KNEE JOINT STIFFNESS DURING RUNNING BETWEEN MINIMALIST AND MAXIMALIST SHOES IN REARFOOT AND MIDFOOT STRIKERS

[1]**Brian J Prejean,** [1]Logan A Ruhde, and [1]Mark D Ricard
[1]The University of Texas at Arlington
Corresponding author email: prejean@uta.edu

INTRODUCTION

The impact force in running has a magnitude of 2-3 BW and it occurs in 20-30 ms. This repetitive, high magnitude and frequency impact is suggested as the mechanism for many chronic running related injuries, including osteoarthritis of the knee. Running surface, footwear, and footstrike pattern as well as leg muscle pre-activation all play a role in the force loading characteristics during ground contact, especially the in the initial instances of impact [1-5]. Previous studies examining the complex interaction between these variables have isolated either the shoe condition [2], footstrike condition [1,3], or employed treadmill [4] or pendulum [5] apparatus. Furthermore, typical analysis of over-ground running kinetics and kinematics in rearfoot (RF) and midfoot (MF) runners across shoe cushioning levels is often limited to 10 or fewer trials with measurements averaged across trials. The purpose of this study is to compare the effects of shoe midsole cushioning (maximal vs. minimal) on initial knee joint stiffness (KJS) during over-ground running in both habitual RF and MF runners when controlling for horizontal velocity of the pelvis, shank Z velocity, initial knee angle, vertical ground reaction force (GRF) at 30 ms, and 30 ms braking impulse in 50 trials per subject.

METHODS

This study analyzed data collected from twenty seven (age 24.7 ± 6.4 years, height 172.4 ± 11.4 cm, mass 68.9 ± 12 kg) RF runners and nineteen (age 24.9 ± 5.8 years, height 175 ± 7.1 cm, mass 74 ± 11.4 kg) MF recreational runners served as subjects. The shoes chosen for this study were the New Balance Minimus (NB) and the Hoka Stenson One One (HK) for their difference in midsole thickness (24mm) and their similar heel-toe drop (4mm). Subjects ran approximately 50 (mean = 48.7) trials in each shoe condition across the 20 m lab space at a self-selected pace. Data were collected using a 16-camera (MX-T40S) Vicon motion capture system sampling video at 500 Hz. Trials were analyzed using Visual3D ver 6. The video data were up-sampled using a cubic spline to match the analog rate of 1000 Hz. Video coordinates were low pass filtered at 7 Hz using a 4th order Butterworth filter and the analog data were low pass filtered at 30 Hz using a critically damped Butterworth filter. Hip, knee, and ankle joint angles were computed using a Cardan sequence (medial/lateral, anterior/posterior, longitudinal axes). Ankle, knee, and hip joint moments were resolved into the proximal segment coordinate system. Initial KJS on impact was determined by dividing the change in knee moment by the change in knee angle during the first 30 ms of ground contact. Rather than averaging variables across trials, a linear mixed model with an unstructured variance-covariance matrix was used to determine differences in initial KJS between shoe conditions (HK vs NB) and footstrike (RF vs MF) with 30 ms braking impulse, horizontal velocity of the pelvis, shank Z velocity, initial knee angle, and vertical GRF at 30 ms as covariates. Subjects and trials were entered as random factors. Random intercepts were determined for each subject. Alpha was set at 0.05.

RESULTS AND DISCUSSION

Knee joint stiffness was found to be significantly ($p = .000$) higher for the HK shoe condition (6.447 ± 0.263 $Nm \cdot kg^{-1} \cdot rad^{-1}$) than NB (5.869 ± 0.262 $Nm \cdot kg^{-1} \cdot rad^{-1}$) for both footstrike groups. MF runners had lower knee joint stiffness (5.538 ± 0.399 $Nm \cdot kg^{-1} \cdot rad^{-1}$) than RF runners (6.778 ± 0.342 $Nm \cdot kg^{-1} \cdot rad^{-1}$), but this difference was only significant ($p = .007$) in the HK condition. There was a significant ($p = .000$) interaction between shoe type and footstrike. When controlling for natural variability in running mechanics, subjects decreased initial KJS at impact when running in footwear with less midsole cushioning. A larger change in KJS between shoes was seen in the RF group. This interaction indicates that RF runners utilize greater kinematic and kinetic adjustments in response to initial impact conditions.

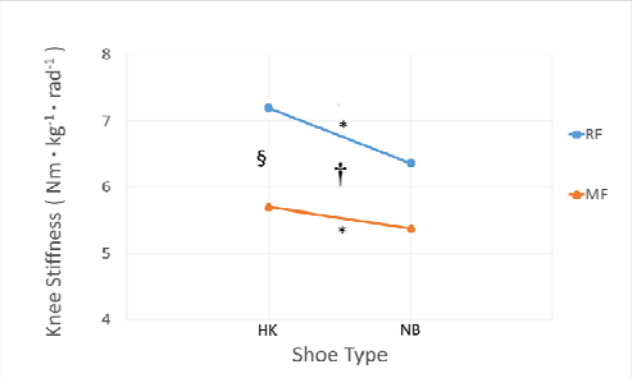

Figure 1: A comparison of knee joint stiffness between footstrike patterns across shoes.
*Significant difference between shoes within subjects
§Significant difference between footstrike groups in HK
†Significant footstrike x shoe interaction

CONCLUSIONS

The conclusion that lower limb joint stiffness is altered in response to GRFs, which are attenuated by shoe cushioning and are dependent on footstrike patterns, is support by previous findings [1-5].

P108 - CORRELATION BETWEEN VOLAR MIGRATION AND ENTRANCE ANGLE OF FLEXOR DIGITORUM SUPERFICIALIS TENDON AFTER CARPAL TUNNEL RELEASE

[1] **Hsiao-Feng Chieh**, [1] Chang-Mu Wu, [1] Chien-Ju Lin, [1] Li-Chieh Kuo, [2] I-Ming Jou, [1] Yun-Nien Sun, [1]Tong-Tai Wu and [1] Fong-Chin Su

INTRODUCTION

Carpal tunnel syndrome (CTS) occurs as a result of compression of the median nerve at the carpal tunnel. In clinic, carpal tunnel release (CTR) is adopted as the surgical treatment by dividing the transverse carpal ligament to reduce the pressure in carpal tunnel. Previous studies demonstrated that the CTR-increased space in the carpal tunnel might increase the volar migration of flexor tendons and possibly cause the trigger finger [1]. However, the direct measurement and investigation on the correlation of tendon migration in the carpal tunnel and the angle which tendon enter into A1 pulley is not fully approached. Therefore, the aim of this study was to investigate tendon volar migration and ulnar migration in carpal tunnel, the entrance angle at A1 pulley, and the correlation between tendon migration and the change of entrance angle.

METHODS

Six fresh frozen cadaver hands were used in the experiments. In the experiment, the cadaver hand was secured to the customized frame in a palm-up posture and the wrist joint was mounted at the posture of flexion 30°. The index, middle, and little finger were fixed with splints in neutral position. The flexor digitorum superficialis (FDS) tendon of ring finger was applied 500 g to simulate the finger motion, and FDS tendons of index, middle and little fingers and flexor digitorum profrundus (FDP) tendons of four fingers were applied 50 g each to maintain the tendon tension. The ultrasonographically-guided carpal tunnel release, which can reduce the damage of anatomical structure in the carpal tunnel, was used in this study [2]. The ultrasound transducer (TerasonTM) was maintained on the carpal tunnel in transverse plane. In the beginning of each test, the ring finger was relaxed in neutral position. The weight applied in FDS tendon of ring finger was from 0 to 500 grams to simulate the finger motion from neutral to full flexion. Images of tendon migration in the carpal tunnel and entrance angle at A1 pulley were recorded and measured. Wilcoxon signed-rank test was used to analyze the parameters of migrations between pre- and post-CTR.

RESULTS AND DISCUSSION

The volar migration of the FDS tendon of ring finger at 30° of wrist flexion under pre-CTR condition and post-CTR condition was 0.785±0.396 mm and 1.725±0.753 mm, respectively (Figure 1a). The ulnar migration of pre- and post-CTR was -0.128±0.321 mm and 0.76±0.276 mm, respectively (Figure 1b). Our results showed significantly greater volar and ulnar migrations of the FDS after CTR. In addition, the change of the entrance angle of the FDS tendon into A1 pulley was 0.37±0.80° in pre-CTR and 3.64±2.64° in post-CTR (Figure 1c). Our results indicated that after CTR the change of entrance angle significantly increased compared to that before CTR. In order to clarify the relationship between tendon migration in the carpal tunnel and the entrance angle at A1 pulley, the correlations between volar migration, ulnar migration and the change of entrance angle were analyzed. Our findings indicated that the change of entrance angle positively highly correlated with volar migration (r=0.797, Figure 1d) but not significantly correlated with the ulnar migration. The highly positive correlation between the volar migration and the entrance angle demonstrated that tendons could migrate to the volar side further without the constraint of transverse carpal ligament after CTR and thereafter the greater volar migration might induce a greater change of entrance angle at A1 pulley. This bowstring effect occurred after CTR might cause greater friction force between the flexor tendon and its sheath in finger pulley system, and was supposed to be the risk of developing trigger finger.

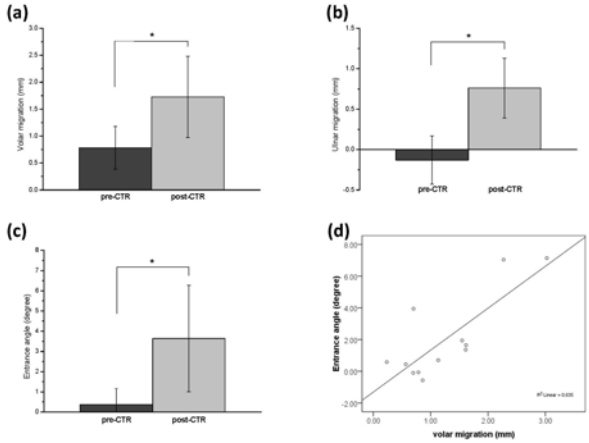

Figure 1: (a) The volar migration and (b) ulnar migration of FDS in carpal tunnel, (c) entrance angle of FDS at A1 pulley under pre- and post-CTR conditions; (d) correlation between volar migration and entrance angle.

CONCLUSIONS

Our findings indicated that finger movements could influence the tendon gliding pattern in carpal tunnel and the entrance angle at A1 pulley after CTR. In particular, the highly positive correlation between tendon volar migration in carpal tunnel and the change of entrance angle at A1 pulley demonstrated that the increase tendon volar migration could cause the bowstring effect which will increase the risk of developing trigger finger.

P109 - TENDINOPATHY REGION CLASSIFICATION IN MACRO-VIEWED MICROSCOPIC IMAGES

INTRODUCTION

In recent years, tendinopathy is one of the popular clinical issues. Tendinopathy may induce motion difficulty of related limb. The major causes of tendinopathy are the repeated or incorrect uses of tendon. In most clinical cases, like trigger finger or tennis elbow, the more severe tendinopathy appears the larger number of nuclei show on the micro-viewed microscopic image. The hematoxylin and eosin (H&E) stained microscopy is usually used to diagnose the severity of tendinopathy. However, most of the diagnoses are subjective and the results vary among observers. In this research, we develop a tissue classification method for macro-viewed H&E stained tendon microscopy. The macro-viewed results are then reconfirmed with the corresponding results on micro-viewed microscopic images. The macro-viewed tendinopathy classification is more clinically applicable if its correspondence with respect to the micro-viewed result can be established

METHODS

In macro-viewed microscopic images, the cell area is separated into normal, abnormal, vessel and calcified areas. We use the color information to segment the different tissues. The artery area is first determined with an empirical threshold value. Considering some darker non-vessel pixels are also extracted as the vessel pixels, the post-processing is applied. A modified opening operator is used to remove the non-vessel pixels.

In microscopy, calcified region is similar to the crack but surrounding with dark region. The candidate calcified pixels are detected by using the pixel saturation. If there are any candidate calcified pixels near to the artery pixels, then both the artery pixels and the candidate calcified pixels are re-classified to the calcified region.

The remained regions can then be used to detect the normal and abnormal regions. As the color of abnormal tissue is gloomier than normal tissue, the saturation information is distinguishable and thus used in the classification of abnormal tissue. We compute the threshold saturation value based on the highest appearance, the normal and abnormal regions are then detected by the computed saturation value.

RESULTS AND DISCUSSION

In order to find the correspondence between micro- and macro-viewed microscopic images, the sampling-based and Laplacian-based thresholding methods [1] are used to detect the nuclei number in micro-viewed images. The micro-viewed images are then classified into normal and abnormal region based on the ratio of normal to abnormal nuclei number. Figure 1 shows the correspondence between the micro- and macro-viewed images. Figure 1(a) is a classified macro-viewed image using proposed method. Green and blue regions are normal and abnormal regions, respectively. Figure 1(b) shows the classification results using micro-views images. Each block is a micro-viewed image, and the color indicates the ratio of detected normal to abnormal nuclei numbers. By comparing the two classification results, we find that the classified regions are similar in both micro- and macro-viewed images.

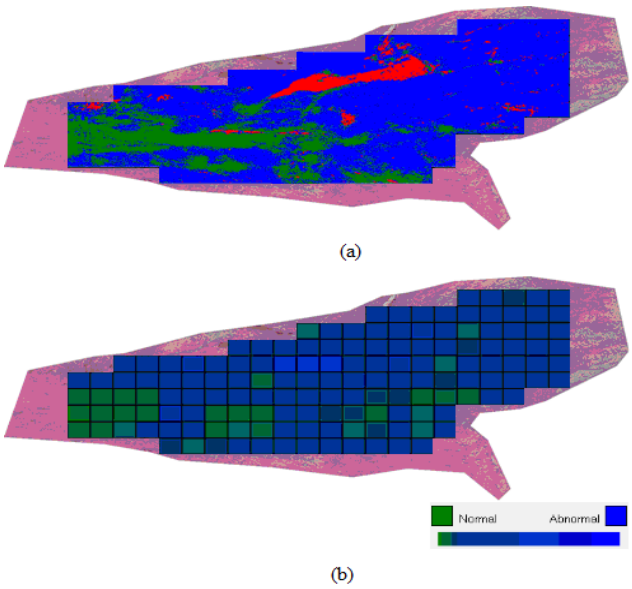

Figure 1: Region classification results. (a) Macro-viewed; (b) micro-viewed.

CONCLUSIONS

We proposed the region classification method for macro-viewed tendon microscopic images. A fast segmentation structure for classifying the normal, abnormal, vessel and calcified tissues is developed. The experiments show the proposed classification method can classify the region well. The classification regions are similar between the micro- and macro-viewed images. This means that the proposed classification method can assist to analyze the severity of the tendinopathy such as trigger finger and tennis elbow with only the macro-viewed images.

INTRODUCTION

Stereophotogrammetry is a widely used technique in the field of three-dimensional (3D) analysis of motion. Several authors describe its use for the study of the wrist and the hand [1-4].

Palpation is an important step in the use of stereophotogrammetry since it allows the construction of anatomical reference frames. Palpation errors can lead to errors in the interpretation of joint kinematics, independent of the quality of the material used for measurements. Improving the method of locating structures can reduce errors. The use of standardized procedures for palpation of landmarks allows a better comparison of the results. This is essential for patient follow-up or the development of a reliable database [6].

This study aimed at investigating the precision, accuracy and reproducibility of manual palpation used in the framework of wrist 3D motion analysis.

METHODS (Figure 1a)

Ten volunteers without forearm, wrist and hand disorders, surgical past or pain participated in our study. Only the right wrist was investigated. The forearm was attached on a specific base. Several reflective markers were fixed on the hand, the forearm and the base.

In a first phase, to investigate the precision and accuracy of manual palpation, four examiners palpated eight anatomical landmarks (ALs) (four on the forearm and four on the hand) in six volunteers. They carried out this palpation on three occasions. After palpation, subjects realized wrist joint movements. One of the examiners palpated once more after the subject's movements.

In a second phase, to investigate the between-day reproducibility, one examiner palpated the eight ALs in ten volunteers. After palpation, subjects realized wrist joint movements. The examiner palpated once more after the subject's movements. The examiner realized the same protocol seven days later.

RESULTS AND DISCUSSION

Inter-examiner precision averaged 6.4 mm and intra-examiner precision averaged 3.2 mm. ICC for intervariation ranged from 0.97 to 0.99. ICC for intravariation varied according to the examiners from 0.96 to 0.99. ICC for between-day reproducibility ranged from 0.93 to 0.97. The 95% limits of agreement approximated 10° and 60% of evaluations were between ± 5°. (Figure 1b)

The results relative to the precision are in concordance with those usually reported in the literature for other joints [7].

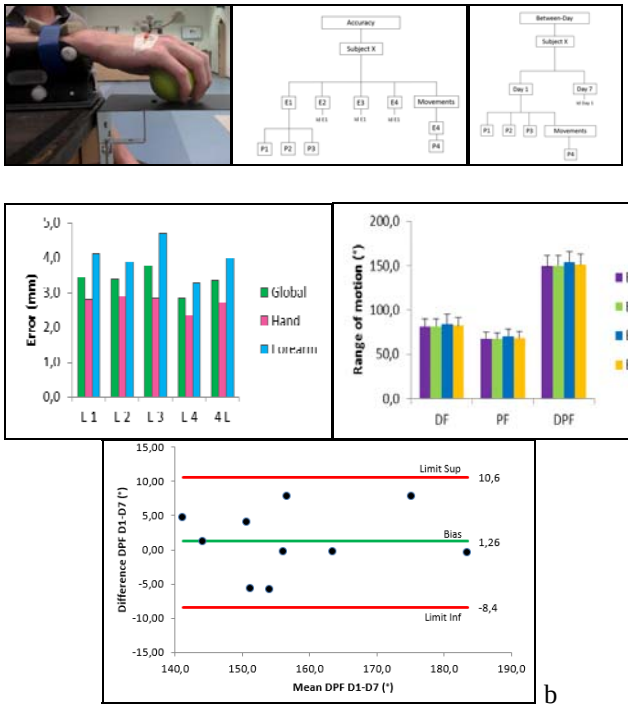

Figure 1. a: Illustration and protocol design. **b**: Intra-examiner variability; error propagation; between-day reproducibility.

CONCLUSIONS

A precise, valid and reliable method for the analysis of the 3D kinematics was developed during this work. It allows envisaging clinical applications for patient evaluation and in-vivo personalized modeling of the wrist joint.

INTRODUCTION

During the past few years, a growing interest for wrist kinematics has emerged. Several methods for the 3D analysis of joint kinematics have been developed in fundamental, functional and clinical approaches. Thanks to the developments of technology, computing methods and medical imaging, more and more techniques were described [1].

Medical imaging represents one of the optimal means for the 3D analysis of wrist kinematics [2-4]. There are several other instruments such as electrogoniometry [5] and stereophotogrammetry [6]. In biomechanics, data can be multiple, diverse and result of different sources. The integration of data in the same interface facilitates their analysis. The lhpFusionBox software allows animating a personalized skeletal model from medical imaging. It is also possible to calculate and visualize (by graphs) joint angle, to define movements and helical axes and the pivot point [7].

The purpose of this study was to develop an in vivo evaluation protocol for three-dimensional kinematics of the wrist by combining stereophotogrammetry and medical imaging.

METHODS (Figure 1a)

Four volunteers without forearm, wrist and hand disorders, surgical history or pain participated in our study. Only the right wrist was investigated. The forearm was attached on a specific base (Figure 1a). Several reflective markers were fixed on the hand, the forearm and the base.

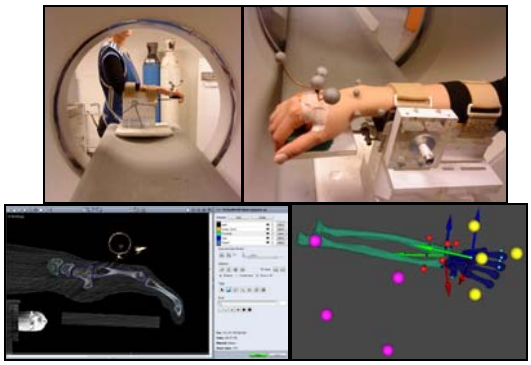
Several anatomical landmarks (ALs) were defined and palpated by the same investigator in all subjects. Manual palpation was performed using a specific splint (A-palp, [8]). Then each subject realized a series of wrist joint movements. Palpation and movements were collected by stereophotogrammetry.

After that, a CT scan of each subject was performed using a low-dose protocol [9]. The computed tomography images were segmented using software (Amira 4.0®, Germany) to reconstruct a virtual skeleton specific to each subject. Then a virtual palpation of the predefined ALs was performed in the software lhpFusionBox [7].

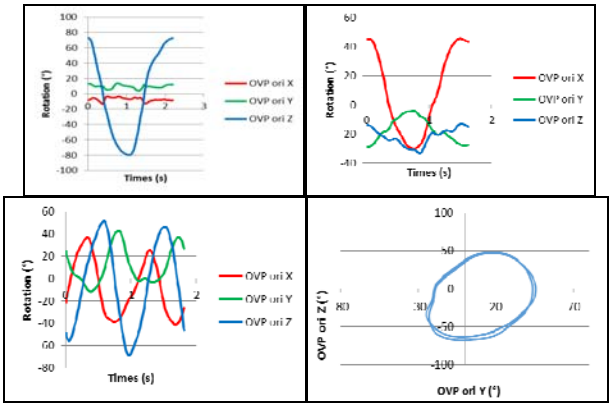
By modeling, we fused the two data sources to animate the virtual skeleton and analyze the kinematics (Figure 1a).

RESULTS AND DISCUSSION

The fusion between data from different sources allows visualizing and analyzing wrist joint kinematics. We thus visualized and analyzed the kinematics of the wrist of each subject. We described a new and original protocol for visualizing and analyzing the in-vivo 3D kinematics of the wrist (primary and associated movements, axes of movements, range of motion, circumduction envelop and helical axis localized in the head of the capitate). (Figure 1b)



a



b

Figure 1. a: Illustration of protocol: CT scan; segmentation; lhpFusionBox. **b**: Movements analysis: dorsopalmar flexion; radioulnar deviation; wrist circumduction: primary and associated movements; circumduction envelop.

CONCLUSIONS

A precise, valid and reliable method for the analysis of the 3D kinematics was developed during this work. It allows envisaging clinical applications for patient evaluation and in-vivo personalized modeling of the wrist joint.

P112 - EFFECTS OF GENDER AND HAND SIZE ON THE DISTAL TRANSVERSE PALMAR ARCH DURING REACH-TO-GRASP TASK

[1]Liang H Y, [1]Kurumadani H, and [1]Sunagawa T
[1]Graduate school of Biomedical & Health Science, Hiroshima University, Hiroshima, Japan
Corresponding author email: m160668@hiroshima-u.ac.jp

INTRODUCTION

Previous studies have examined a modulation of hand shape during the reach-to-grasp tasks to exam the finger excursion, arm transport, and grip aperture [1]. Currently, a majority of reaching and grasping studies have focused on hand-arm orientation, grasping component, and object contact [2]. However, fewer studies have investigated whether the gender difference and the hand parameter: hand size and hand circumference affect the hand palmar arch movement. The aim of this study was to examine the relation between the distal transverse palmar arch movement and the hand parameters and the gender difference when grasping different shape and size objects.

METHODS

Twenty healthy right-handed adults (ten males and ten females) participated in this study. These individuals had no history of injuries or neurological disorders of the upper extremity. The individuals performed reach-to-grasp tasks with objects in different shape and size. The shape of objects was spherical, cylindrical, and cubical, and the size of object was a diameter of 50 mm and 100 mm. The individuals carried out ten trials with each shape and size.

In this study, we captured 22 reflective marker displacements of the dorsal hand using nine cameras three-dimensional motion analysis system (VENUS 3D, Nobby Tech Inc.) with a sampling frequency of 100Hz. For analyzing the hand palmar arch movement, four planes: thenar, middle, ring, and hypothenar, were calculated by hand marker displacements. The hand palmar arch angle was calculated as the angle between two planes, and we computed three hand palmar arch angles: thenar, ring, and hypothenar arch angle.

We measured three hand parameters: hand length, hand circumference, and hand span. Hand length was the distance from the tip of middle finger to the distal wrist crease. Hand circumference was the perimeter around the metacarpal heads at widest point. Hand span was the distance from the tip of the thumb to the tip of the little finger when opening the hand as wide as possible.

For analysis of kinematic data, in the hand palmar arch angle, the differences between two object sizes, among three object shapes, and between gender were examined by a repeated-measure ANOVA. Pearson correlation analysis was used to exam the relationships between each hand parameter and each hand palmar arch angle.

RESULTS AND DISCUSSION

In the three hand palmar arch angles, as for the same object shape, 50mm objects were larger than 100mm objects ($p<0.05$).Moreover, for the same object size, 100mm spherical objects were larger than 100mm cubical objects ($p<0.05$).There was no significant difference between male and female in all hand palmar arch angles when grasping the object of each shape and size. There was no significant correlation between each hand, parameter and each hand palmar arch angle regardless of object shapes and sizes.

Table 1. Results of subjects when grasping the three types of objects in the thenar, ring, hypothenar arch.

50mm		spherical	cylindrical	cubical
Thenar	F	37.5±8.9	34.8±9.5	34.4±6.9
	M	38.4±7.8	37.4±10	33.2±5.9
Ring	F	8.4±3.6	8.1±4.0	7.7±4.2
	M	8.3±2.4	8.3±3.1	7.3±2.7
Hypo-thenar	F	20.8±7.0	20.6±7.2	19.4±7.9
	M	19.4±7.4	18.9±7.3	17.1±8.1
100mm				
Thenar	F	28.2±6.6	22.9±8.3	11.8±3.6
	M	27.5±7.7	27.2±7.8	15.7±3.8
Ring	F	7.7±2.8	6.9±2.4	6.0±3.0
	M	6.9±2.5	6.5±2.8	5.0±1.5
Hypo-thenar	F	15.7±5.1	14.2±4.7	12.1±8.7
	M	15.5±7.7	13.4±6.6	11.0±6.1

Thenar: Thenar arch angle, Ring: Ring arch angle (deg)
Hypothenar: Hypothenar arch angle, F: Female, M: Male

The results of hand length, hand circumference, hand span were 17.6cm±1.2cm, 18.6cm±1.2cm, and 18.3cm±1.2cm. There was no significant correlation between each hand parameter and each hand palmar arch angle regardless of object shapes and sizes.

Our results show that there are significant differences between object sizes and between object shapes, and these findings are similar to previous studies [3]. The gender and the hand parameters: hand length, hand circumference, and hand span, might have an insignificant effect on the distal transverse palmar arch angle.

CONCLUSIONS

There were no significant differences between male and female, and between hand parameters in the hand palmar arch angle regardless of object sizes and shapes. Therefore, the gender and the hand parameters might contribute little to form the distal transverse palmar arch.

INTRODUCTION

Carpal tunnel syndrome (CTS) is a common peripheral neuropathy caused by chronic compression of the median nerve, led patients having many uncomfortable manual activities in daily life [1]. The experiments uses surface electromyograms (sEMG) recorded from wireless EMG system to analyze the amplitude, median frequency and coherence of signals to understand whether and how the CTS affects the muscle activities of the APB and FDI during precision grip [2].The different visual feedbacks also affect the several characteristics of the sEMG signal.

Our purpose was to investigate the effects of carpal tunnel syndrome on hand intrinsic muscle activities using surface sEMG during precision grip. And we had some hypotheses as follows: the CTS subjects, compared to the controls, would performed precision grip with higher amplitude, lower median frequency and lower coherence of sEMG on both the APB and FDI, particularly under the condition without visual feedback.

METHODS

There were 12 subjects participating in the experiment, including 6 patients and 6 healthy subjects. All participants' dominant hands are right.

Grip force was measured using two miniature 6-component force/torque transducers (ATI Industrial Automation, Inc., Apex, NC) and sEMG signal was recorded by Wireless EMG System.

Each subject was required some questionnaires including Semmes Weinstein Monofilament, Michigan hand outcomes questionnaire, Levine's severity questionnaire, and tested for their both hands in two situations-with or without visual feedbacks using the least effort to stably grip the object for a lasting time (80 s).

The RMS value was calculated as the amplitude, the median frequency (MF) and the coherence [3,4,5] of the two intrinsic muscles were evaluated.

RESULTS AND DISCUSSION

CTS led to an increase in sEMG signal amplitude on without visual feedback condition. The MF in CTS APB muscle had a decrease compared to control group and the CTS left hand had an increase MF in FDI muscle, no significant difference in dominant right hand FDI muscle. CTS did not affect the coherence between APB and FDI muscles in value and the correlation coefficient was between 0.32 and 0.34 showing a low coupling level.

According to RMS value and the SWM scores, CTS patients had bad finger tactile, they could not feel the position of the objects and keep the balance well with the least force as the healthy, however, they could compensating for the sensorimotor deficits with visual feedback.

CTS and prefer hand can affect the muscle activities for the differences from the MF in both hands of both groups. CTS did not affect the coherence between APB and FDI muscles. There should be another ways to control the coupled muscles activities needed to deeper exploring.

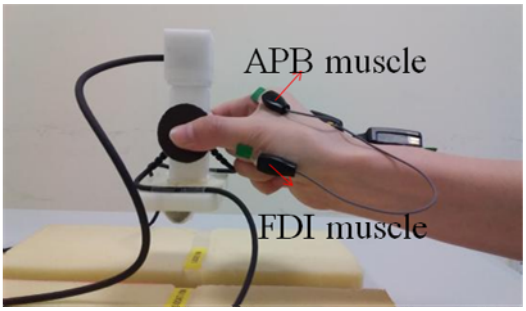

Figure 1: The experiment performance and hand muscles.

CONCLUSIONS

This study demonstrated that the amplitude of the APB and FDI innervated by the median nerve effected by the CTS. The median frequency was effected by both the dominant hand and the feedback condition. The coherence of the two muscles-APB and FDI shows a low coefficient supporting that less coupled intrinsic muscles contribute to digit dexterity [6].

INTRODUCTION

Carpal tunnel syndrome (CTS), resulting from long-term median nerve compression at the wrist, is the most common peripheral compression neuropathy [1]. Sensory symptoms of CTS include paresthesia [2], numbness or tingling [3] and motor symptoms such as stiffness, clumsiness and weakness of the hands. The thumb is considered as the central component in human hand dexterity because its function accounts for 40% to 50%of the hand's usefulness [4]. While completing functional tasks, thumb is required to move in multiple direction through coordinated articulations at the carpometacarpal (CMC), metacarpophalangeal (MCP), and interphalangeal (IP) joints [5].

The aim of this study was to investigate the flexibility; and the motion deficits of the thumb associated with CTS. Two tasks-thumb opposition and circumduction were used to assess the effected of CTS on range of motion (ROM) of the thumb. We hypothesized that CTS would lead to reduced flexibility, a decrease of ROM during thumb opposition and circumduction movement.

METHODS

Twelve volunteers (6 patients with CTSs; 6 controls) participated in this study. For the both groups, exclusion criteria included: (1) any history of musculoskeletal or neurological disorders; (2) severe cervical spondylosis; (3) severe depression, anxiety, cognitive difficulties; (4) the tumor; (5) severe malnutrition; (6) history of hand surgery; (7) diabetes mellitus and pregnancy.

Each subject was right-handed and required to fill out some questionnaires. A Purdue pegboard was used to measure the finger flexibility for all of the subjects. An electromagnetic motion capture system (FASTRAK California, USA) was used to collect movement data of the thumb during opposition and circumduction movement. Pinch strength and grip strength were measured using a pinch dynamometer (E-link, Biometrics Ltd, UK) and a grip strength dynamometer (E-link, Biometrics Ltd, UK), respectively. The sensitivity of the fingers was measured using the Semmes Weinstein monofilaments. The path length of the opposition and circumduction movement was calculated by distance formula. For the opposition and circumduction tasks, the IP joint range of motion was calculated using cosine formula.

RESULTS AND DISCUSSION

The patients with CTS significantly reduced for finger sensitivity during the monofilament touch instrument test. And CTS had worse figure flexibility compared with control subjects, and there was more significant differences during the unilateral right hand test, both hands test and both hands assembly test. CTS reduced the bending capacity and had a poor ability during the thumb of opposition and movement from Figure 1.

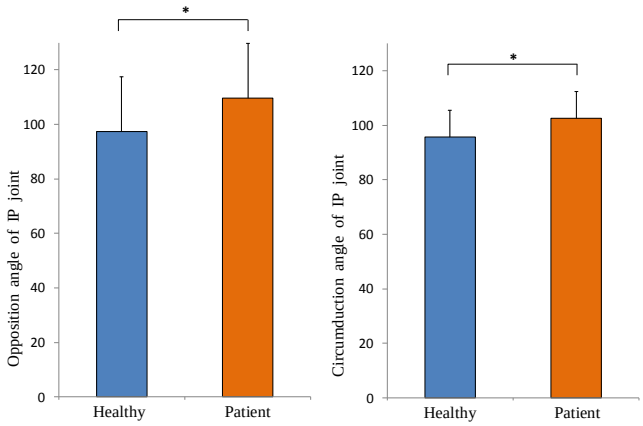

Figure 1. Angle of IP joint for opposition (a) and circumduction (b). * Significant differences between the patients and controls ($p<0.05$).

CONCLUSIONS

Impaired and angular motions were observed to be associated with CTS although there were no difference in maximum pinch and grip strength between two groups. And strength had been used to assess CTS, however the result was not ideal [6]. Both groups had increased the path length and ROM during circumduction and opposition motion. The patients with CTS may limit their IP joint motion to mitigate carpal tunnel pressure increases or additional median nerve impingement that may aggravate symptoms.

INTRODUCTION

The fingertip center of pressures (COPs) serve as an interface between the internal sensorimotor system and the external environment, and provide a linkage between the control of digit forces and of the moments [1, 2]. With compromised fingertip tactile sensation, it is possible that the COPs would deviate from the normal distribution and thus impair the force and torque control [3, 4]. But few studies have examined the relationship between the tactile sensitivity and fingertip COP distributions.

METHODS

Thirty healthy subjects (15 males) participated in the study. Their ages were 22.5 ± 1.2 y; heights were 168.4 ± 9.5 cm and weights were 61.4 ± 9.6 kg. There were totally 4 conditions: (1) Neither the thumb nor the index finger was blocked; (2) The thumb was blocked but not the index finger; (3): Only the index finger was blocked but not the thumb; and (4): Both the two digits were blocked. Test the Semmes Weinstein Monofilament (SWM) of all the participants' right hand according to those four conditions [4].

Force and torque signals are mesured by an apparatus, and the resolutions of was equally 0.0125 N.The distributions of COP coordinates of each digit were estimated ellipses using a principal component analysis (PCA) approach within 95% confident intervals (CI). To evaluate the COP, subjects were instructed to grip and hold the apparatus with the pulps of their thumb and index finger as stably as possible for 60 s. The algorithm of COP was as follows:

$$COP_x = -T_y / F_z \quad (1)$$

$$COP_y = T_x / F_z \quad (2)$$

A paired t-test was used to examine the effect of tactile block with respect to the baseline condition 1.Three-way repeated measures ANOVAs were applied to examine the effects of tactile block (1-4), load conditions (stable and unstable) and digits (thumb and index finger) on the COP area, lengths of semi-major and semi-minor axis, angles of semi-major axis($p<0.05$).

RESULTS AND DISCUSSION

The COPs of the thumb and index finger are not covered by each other and show slight differences in the distribution. There were no significant interaction between the digits and tactile conditions with stable ($p = 0.682$) and unstable load ($p = 0.872$). There were a significant interaction between the digits and tactile conditions with stable load ($p = 0.045$), but not with unstable load ($p = 0.466$). No significant difference of COP semi-major axis and COP semi-minor were found between the stable and unstable load.

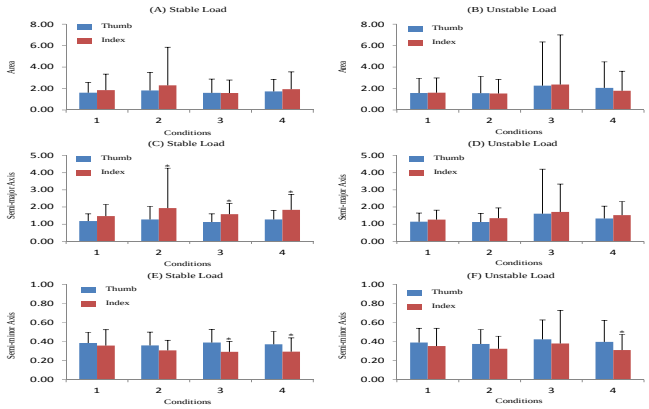

Figure 1: Statistical results of the thumb and index finger. * represents significant difference between the thumb and index finger.

The blurred tactile information did not affect the fingertip COPs distribution, and that the fingertip COPs were under an experienced-based feed-forward control, instead of under a tactile-based feedback control. The differences between the thumb and index finger's COP distributions may be related to the different roles of the two digits during stable grip control [5,6].With unstable load the two digits may be more tightly coupled by a feed-forward control instead of feedback control in order to avoid slipping or titling of the object during holding [1].

CONCLUSIONS

This study demonstrated that the distribution of fingertip COPs with compromised tactile sensation and normal tactile sensitivity. Tactile sensitivity did not affect the COP areas but influenced the COP distributions of each digit.

P116 - COMPARISON OF VOLAR MIGRATION OF THE FLEXOR DIGITORUM SUPERFICIALIS TENDON UNDER DIFFERENT COMPRESSIVE FORCES AFTER CARPAL TUNNEL RELEASE

[1]**Chien-Ju Lin**, [1]Yi-Kuan Liu, [1]Hsiao-Feng Chieh, [1]Chang-Mu Wu, [1]Li-Chieh Kuo, [1]Tong-Tai Wu, and [1]Fong-Chin Su

INTRODUCTION

Carpal tunnel syndrome (CTS) is a common condition resulted from compression of the median nerve in the carpal tunnel and causes pain, numbness, and tingling in the hand. Carpal tunnel release (CTR) surgery would be applied if nonoperative treatment fails for patients with chronic CTS. However, division of transverse carpal ligament leads to incapability to retain flexor tendons in the carpal tunnel. The bowstring phenomenon, caused by increased volar migration of flexor tendon, was observed in CTS patients after CTR [1], and these CTS patients may be more likely to develop trigger finger. Nevertheless, whether an eternally applied force help diminish bowstring phenomenon was not investigated. Thus, the aim of this study is to explore effects of the compressive force at the carpal tunnel on tendon migration after CTR.

METHODS

Five fresh frozen cadaver hands (4 left hands and 1 right hand) were used in this study. Each specimen received the ultrasonographically-guided carpal tunnel release surgery. The flexor digitorum superficialis (FDS) tendons and flexor digitorum profundus (FDP) tendons of index, middle, ring, and little finger were applied 100g weights each to simulate the tendon tension. An additional 500g weight was applied to the FDS of the middle finger to drive the finger from extension to flexion. In order to prevent motions of other fingers, splints were applied on the index, ring, and litter finger to restrict finger movements.During the experiment, the cadaveric hands were secured on a customized frame with the wrist joints set at 30° of flexion. The ultrasound system (TerasonTM) was utilized to record images inside the carpal tunnel with the transducer positioned on the carpal tunnel in the transverse plane by a custom made fixture. Each specimen underwent the same experiment in 5 conditions, the intact condition and four conditions after CTR. In addition to post-CTR condition, three different compressive forces (100±50g, 600±50g and 1000±50g) were applied to the carpal tunnel of the cadavers by the transducer of the ultrasound system after CTR, named CTR-100g, CTR-600g, and CTR-1000g conditions, respectively. Thus, a load cell (339590 – MLP-25, Transducer Techniques, USA) was mounted on the fixture to control the initial compressive force. The migration of the FDS tendon and the ratios of the migrations in each condition after CTR related to that in the intact condition were analyzed in this study. Non-parametric Friedman's test was used to examine differences between variables with the p value set as less than 0.05.

RESULTS AND DISCUSSION

Migrations of the FDS tendon of the middle finger in the volar-dorsal direction were shown in Figure 1. The average volar migration of intact condition, post-CTR, CTR-100g, CTR-600g, and CTR-1000g are 0.98 ± 0.25 mm, 1.52 ± 0.45 mm ,0.91 ± 0.27 mm, 0.75 ± 0.36 mm and 0.54 ± 0.16 mm, respectively. Significant difference was observed between the intact and the CTR-1000g conditions and between post-CTR and CTR-1000g conditions. The average migration in the ulnar-radial direction are -0.01 ± 0.27 mm, -0.10 ± 0.317 mm, -0.49 ± 0.27 mm, 0.66 ± 0.32 mm and -0.37 ± 0.48 mm, respectively, for the intact condition, post-CTR, CTR-100g, CTR-600g, and CTR-1000g. The average ratios of the volar migrations in post-CTR, CTR-100g, CTR-600g, and CTR-1000g related to that in the intact condition are 1.62 ± 0.55, 0.93 ± 0.20, 0.80 ± 0.42, 0.57 ± 0.15, respectively.

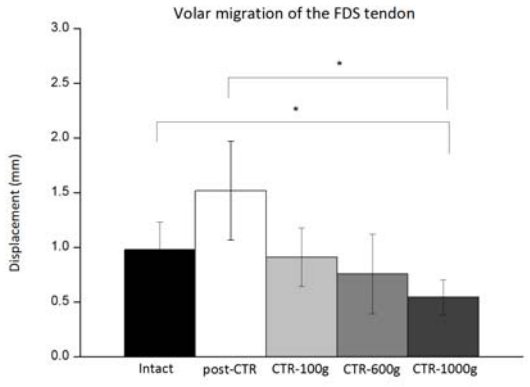

Figure 1: Volar Migrations of the FDS tendons.

After carpal tunnel release surgery, the volar migration of the FDS tendon increased, which was shown to be a potential risk factors resulting in trigger finger. Although the migrations of the FDS tendon in the ulnar-radial direction still increased with compressive force, there is a trend that the volar migration of the FDS tendon decreased with increasing compressive force. According to the results of the ratios between CTR conditions and intact condition, it exhibited that with the externally applied compressive force of 100g, the volar migration of the FDS tendon was successfully suppressed to the level similar to that in the intact condition. Although volar migration can be further decreased with greater compressive force, in clinical, more compressive force may cause discomfort such as pain and numbness in the hand.

CONCLUSIONS

Findings of this study conclude that an externally applied compressive force of 100g at the carpal tunnel in patients after CTR could well reduce volar migration of the FDS tendon leading to bowstringing phenomenon.

P117 - MIMICKING KINEMATIC SINERGIES UNDERLYING ACTIVITIES OF DAILY LIVING FOR REHABILITATION

[1]Verónica Gracia-Ibañez, [1]Margarita Vergara, [1]Joaquín L. Sancho-Bru**,** [2]Denis Mottet, [2,3]Isabelle Laffont, [2,3]Karima Bahkti, [1]Immaculada Llop-Harillo, [1]Antonio Pérez-González

INTRODUCTION

Rehabilitation to recover functional kinematics of the hand is commonly based on training the range of motion of joints, and rarely focused on activities of daily living (ADL), probably because it is time consuming and requires a big set of facilities to train different ADL under professional supervision. In a recent work, hand kinematics in a representative set of ADL was characterized and 5 underlying synergies were found [1]. This work tests the validity of a set of proposed movements to reproduce these synergies as a first step to propose rehabilitation through the training of these movements for improving the functional performance during ADL.

METHODS

The experiment, approved by the University Ethical Committee, was carried out by 18 subjects free of hand pathologies and by 13 patients: multiple sclerosis (2), cervicobrachial neuralgia (1), scoliosis & right shoulder tendinopathy (1), rheumatoid arthritis (2), post-poliomyelitis syndrome (1), finger arthrosis (1) and stroke (5). All subjects performed 5 movements (Mov_1 to Mov_5 of Figure 1), mimicking the 5 *functional synergies* (Syn_1 to Syn_5) found in the previous work [1]. Kinematics of the hand was measured with a Cyberglove (16 joint angles) using a previously validated protocol [2]. Two analyses were performed for each movement: Analysis 1 to test the similarity of the movements performed by the healthy sample with the original mimicked synergies, and Analysis 2 to check differences between the patients and the healthy sample while mimicking.

For Analysis 1, principal component analysis (PCA) was applied to the 16 joint angles of the healthy sample (normalized factors, eigenvalues>1, varimax rotation). For each movement, the deviation angles (DA) between the first principal component obtained and all functional synergies were computed to check similarity of the movements. To test correspondence in the ranges of motion, the *functional ranges* of the synergies, computed in the previous work [1] as the percentiles 5^{th} and 95^{th} of the scores in all the 24 ADL and 24 subjects, were compared to the movement ranges of the 5 mimicking movements, computed as the mean across subjects of the extreme values of the scores of the synergies.

For Analysis 2, PCA was also applied to each of the 13 patients when performing each mimicking movement and the DA between the first component and that of the healthy sample was computed. Movement ranges were also obtained for each pathology and 7 ANOVAs used to check differences between the movement ranges achieved by the healthy sample and those of each pathology.

RESULTS AND DISCUSSION

In Analysis 1, the proposed movements were representative of the pretended functional synergy, as lowest DA corresponded to the pretended synergy, except for Mov_5. Although Mov_4 corresponded to Syn_4, the DA was poor (48º). Additionally, the movement ranges achieved by the healthy sample covered the functional ranges required in ADL, except in Mov_4 & Mov_5, as can be seen in Figure 1.

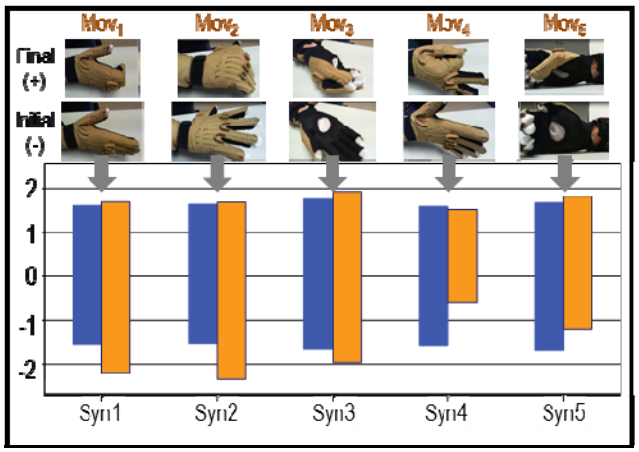

Figure 1: Comparison between *functional ranges* of the synergies (blue) and movement ranges achieved (orange).

In Analysis 2, the patients' motion patterns differed from those of the healthy sample: in 72% of the cases the DA values were above 45º, up to 89º. Also, the ANOVAs showed that the patients used significantly smaller movement ranges in all pathologies except in scoliosis and shoulder tendinopathy. However, no anomalies were expected in this pathology, given the body posture used to perform the movements.

CONCLUSIONS

The movements proposed to mimic the first three *functional synergies* underlying ADL have been found to be representative both in terms of coordination and range of motion. The movements corresponding to Syn_4 and Syn_5 need improvement before being used in rehabilitation. Further research should test the benefits of training them for the kinematic functional recovery, so as to be included in rehabilitation strategies, which could be implemented in serious games.

P118 - NEUROMUSCULAR TESTING AT RETURN TO PLAY AFTER ACL INJURY - A CASE STUDY

[1] **Jesper Bencke**, [1]Hanne B. Lauridsen, [2]Mette K. Zebis
[1]Copenhagen University Hospital, Amager-Hvidovre, Copenhagen, Denmark.
[2]Metropolitan University College, Copenhagen, Denmark.

INTRODUCTION

When assessing athletes before allowing them to return to play (RTP), physical strength and performance tests are usually performed. In studies on healthy athletes, adequate medial hamstring preactivity during sidecutting in handball or football has shown to be important in order to prevent ACL-injury [1]. Furthermore, studies have shown increased medial hamstring (MH) activity during kettlebell exercises and landing exercises on unstable surfaces [2].
The objective in this case study was to investigate neuromuscular parameters at RTP and after an extra 10 week-period of specialized training aimed to improve activity in MH.

METHODS

This case study involved an 18 year-old elite female handball player cleared for return-to-play (RTP) after ACL-injury surgery. Neuromuscular activity pattern during sidecutting was tested 3 times in a biomechanics laboratory; 1) at initial RTP primo June 2014, 2) in ultimo August after a period of normal handball training and extra agility exercises, and 3) primo November after handball training and extra exercises of stiff-legged kettlebell swings and jump-landing exercises. Dynamic EMG recordings were obtained from the medial and lateral knee extensors and medial and lateral hamstrings and synchronized to initial contact. At each test maximal EMG activity from each muscle was obtained during a maximal isometric contraction and used for normalization of the dynamic EMG. Outcome parameters were then normalized EMG preactivity during the last10 ms prior to initial ground contact during sidecutting. The mean of 5 trials from each test session is presented. Results are compared to average values from a cohort study in female elite athletes using the same procedures.

RESULTS AND DISCUSSION

EMG preactivities of medial and lateral knee extensors were 57%, 56%, 51% and 62%, 72%, 66% at the three tests, respectively, which is comparable to the cohort study. For the medial hamstrings the measured EMG preactivities were: 16%, 18% and 41% at test 1, 2 and 3, respectively, compared to 40% in average in the cohort study. This increase between test 2 and 3 may be a result of the special added kettlebell and landing exercises, which have been shown to elevate medial hamstring activity during exercise [2].
The lateral hamstrings showed less markedly changes between tests: 15%, 22% and 31%, for tests 1-3 respectively. See figure 1.

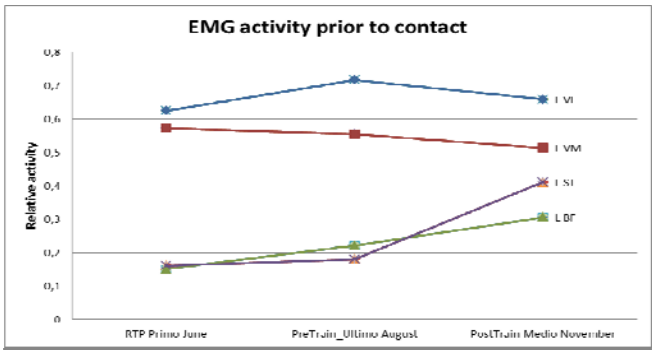

Figure 1. Development of knee joint muscle EMG preactivity during sidecutting in a single female athlete

CONCLUSIONS

Based on neuromuscular evaluation, the athlete had a very low activity in MH at RTP, with no improvement after handball and agility training at test 2. The added exercises may thus be an important factor for the doubling of her MH activity observed at test 3. This type of training may be beneficial as late rehab or prehab in athletes with low MH activity. Further studies may evaluate the potential of neuromuscular evaluation in RTP tests.

P119 - CLINICAL ASSESSMENT OF REACTIVE BALANCE CONTROL IN ACQUIRED BRAIN INJURY AND STROKE: A COMPARISON OF MANUAL AND CABLE RELEASE-FROM-LEAN PERTURBATION METHODS

INTRODUCTION

A recent Ontario survey revealed that few physiotherapists regularly assess reactive balance control in individuals with stroke [1]. One commonly-cited barrier is the lack of access to affordable assessment tools. We aimed to determine the agreement of two testing methods to assess reactive balance control in the sub-acute acquired-brain-injury population. Both methods involved the assessment of forward stepping reactions evoked by sudden release-from-lean perturbations. One method, in which perturbations were applied manually (MRFL), required no equipment whereas the second method required use of a cable-controlled system (CRFL).

METHODS

Twelve female and 23 male participants (age 52±16, 20-83; N=19 with stroke, N=16 with other causes of brain injury; <four months post-acquired brain injury) were recruited from an inpatient rehabilitation hospital unit. All participants were able to stand independently for 30 seconds and tolerate postural perturbation.

Each participant was tested using both MRFL and CRFL perturbation methods (1-2 trials for each method). Test performance was scored by the test administrator as per the instructions for the forward-compensatory-step component of the mini-Balance Evaluation Systems Test [2]. The inter-method reliability and test-retest reliability of the clinical scores were assessed using weighted Kappa. Inter-method reliability of secondary outcome variables (foot-off time, swing time, step length and support release time) was analyzed using ICC. Two-way repeated measures analysis of variance (rmANOVA) was used to test for systematic differences in the clinical score and secondary outcome variables, due to perturbation method or diagnosis. In addition, for the stroke group, two-way rmANOVA was used to test for differences in clinical score due to perturbation method or testing order (i.e. which perturbation method was tested first and which was tested second).

RESULTS AND DISCUSSION

There was moderate agreement between the two methods (κ=0.67) with respect to the clinical score (Table 1). ANOVA showed no evidence that the clinical score was systematically affected by test method, test order (assessed only in the stroke group) or diagnosis (p's>0.18). Test-retest reliability was moderate (κ>0.6) for each method.

The CRFL test resulted in faster onset of foot-off (335±77ms vs 393±155ms for MRFL; p=0.01) and shorter time to completion of the lean release (2±2 ms vs 119±64ms for MRFL; p<0.0001). Swing time (CRFL 156±53ms, MRFL 159±61ms) and step length (CRFL 0.27±0.09 m/height, MRFL 0.25±0.08 m/height) were comparable between the two perturbation methods (p's>0.10). Inter-method reliability was quite strong for step length, foot-off and swing duration (ICC(3,2)>0.7). Inter-method reliability was poor for lean–release completion time (ICC(3,2)=0.34).

Table 1: Classification matrix for the CRFL and MRFL perturbation tests. Matrix entries represent the percentage of trials (rounded to the nearest percent). The shaded diagonal cells represent perfect agreement between the test methods.

		CRFL Score				
		0	0.5	1	1.5	2
MRFL Score	0	9	0	6	0	0
	0.5	0	0	0	0	0
	1	0	0	29	0	6
	1.5	0	0	11	3	9
	2	0	0	0	3	26

Completion of lean-release took ~100ms longer in MRFL tests compared to CRFL tests. This (and other differences) in the biomechanical features of the MRFL and CRFL perturbations were likely responsible for the ~60ms delay in onset of foot-off (measured relative to onset of lean-release) observed in the MRFL tests. This methodological discrepancy in determining timing is of potential clinical importance given, for example, evidence that temporal dyscontrol in foot-off time is linked to falls after stroke [3].

CONCLUSIONS

These preliminary findings suggest that the MRFL may be a viable equipment-free alternative to the CRFL, in that both perturbation methods yielded similar observations of gross balance performance. Further work is needed to fully characterize the biomechanical features of the two perturbation methods and to determine the impact of any differences on the features of the evoked balance-recovery reactions.

P120 - EFFECTS OF CORE STRENGTH ON LOWER EXTREMITY BIOMECHANICS DURING CUTTING MANEUVER

[1] **Jiyoung Jeong**, [1]Dai-Hyuk Choi, [2]Yongnam Song, and [1]Choongsoo S. Shin
[1]Sogang University, [2]Korea University
Corresponding author email: cshin@sogang.ac.kr

INTRODUCTION

Core strengthening has become a major interest in professional sports, and is considered to aid in injury prevention and improve athletic performance [1]. Studies linking the core to aspects of anterior cruciate ligament (ACL) injury have reported that athletes with poor core stability sustained more ACL tear [2]. Also, previous study has suggested that lateral trunk lean away from the direction of the cutting was associated with greater peak knee valgus moment [3], which causes higher ACL strain [4]. However, it is unclear what role the core stability plays in the lower extremity joint kinematics/kinetics and muscle activation, and no longitudinal studies have investigated the effects of core strength on ACL injury risk factors. Therefore, the purpose of study was to examine the effect of core strength on lower extremity joint kinematics/kinetics and muscle activations during side-step cutting maneuver.

METHODS

Sixteen males without any current pain or history of lower extremity musculoskeletal injuries requiring surgery participated (age: 22.9±2.7 yrs, height: 1.76±0.03 m, mass: 72.8±7.8 kg). All subjects were participated in the 10-week core muscle strength training program including plank, bridge, superman, crunch, leg-raise, and side-plank. Each exercise consisted of 3 sets and each set lasted approximately 15-20 seconds, with 10-15 repetitions. All subjects performed the program 3 days a week, on alternating days. To test the core stability, a trunk endurance test was used. During this test, the plank and side-plank positions were maintained for as long as possible.

A motion capture system and a synchronized force plate were used to obtain the joint kinematics and kinetics during cutting maneuver. Reflective markers were placed on the anatomical bony landmarks in trunk and lower extremities. The electromyography (EMG) system was used to measure the muscle activation of rectus abdominis, erector spinae, gluteus maximus, quadriceps and hamstrings. Each participant performed side-step cutting maneuver at an angle of 45° direction of progression. Kinematic and kinetic data were obtained during stance phase from initial contact to toe-off. Mean EMG amplitudes of each muscle were quantified during pre-activation phase, which was defined as the 50-millisecond time period before initial contact. Joint moments were normalized to the body weight and height of each subject, and EMG amplitudes were normalized to the peak EMG amplitude during stance phase. H:Q ratio was calculated as the average amplitude of hamstrings divided by the average amplitude of quadriceps. The two successful trials were averaged individually and then averaged to generate group mean values and standard deviation. For the kinematic/kinetic and muscle activation parameters, two-tailed paired t-tests were performed using MATLAB version R2015b. Significance levels set at $P < 0.05$.

RESULTS AND DISCUSSION

Greater plank and left/right side plank record were found in post-training ($p=0.008$, $p=0.049$, and $p=0.007$ respectively), but no differences were found in quadriceps and hamstring muscle strength. Thus, only the core muscle strength increased after training. After training, knee flexion angle at initial contact significantly increased ($p=0.01$, Table 1). Since non-contact ACL injury often occurs when the knee flexed less than 30° at initial stance phase [5], core muscle training seems to be beneficial to reducing ACL injury risk. Results show that hip adduction angle significantly decreased ($p<0.05$, Table 1). Since excessive hip adduction is expected to strain the soft tissue restraints that limit knee valgus, which has been implicated in contributing to numerous knee injuries [6], lower hip adduction angle may decrease the potential risk of ACL injury. In addition, significantly increased H:Q ratio after training ($p=0.01$, Table 1) indicates that strengthening of core muscle is beneficial for reducing the risk of ACL injury, because the large quadriceps contraction at small knee flexion angle with small hamstring activity increased the risk of ACL injury [7]. No significant differences were found in trunk motion and other kinetic parameters

Table 1: Kinematics at initial contact and mean EMG amplitudes in pre-activation phase both in pre- and post-training during side-step cutting (Mean ± SD).

	Pre	Post	p
Knee flexion [°]	28.9±4.6	33.1±6.6	**0.01**
Hip flexion [°]	41.3±7.0	47.4±4.9	**0.00**
Hip adduction [°]	3.17±6.49	-0.15±6.53	**0.05**
Rectus abdominis [μV/μV]	0.54±0.35	0.45±0.29	0.52
Erector spinae [μV/μV]	0.52±0.27	0.35±0.20	**0.03**
Gluteus maximus [μV/μV]	0.26±0.20	0.14±0.07	**0.02**
H:Q ratio	0.74±0.33	1.16±0.49	**0.01**

CONCLUSIONS

In conclusion, strengthening of core muscle may reduce the ACL injury risk by increasing knee flexion angle at initial contact, increasing H:Q ratio of activation in pre-activation phase, and decreasing hip adduction angle.

P121- THE INFLUENCE OF A TRI-AXIAL HINGED KNEE BRACE ON MUSCLE ACTIVITY DISTRIBUTION IN HEALTHY INDIVIDUALS

[1]**Carl Jewell**, [1]Joseph Hamill & [1]Katherine A. Boyer
[1]University of Massachusetts Amherst
Corresponding author email: cjewell@kin.umass.edu

INTRODUCTION

Anterior knee pain, or patellofemoral pain (PFP), makes up 20 percent of all running-related injuries[1]. Despite being one of the most common running injuries, it is persistent with frequent reoccurrence. To date, no universally effective method of treatment has been found. Once thought to be self-limiting, evidence now links PFP to eventual structural damage and degenerative diseases such as osteoarthritis[2]. Thus, treatment beyond pain management is important in restoring function of the knee and preventing disease progression.

Knee bracing has been considered an option for treatment of PFP by preventing excess lateral patellar tracking and increasing the joint contact area. The effects of modern, tri-axial hinged knee braces on muscle activity and the resulting joint mechanics of healthy gait remain unclear. Previous brace studies have found a reduction in knee pain accompanied by reduced knee extensor moments with a concomitant increase in hip and ankle impulse in injured runners compared to healthy controls [3,4]; however, these results have not been consistent across the literature. Therefore, the purpose of this study was to investigate how healthy individuals alter their muscle activation patterns with a modern, hinged knee brace. Our hypothesis was that these individuals will adapt their movement patterns to reduce knee extensor activity in response to the reduced degrees of freedom of the braced knee. In addition, we expect to find a reduction in the knee extensor moment and knee flexion angle range of motion accompanied by an increase in peak plantar flexion angles and moments.

METHODS

Five male participants completed this study (age: 24.6±4.6 years). Kinematic, ground reaction force and electromyographic (EMG) data were collected as participants ran at 3.2 m/s over a force plate in a 20m long runway. Participants completed 5 trials in each condition; braced (Meuller Wraparound Hinge brace) and no brace. EMG was recorded for the following seven muscles: Tibialis Anterior (TA), Lateral and Medial Gastrocnemius (LG, MG), Biceps Femoris (BF), Vastus Medialis (VM), Vastus Lateralis (VL), and Rectus Femoris (RF).

Ankle and knee kinematics and kinetics were averaged over 5 stance phases recorded. EMG were analyzed 150 ms preceding ground contact to 150 ms post right toe-off. A linear envelope was calculated to determine onset timing as well as integrated EMG (iEMG) during the following phases: pre and post foot contact.

The primary outcome measures of interest for EMG were muscle onset times relative to foot strike, iEMG over the given phases, and peak stance activation. For the kinematic and kinetic measures, peak angles and moments, as well as overall range of motion will be analyzed. Student's paired t-tests will be used to test the hypothesis that braced gait differs from normal with an $\alpha = 0.05$ for each of the outcome measures.

RESULTS AND DISCUSSION

Peak TA activity in early stance decreased significantly while peak LG activity in terminal stance increased in the braced condition. Despite reduced initial peaks, post foot contact iEMG increased for the TA while wearing the brace, suggesting that the duration of activation was increased. Initial ankle dorsiflexion angle decreased significantly, accompanied by a decreased knee flexion range of motion.

In partial agreement with our hypotheses, there was a reduction in the knee flexion range of motion in response to the tri-axial knee brace. There was also a decrease in ankle dorsiflexion at initial contact which suggests that foot contact strategy may be altered in the braced condition. However, contrary to our initial beliefs, the brace did not have any modifying effect on peak knee moments. There were small, yet significant differences in muscle activation patterns. Increased LG peak activity in terminal stance may be indicative of either a greater reliance on plantar flexion for propulsion or an increase in co-activation about the knee joint, likely for stability during the novel task of wearing the brace. Further analysis of the timing of knee and ankle moments and joint powers is needed to better understand this relationship.

Table 1. Findings that are significant at α=0.05. NB=no brace, B=brace.

Measure	NB mean(SD)	B mean(SD)	Units	-value
TA peak	172.96(60.96)	146.23(50.56)	%max	0.006
LG peak	139.93(50.04)	169.25(68.14)	%max	0.045
TA iEMG post foot contact	63.96(22.70)	82.76(38.13)		0.045
Initial Ankle Dorsiflexion	13.04(2.95)	10.83(4.57)	Deg.	0.042
Knee Flexion ROM	31.21(5.12)	30.02(5.22)	Deg.	0.050

CONCLUSIONS

Changes in ankle and knee kinematics, coupled with the observed lower limb EMG changes, suggest that participants may alter their foot contact strategy in order to compensate for the knee brace. The potential implications for both performance and clinical efficacy merit further investigation in both healthy and injured individuals.

P122 - A HAND GESTURE RECOGNITION SYSTEM USING AN 8-CHANNEL ARMBAND EMG SENSOR

INTRODUCTION

The world's deaf population is estimated to be about 360 million people, and most of them use sign language. Because of the different sign language systems depending on the country and communication restrictions with people who do not use sign language, deaf people suffer from social inequalities and financial losses in many areas of life (education, welfare etc.). Sign language recognition system will play an important role solving the above problems.

A technique of classifying hand gestures is the most important in sign language recognition system. Although various hand gesture recognition techniques using cameras, gloves and attachable sensors have been developed, they have not been practically applied due to the obstruction in daily life or the inconvenience of their use. Therefore, the purpose of this study is to develop a new hand gesture recognition system using an armband-type electromyography (EMG) and to evaluate its accuracy according to the training database size.

METHODS

There are numerous forearm muscles that control wrist flexion/extension and fingers flexion/extension such as flexor carpi radialis, extensor digitorum etc. Because these muscles are distributed in the belly of forearm, an armband-type multi EMG could be used to recognize hand gestures.

In this study, an easy-to-wear armband sensor consisting of 8 EMG channels was developed. The sampling frequency was 600Hz and the measured data was transmitted to the PC via wireless communication.

EMG signals were filtered through 10-300Hz bandpass filter. Since it was difficult to obtain onset and offset of EMG signals when the fingers move, the Teager-Kaiser Energy (TKE), in which increasing the signal-to-noise ratio (SNR), was calculated to minimize the baseline noise effects [1]. Root Mean Square (RMS) of TKE was calculated and window width was defined as 500ms. In order to convert 8 signals into 1-dimensional signal, all RMS signals were summed. Threshold was compared to determine the onset and offset of EMG activation. Because the threshold value differs for each subject, it was applied after a preliminary measurement. EMG feature vector was defined as Mean Absolute Value (MAV) of each EMG channel in the muscle activity section. All feature vectors were resampled into constant time to normalize the muscle activation time.

Artificial Neural Network (ANN) was used for classification of signals. classification parameters of each neuron were obtained by using the MATLAB Neural Network toolbox using the error backpropagation learning algorithm.

An armband was worn on the right forearm muscle's belly. Two sensors were placed on the flexor digitorum superficialis and the extensor digitorum. The remaining sensors were arranged at regular intervals. Since the circumferential length of the forearm was measured differently for each subject, the interval length was defined as the circumferential length divided by 8.

Ten subjects without musculoskeletal diseases were recruited to evaluate classification accuracy. Five gestures (wrist flexion/extension, all fingers flexion/extension, double tap) were selected and forty feature vectors were obtained per gesture. Thirty feature vectors were used for classifier training and ten feature vectors were used for evaluation. Optimal training database size was determined by comparing the accuracy.

RESULTS AND DISCUSSION

Table 1 shows the classification accuracy and the standard deviations (SD) according to the training database size. High accuracy (>98%) with small SD (<5%) was shown for every database size. As the size of the training database increased, the accuracy became higher and SD smaller. However, the feature vector should have been trained for at least 20 times per gesture because some subjects (7, 8 and 9) showed relatively large SD (>5%).

Table 1: The accuracy and the standard deviation according to the training database size

Subject	Training database size		
	10	20	30
1	100.00±0.00	100.00±0.00	100.00±0.00
2	100.00±0.00	100.00±0.00	100.00±0.00
3	100.00±0.00	100.00±0.00	100.00±0.00
4	100.00±0.00	100.00±0.00	100.00±0.00
5	100.00±0.00	100.00±0.00	100.00±0.00
6	100.00±0.00	100.00±0.00	100.00±0.00
7	96.00±8.94	98.00±4.47	100.00±0.00
8	94.00±5.48	98.00±4.47	100.00±0.00
9	96.00±5.48	100.00±0.00	100.00±0.00
10	100.00±0.00	100.00±0.00	100.00±0.00
Total	98.60±4.05	99.60±1.98	100.00±0.00

CONCLUSIONS

A hand gesture recognition system was developed using an 8-channel armband type EMG in this study. The evaluation of the algorithm showed that the average accuracy was more than 99.5% when trained over 20 signals per gesture.

P123 - VARIABILITY IN INTER-SEGMENTAL COORDINATION DURING EACH STANCE PHASE OF GAIT IN PATIENTS 12 MONTHS AFTER ANTERIOR CRUCIATE LIGAMENT RECONSTRUCTION AND ITS ASSOCIATION WITH GAIT PARAMETERS

[1,2] **Takashi Kondo**, [1]Takeshi Muneta, [2]Tsutomu Fukui and [1]Mai Katakura
[1]Department of Joint Surgery and Sports Medicine, Graduate School, Tokyo Medical and Dental University
[2]Sports management center, Graduate School, Bunkyo Gakuin University

INTRODUCTION

Previous research studies have showed that only about fifty percent of patients with anterior cruciate ligament reconstruction (ACL-R) could recover preoperative sports activity levels even 12 months after surgery [1,2]. The ACL-R patients who could not return to preoperative sports activity levels were indicated to have the several factors (poor knee function, asymmetries of body movement, and mental depression) [1,2]. Some studies have indicated the ACL-R patients the gait asymmetries 12 months after surgery [3], whereas other studies have not indicated them [4]. The asymmetries of human movement are related to the fear of re-injury and knee osteoarthritis progress of ACL-R patients [5]. Most of the previous studies regarding gait of ACL-R patients have simply examined the comparisons of maximal and minimal values of gait parameters. Therefore, we thought to use other references and methods will be more valuable to understand the gait asymmetries of ACL-R patients. Accordingly, we examined the variability in inter-segmental coordination during gait of ACL-R patients using continuous relative phase (CRP) method [6,7].

The purpose of this study were 1) to evaluate the values of variability in inter-segmental coordination during each stance phase of gait (early/late double support phase, and single support phase) between the operative and the non-operative sides in ACL-R patients about 12months after surgery, and in the normal subjects, 2) to evaluate the relationships between the values of the variability in inter-segmental coordination and the gait parameters (joint angle, joint moment, and ground reaction force) during each stance phase of gait.

METHODS

Twenty-six healthy subjects (13 men and 13 women, average age of 21.4 (± 1.2) years), and seventeen ACL-R patients (7 men and 10 women, average age of 20.2 (± 3.2) years, average time after surgery: 362.5 (± 64.4) days) participated in this study. All the ACL-R patients of this study had already fully returned to preoperative sports activities. Gait kinematics was recorded using a Vicon motion system and a force plate. Subjects were asked to walk at a pace of 110 steps/min for 5 trials. The CRP values were examined under the following process in conformity with the previous studies [6,7]. The phase angles were calculated between the segment angles (thigh, shank, and foot segment) and the segment angular velocities. The CRP values were calculated by subtracting from distal segment's phase angles to proximal segment's phase angles (shank-thigh, and foot-shank). Additionally, deviation phase (DP) values, which were the variability in inter-segmental coordination indicators, were calculated using the CRP values during each stance phase. A lower DP values indicated a better inter-segmental coordination between two segments [6]. Moreover, the peak values of joint angle, joint moment and ground reaction force in the sagittal plane were calculated during each stance phase. Statistical analysis were 1) the comparisons of the DP values during each stance phase were examined between groups (operative and non-operative side of ACL-R patients and normal subjects) using one-way repeated measured analysis of variance which were conducted to examine the relationships between groups. Tukey post-hoc analyses were performed to clarify significant main effects, 2) the correlation coefficients between the DP values and gait parameters during each stance phase were examined using Spearman's correlation analysis. The statistical significance was set at the level of $p < 0.05$.

RESULTS AND DISCUSSION

Result 1): At the early double support phase and late double support phase, the DP values between shank and thigh in ACL-R patients of operative side were higher than the values of non-operative side, and normal subjects.

Result 2): The DP values between shank and thigh in ACL-R patients of operative side were significantly related to the knee flexion angles ($r = -0.52$), the knee extension moments ($r = -0.46$) at the early double support phase, and the hip flexion moments ($r = -0.42$) at the late double support phase.

We found the differences of the variability in inter-segmental coordination between shank and thigh segment existed in ACL-R patients about 12 months after surgery. Since the higher DP values indicated poor inter-segmental coordination between two segments, the gait of ACL-R patients still did not recover normal gait performances enough as the normal subjects and the non-operative side, after they had already been participated in sports activities. Furthermore, ACL-R patients showed the decreasing knee flexion angle and knee extension moment during early double support phase, and decreasing hip flexion moment during late double support phase were related to the values of the variability of inter-segmental coordination, therefore the consideration of these relationships were important for the rehabilitation of ACL-R patients.

CONCLUSIONS

We confirmed the differences of the variability in inter-segmental coordination between shank and thigh segment during early and late double support phase in ACL-R patients' operative side even after return-to-sport.

P124 - KINEMATICS AND KINETICS IN FORENSIC RESEARCH- CAUSE OF OVER BOARD ACCIDENT

[1] **Petr Kubovy**, [1]Frantisek Lopot, [1]Lubos Tomsovsky and [1]Karel Jelen
[1]Charles University
Corresponding author email: kubovy.petr@seznam.cz

INTRODUCTION

Human memory is of a volatile nature and if there is no intersection of testimonies, intra- nor inter-individually, specially in the presence of their temporal progression, measurement technologies must employed. Our task was to determine what type of sport boat manoeuvre that an injured party could have fallen overboard and be hit by the rear part of the boat. We focused therefore the forces acting on humans of various driving modes. Experiments were performed with a human crash test dummy in different positions and locations on the boat.

METHODS

To find the manoeuvres corresponding to the court file findings, it was necessary to know directions and time courses of forces acting on passengers with the simultaneous motion of the boat (direction, velocity, acceleration, tilt, turning radius, etc.). The dummy Hybrid-III50th (JASTI Co) was used to eliminate the different responses of a human stabilizing to cope with pseudorandom impulses of forces. The dummy was firmly anchored in different positions and thus firmly tied to the boat. Forces in anchors were measured using three preloaded piezoelectric 3-component sensors of Kistler 9317C. Data from these sensors were used to calculate magnitudes and directions of reactions that a human must eliminate to keep a stable position. A triaxial accelerometer of Kistler 8766A was placed in the dummy's CG to determine the forces acting on the mass of the body independent of the position relative to the boat. The signal conditioning and recording took care amplifier Kistler 5080 and acquisition system DEWESoft Sirius. The equipment was supplied by portable generator located on the boat.

The experiment was performed at the accident site, under similar water conditions, as recorded by the Hydrometeorological Institute, with the same boat load distribution. Recording of kinematic data was a challenge. At first a Qualisys system with active markers was trialed, but direct sunlight light conditions and the long distance from the boat to the cameras made this impossible. Video recordings were therefore provided by a drone with a high resolution camera that captured the boat and dummy movement in the horizontal plane, as well as least two fixed points on the shore. An onboard camera enabled measurement of the lateral tilt of the boat. Synchonization of the various measurement systems was achieved by their simultaneous recording while the dummy was rapidly moved.

Camera recordings were analysed using the Qualisys Video Analysis software. Time courses of the boat movement in a horizontal plane were measured relative to the land. Drone movement, while capturing, was eliminated by using the fixed points on the shore to calibrate each video image. The tilt of the boat along the anteroposterior axis was acquired using "undoubtedly vertical objects" recorded by onboard camera, e.g. columns of traffic signs and street lighting. The lens distortion was eliminated by computing the average of several objects.

RESULTS AND DISCUSSION

Possible "accident sites" were detected by the intersection of measured values and boundary conditions. Synchronous graphs (Figure 1) shows time courses of reaction, centrifugal and acceleration forces, and their directions together with tilt, drift, turning radius and velocity of the boat.

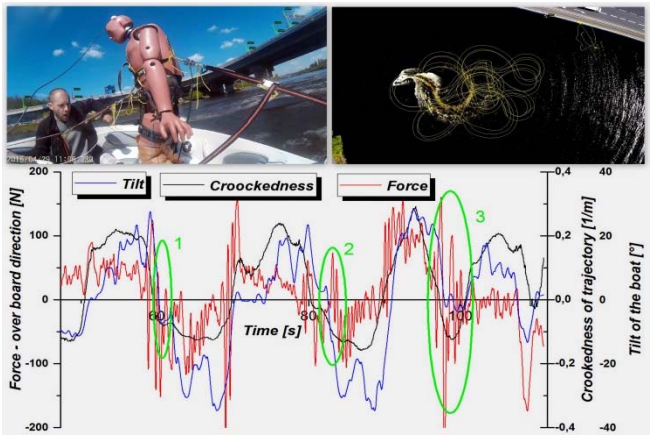

Figure 1: Top row pictures shows the experimental setup and the boat movement recorded by the drone video. The graph shows the forces dragging the body off the boat, the boat tilt and the curvature of trajectory of its motion (down). Green ellipses show potential periods of an overboard phase.

The results were quite clear. A human falling out of the boat could have occurred only on the side of boat on the outer side of the curved turn at either (i) low speeds (up to 10 km/h), or (ii) the beginning of a sharp curve while driving faster. At other times, the tilt of the boat was too large, or the body would not have hit the croup. However, the passenger must stand or kneel on the seat side or sit on the board. Centrifugal forces on humans are well eliminated by boat tilts. A sufficient impulse for an overboard situation requires some other external forces, e.g. hitting a wave. However, the results and conclusions mentioned above cannot be directly related to the case of the human propositus due to the lack of objective data of the incident.

CONCLUSIONS

The described forensic case has methodological value. We showed the integrated use of available technologies in a difficult water based boating application. We were able to collect large amounts of data to make objective conclusions about the potential for "person overboard" while boating.

P125 - ASSESSMENT OF CHRONIC ANKLE INSTABILITY USING INERTIAL SENSOR

[1,2] **Shintarou Kudo**, [1] Toshinori Miyashita, [2]Raita Takasaki and [3]Hidetoshi Hayashi
[1] Graduate school of Health Sciences, Morinomiya University of Medical Sciences

INTRODUCTION

Acute and chronic lateral ankle instabilities are common in patient populations with high physical demands. Lateral ankle sprains (LAS) are common injuries that affect athletes in all sporting activities. Many LAS are treated conservatively, however, 32 to 74% of patients with a previous ankle sprain report some type of chronic symptom such as pain, swelling, ‘‘giving way,’’ and loss of motion [1]. These symptoms are called “Chronic Ankle Instabilities (CAI).' LAS occur commonly during plantar flexion and inversion with excessive ankle supination because the ankle joint is more unstable in plantar flexion. Mechanical instability can be identified on physical examination, stress radiographs, and stress ultrasound in non-weight loading condition. However, using three dimensional motion analysis techniques, LAS has been shown to occur during not only inversion with plantar flexion, but also internal rotation of the ankle with slight dorsiflexion [2]. Therefore, it is important for athletes with CAI to assess the mechanical instability of the ankle in conservative treatment. However, there are no invasive methods to assess ankle instability during weight loading condition. The aim of this study was to develop assessments of CAI during induction of rotatory instability in weight loading conditions.

METHODS

A total of 56 subjects, 23 control (6 male and 17 female; mean age, 19.7±0.5 years old; mean height, 1.62 ±0.07 m; mean weight, 54.7±8.4 kg) and 33 subjects with CAI (13 male and 20 female; mean age, 21.3±7.1 years old; mean height, 1.65±0.07 m; mean weight, 56.0±8.3 kg) participated in this study. Subjects are recruited from a university setting and a co-author’s sports clinic. The control group was subjects with no history of ankle sprain and no pain of the foot and ankle region. The CAI group were patients with a history of at least one substantial ankle sprain, with the first sprain occurring more than 1 year prior to the study, a self-reported history of multiple recurrent episodes of their ankle giving way during functional activities, and no pain of the lower limb at the time of testing. Subjects with ankle sprain within a month of the time of testing or have some pain of the foot and ankle region were excluded. This study was approved by the local ethics committee and all subjects signed informed consent. All subjects were able to perform a 180 degree turn on either the affected or non-affected side from a bilateral standing posture with the feet at 1 foot-width apart, and without flexion of the hip or knee during the turn tasks (Active turn test). All subjects were manipulated by a single tester who, from behind, rotated the subject's pelvis 180 degrees on the testing side in a sudden movement and in the same standing posture as the active turn test (Passive turn test). Acceleration of inertial sensor (Microstone Co., MYP-RF8-TS, Japan) during both turn above the lateral malleolus of the testing side. The acceleration was measured in the anteroposterior axis (Ax), vertical axis, and medio-lateral axis (Az), and the minimum value of Ax and Az during both turn tests (Fig. 1) were recorded to evaluate rotational instability and were compared between the 2 groups using Man-Whitney test. And Reliabilities of those tests were examined using ICC(1,*k*).

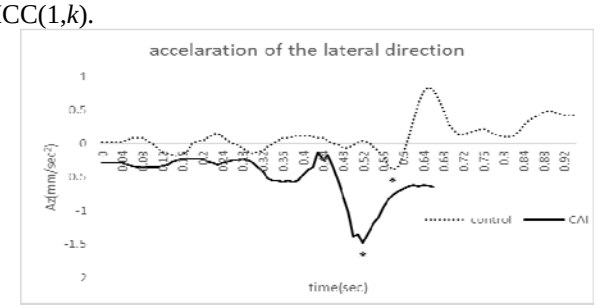

Figure 1: Graph of the Az during the passive turn task. The dashed line is control, and the solid line is a patient with CAI. * is minimum value of the Az.

RESULTS AND DISCUSSION

The ICC values both 2 tests were higher than 0.9, reliability of both tests were excellent. *Az* of the CAI group [Active, -1.53 (-3.64 to -0.82) mm/sec2; Passive,-1.73 (-2.52 to -1.15) mm/sec2] were significantly lower than that of the control group [Active, -0.91 (-1.63 to -0.70) mm/sec2; Passive, -1.29 (-1.61 to -0.93) mm/sec2] in both turn tests. In Figure 1, the *Az* is indicated on the medio-lateral directions of the lateral malleolus. A negative peak of *Az* occurs when restraining the lateral malleolus thrust under unstable conditions. With an anterior cruciate ligament injury, the pivot shift test has an important role in the diagnosis of instability of the knee. Limitations of the pivot shift test are that it is not quantitative and cannot overcome subjective determination of the testers. Recently, rotatory instability of the knee during the pivot shift test has been assessed quantitatively using an inertial sensor [3]. Limitations of previous studies of ankle instability are due to the inability to assess the instability quantitatively in patients during daily and sports activities. The present assessment using an inertial sensor is able to measure quantitatively the instability of the ankle in weight-loading conditions.

CONCLUSIONS

Our results indicate that non-invasive inertial sensors have promising capabilities to assess the dynamic stability of the ankle in CAI patients.

P126 - THE EFFECT OF SPRAINO® SLIDE PATCHES DURING 180° CHANGE OF DIRECTION MANEUVERS

[1]**Filip G Lysdal**, [2]Thor B Grønlykke, [3]Jens L Olesen and [1]Uwe G Kersting [1]Department of Health Science and Technology, Aalborg University, Denmark [2]Grønlykke Medical, Copenhagen, Denmark
[3]Institute of Sports Medicine Copenhagen, Bispebjerg Hospital, Denmark

Corresponding author email: fgly@hst.aau.dk

INTRODUCTION

Ankle sprains are perceived as the single-most common injury in sports [1]. Eighty-five percent of all injuries to the ankle joint affect the ligamentous structure with another 85% of these involving the lateral side of the ankle complex [2].
Accounting for up to one sixth of all injury lay-off from sports activity ankle sprains are an important issue to address [1,2].

The Spraino® Slide is a prophylactic innovation by the Danish company Grønlykke Medical. The Spraino® Slide is an adhesive polytetrafluoroethylene (Teflon) patch that is attached to the lateral edge of the shoe. Spraino® Slide is intended to reduce friction between the lateral edge of the shoe and the playing surface when experiencing critical inversion situations, thus creating a sliding motion during initial contact to prevent the occurrence of lateral ankle sprains.
The objective of present study was to test the clinical effect of Spraino® Slide during full-effort 180° change of direction maneuvers.

METHODS

Eight healthy female athletes (age: 21.3 ± 0.7 years, height: 172.0 ± 3.6 cm, mass: 66.4 ± 8.5 kg) participated in this preliminary single-blinded randomized cross-over study.
Each subject performed the 180° cutting maneuvers while wearing a pair of commercially available Adidas Stabil Boost™ handball shoes (Adidas AG, Herzogenaurach, Bavaria, Germany).

The eight subjects were randomized to start with either the control or intervention condition. A Spraino® Slide was attached along the lateral edge of the shoe with a 10 mm margin below the sole in the intervention condition. The Spraino® Slide was not attached below the sole in the control condition but only attached for blinding purposes. Each subject completed eight trials in both conditions.

Ground reaction forces (GRF) were collected at 1000 Hz using a force plate (AMTI OR6-7-1000, Massachusetts, USA). Kinematic data were collected with a sample rate of 500 Hz using eight infrared Qualisys Oqus 300+ series cameras and processed in Qualisys Track Manager (Qualisys AB, Gothenburg, Sweden). Kinematic data were low-pass filtered using a 4th order Butterworth filter with a cut-off frequency of 14 Hz.

Ankle joint kinetics were analyzed between touch down and toe-off using Visual 3D (C-Motion Inc., Germantown, Maryland, USA). IBM SPSS Statistics (PASW statistics, version 24, IBM Corporation, New York, USA) was used to conduct a Paired Sample T-Test on contact time and peak inversion moment.

RESULTS AND DISCUSSION

No statistical difference was shown in contact time and peak inversion moment. These results along with the mean inversion moment during the stance phase (Figure 1) indicate that the use of Spraino® Slide patches does affect the movement or the performance when performing 180° change of direction maneuvers.

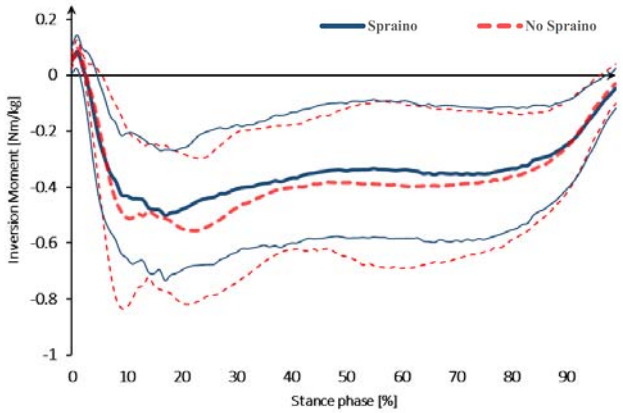

Figure 1: Mean Inversion Moment ± SD in Nm/kg.

In all cases the subjects changed direction with initial contact on the medial side of the foot with an average medial/lateral foot-ground inclination angle at 17.4° ± 6.8. This might explain the unaffected movement with Spraino® Slide attached to the lateral edge of the shoe.

CONCLUSIONS

Attaching Spraino® Slide on the lateral edge of the shoe does not affect a full-effort 180° change of direction when initial contact is being made with the medial side of the foot.

No conclusion on the effect in critical situations can be made, however future studies have been planned to examine the preventative effect of Spraino® Slide when initial contact is carried out on the lateral edge of the shoe.

P127 - THE EFFECT OF A COGNITIVE INHIBITION TASK ON GAIT PERFORMANCE DURING SELF-PACED TREADMILL WALKING

INTRODUCTION

Gait analysis can be used to predict health status in the elderly (1). Gait is no longer postulated as a totally automated motor task. It requires multiple executive function processes to utilise safe and efficient gait (2). With advanced age, executive function declines, which is linked to an increase in gait variability and fall-risk. Dual-task paradigms have been introduced to explore the automaticity of gait by challenging inhibition and/or attention (i.e. executive function). The utility of using dual-tasking has become more evident (2). However, the great variability of the dual-tasking paradigms limits its use in clinical gait assessment. There is also a lack of evidence for the consistency of dual-task effects upon gait performance. This may be due to the limited number of consecutive strides included during over-ground walking and effects of treadmill's speed on gait patterns (3).

The aim of this study was, therefore, to explore the effect of an inhibition response task on gait performance during self-paced treadmill walking and the consistency of gait measurements between days.

METHODS

Twenty-three healthy male subjects (mean age: 34.56 + 5.12 years) walked on a GRAIL system (Gait Real-time Analysis Interactive Lab, Motek Medical B.V.) at two different sessions, 5 ± 3 days apart. The GRAIL system consists of an instrumented dual-belt treadmill with a twelve-camera Vicon capture system. The self-paced mode was used with virtual-endless scene. Each subject walked randomly under two conditions: 1) Free walking (FR); 2) walking while performing a Colour Stroop test (read the colour not the word) (DT). The average values of temporal-spatial gait parameters (speed, step length, stride time and step width) and variability across 100 consecutive gait cycles were computed. A repeated measures ANOVA was used to explore the effect of inhibition response tasks on these outcomes. The level of statistical significance was set at $p<0.05$.

RESULTS

Descriptive statistics for average and variability values of temporal-spatial gait parameter for each walking condition are presented in Table 1. In the first day, there was a significant effect of dual-task on both average mean of step length and width. In the second day, there was significant effect on all average gait parameters, except step width. On gait variability, there was no significant difference in all gait parameters in two days. The number of correct Stroop task answer showed significant improvement in second session.

DISCUSSION AND CONCLUSIONS

The present findings showed that the dual-task significantly altered subjects' gait stability during their first visit, as reflected in the mean values of step-width. This was not the case during the second visit. However, due to the significant improvement in correctly reading the 'colour' of presented words during the second visit, walking speed, step-length, and stride-time have been significantly increased during the dual-tasking walking. This may lead to suggest that the alterations in the mean values might be associated with improvements in cognitive process. This has also been reflected by the fact that there was no effect of dual-tasking on gait variabilities. Alterations in gait variability have been related to executive function impairments (4). Taken together, this supports results obtained from healthy subjects. In terms of consistency, the results indicate that the GRAIL system provided consistent gait spatial-temporal parameters between days across walking conditions. Future research should explore the utility of our dual-task paradigm in patients with neurological conditions.

Table 1: Descriptive statistics (means and standard deviations (sd)) of gait parameters during two walking conditions: FR (single walking task), DT (walking while performing Stroop task), and p= p value.

P128 - ASSESSMENT OF ANKLE FUNCTION DURING THE TERMINAL STANCE PHASE OF GAIT USING AN INERTIAL SENSOR

1 Toshinori Miyashita, 1Shintarou Kudo 1Graduate school of Health Science, Morinomiya University of Medical Science Corresponding author email: miyashita.osaka@gmail.com

INTRODUCTION

Physical therapy is performed not only at rehabilitation centers, but also in the home and community of patients. However, gait analysis by physical therapists remains important. In the gait analyses, the largest power burst occurs at the ankle during pre-swing. Seven plantar flexor muscles peak in activity during the terminal stance, contributing to a high plantar flex moment [1].

In the ankle during walking, the ankle plantar flexion power propels the leg into the swing and accelerates the body mass forward [2]. Therefore, the function of the ankle plantar flexors is important for the generation of forward progression during the terminal stance phase of gait. However, physical therapists are unable to assess gait quantitatively in the home and community of the patients. Recently, inertial sensor-based activity monitors have become popular, and can be used to evaluate the gait of patients during rehabilitation. Inertial sensors are recognized as validated, objective tools for quantitative assessment without the need for specific environments. The purpose of this study was to develop an assessment that reflects plantar flexor moment of the ankle during the terminal stance of gait using an inertial sensor.

METHODS

Thirty seven limbs of 19 healthy male subjects (mean age, 22.7±4.6 years; mean height, 1.71±0.47 m; mean weight, 61.7±4.5 kg) were included in this study. Subjects who performed kinematics parameters outside of normal ranges were excluded. All subjects were required to perform 5 straight-line walking trials along a 10 m level walkway with step length calculated by height at 3 rhythms as slow (76 steps/min), middle (108 steps/min), and fast (125 steps/min). This study was approved by the local ethics committee and all subjects signed informed consent. Subjects were instrumented with an inertial sensor mounted on the lower leg at the fibula head.

The inertial sensor recorded acceleration of the proximal shank as anterior-posterior, vertical, and medio-lateral directions during gait. Gait cycle was detected using video image files captured by tablet PC (MicroStone Corporation, motion recorder MYP-RF8-TS; sampling frequency, 100 Hz) synchronized with the inertial sensor. Both Ax and Ay were at peak values of each parameter from heel-off to toe-off.

A three-dimensional gait analysis system (Vicon) was used for movement date acquisition. The system consisted of 6 infrared cameras (Vicon; sampling frequency, 100 Hz) and two force plates (AMTI; sampling frequency, 1,000 Hz). Thirty-five reflective markers were mounted on the skin following the Plug in gait model using double-sided adhesive tape. Kinetics and Kinematics data of the lower limbs were calculated using Nexsus (Vicon), and filtered with a low-pass at 10 Hz. Ankle plantar peak moments, peak power, and hip, knee, and ankle angles were calculated from the Nexus (Vicon). Moreover, to calculate the synthetic vector (Av), the following formula was used: $Av=\sqrt{(Ax)}^2+(Ay)^2$.

All parameters were assessed among the 3 conditions (slow, middle, and fast) using repeated ANOVA. Relationship acceleration parameters (Ax, Av) and kinetics of the ankle during gait were assessed using Spearman coefficient correlation.

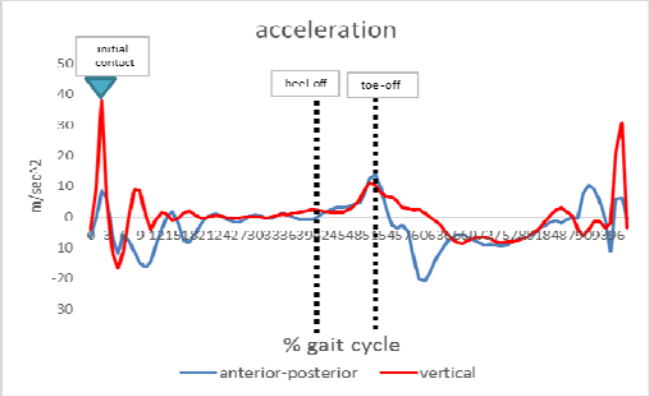

Figure 1: Acceleration of the Fibula head during gait. The peak values of both antero-posterior direction (blue) and vertical direction (red) from heel-off to toe-off were measured.

RESULTS AND DISCUSSION

Ax, Av, peak plantar flexion moment, and peak power of the ankle were significantly different among the 3 conditions ($p<0.05$). There was a significant correlation between Av and peak power of the ankle ($r=0.67$, $p<0.05$). Therefore, the inertial sensor mounted on the fibular head can assess function of the ankle, which is important for forward progression force during the terminal stance phase. Previous studies of gait analysis have used inertial sensors. The sensor provides information such as stride frequency, step symmetry, stride regularity, cranial-caudal activity, harmonic analysis, and kinetic variables during walking [3]. These parameters are able to assess gait abnormalities quantitatively. However, those analyses do not indicate improvement in gait function through physical therapy. Limitation of this study was that it used a database for standardized walking by healthy young men from 20 to 35 years old. Further studies are needed to evaluate gait disorders in older adults.

CONCLUSIONS

We found a novel method for gait analysis using an inertial sensor can assess function of the ankle during terminal stance phase of gait.

INTRODUCTION

Traumatic brain injury (TBI) is well known to trigger multiple brain parenchymal and vascular responses. The immediate and prolonged opening of blood-brain barrier (BBB) is a hallmark of TBI pathophysiology, and results in extravasation of blood components, including red blood cells, plasma proteins and water (vasogenic edema) [1]. On the other hand, Studies in impact biomechanics have demonstrated a number of brain injury mechanisms [2]. These mechanisms include positive pressures at the impact site, negative pressure at the site opposite of impact. Recently, Hardy et al. demonstrated the presences of transient pressure pulses with impact conditions. Coup pressures measured within a pressurized cadaver head after impact ranged from 34 to 160 kPa, and the contrecoup pressures ranged from −2 to −48 kPa [3]. Pamela et al. tested the effect of overpressure from positive pressure to negative pressure on astrocytes. Pressure wave generated by the barochamber, with high amplitude and short duration in the first pulse [4]. However, there is a lack of information with regards to the effect of impact pressure on endothelial cells in vitro, which are the components of BBB.

In this study, we developed an impulsive pressure loading device that is able to exposure cultured endothelial cells to negative pressure with ultra-short duration and examined the effect of impulsive pressure on endothelial morphology.

METHODS

Pressure loading device

The pressure loading device consisted of a cylinder, piston, pendulum impactor, pressure chamber, and pressure transducer. A pressure chamber equipped with a pressure transducer is connected to the cylinder. The compartment connected between the cylinder and the pressure chamber is filled with water. The lower part of the pressure chamber, which is divided by a silicone membrane, is filled with culture medium. Pressure is generated by striking the piston with the pendulum.

Endothelial cell culture

Human umbilical vein endothelial cells (HUVEC) purchased from Lonza were cultured in Endothelial Basal Medium-2 (EBM-2) supplemented with an EGM-2 SingleQuots containing recombinant human epidermal growth factor (rhEGF), heparin, hydrocortisone, recombinant human fibroblast growth factor-basic (rhFGF-B), ascorbic acid, recombinant human vascular endothelial growth factor (VEGF), recombinant long r insulin-like growth factor-1 (R3-IGF-1), gentamicin sulphate amphotericin-B (GA-1000), and foetal bovine serum (FBS) under conditions of 5% CO^2 and 100% humidity at 37°C. HUVEC from passages 3–5 were seeded at 30×10^4 cells on BD Matrigel matrix-coated 35-mm culture dishes and were grown to confluent monolayers. Cultures were stained with 2 μM calcein-AM at 24 h post loading and observed by using an inverted fluorescence microscope. Cell detached area were manually measured using 5 randomly selected regions per experiment.

RESULTS AND DISCUSSION

2 types of pressure fluctuation shown in figure 1 are generated by the developed device. An initial pulse is negative (figure 1A) or positive (figure 1B). The amplitude of the generated pressure were controlled by the incidence angle of the pendulum. The amplitude of generated pressure fluctuated between -80 kPa and +80 kPa with a cycle of 2 or 3 ms.

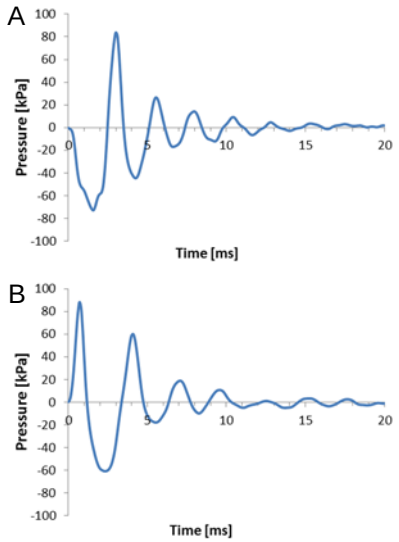

Figure 1: Pressure waveform that an initial pulse is negative (A) or positive (B)

Cells exposed to impulsive pressure were partially detached at 24h after pressure loading. Recently, some studies have suggested that delayed and progressive haemorrhage during the first several hours after head impact are attributed to molecular events initiated at the time of impact, which lead to later structural failure of microvessels [5]. Simard et al. showed that necrotic death of endothelial cells results in physical disruption of capillaries, leading to the extravasation of blood and formation of petechial haemorrhage in a contusive animal experiment [6]. However, the mechanical factor that influences the molecular abnormality has not been identified. A further detailed investigation of the molecular mechanism of capillary fragmentation using an *in vitro* model is required.

P130 - SAGITTAL PLANE TRUNK POSITION IS CORRELATED TO HIP EXTENSOR MOMENT DURING SINGLE LEG SQUAT IN FEMALES WITH AND WITHOUT PATELLOFEMORAL PAIN

[1]**Guilherme S. Nunes,** [1]Fábio Viadanna Serrão
[1] Federal University of São Carlos
Corresponding author email: nunesguilherme@live.com

INTRODUCTION

Sagittal plane trunk position might influence on hip and knee extensor muscles action during weigh bearing exercises [1]. Previous studies indicate that trunk flexion is related to lower knee extensor moment during stair climbing and jumps [2,3]. Consequently, trunk position also could modulate patellofemoral (PF) stress due to its influence on knee extensor moment magnitude. Running with trunk extension increases knee extensor moment and PF stress [4]. Furthermore, greater trunk flexion during weigh bearing activities might increase hip extensor moment [1]. Therefore, people could use strategies regarding trunk position to counterbalance hip or knee extensor muscle weakness.

Females with patellofemoral pain (PFP) have weakness in these both muscle groups [5,6]. Thus, in this population, trunk position might present specific characteristic. The knowledge regarding trunk position and its relation with hip and knee extensor muscle action in females with PFP could support different approaches during rehabilitation according to treatment goals. The objective of the present study was to assess the relationship between sagittal plane trunk position and hip extensor moment, knee extensor moment, and PF stress during single leg squats, as well as comparing those measures between groups.

METHODS

15 females with PFP (aged 24.0 ± 3.2 years; pain onset 3.9 ± 2.9 years) and 15 healthy females (aged 22.7 ± 2.1 years) participated. Inclusion criteria for the PFP group involved I) insidious onset of symptoms; II) retropatellar or peripatellar pain (3/10 VAS points) in at least three of the following actions: stair negotiation, running, kneeling, squatting, prolonged sitting, jumping, isometric contraction of quadriceps, and palpation of the medial or lateral facet of the patella; IV) presence of pain for at least two months. The control group had no history of injury or pain in the knees. Exclusion criteria for both groups included a history of surgery, injury or pain in the hips, patellar instability, pain on palpation of the patellar tendon area, Hoffa's fat pad, iliotibial band, pes anserinus tendon or knee joint line, signs or symptoms of meniscal or knee ligament injuries.

The participants performed five single leg squats with one minute interval between each trial. Squats were performed with at least 60° of knee flexion, and kinematic (7 cameras Qualisys Motion Capture System) and kinetic (Bertec force plate) data were collected. The interested variables were acquired at the peak of knee flexion during the squats: internal hip extensor moment, internal knee extensor moment, sagittal plane trunk position, and stress PF calculated according to a model previously published [7]. Data was analyzed using the Person correlation and independent t test (α=0.05).

RESULTS AND DISCUSSION

Peak knee flexion angle was 75.2 ± 8.8 deg. Trunk flexion angle was positively correlated to hip extensor moment (r=0.57; p<0.01). There was no correlation between trunk flexion angle and knee extensor moment (r=-0.21; p=0.28), as well as PF stress (r=-0.27; p=0.15). Regarding the comparison between groups, the PFP group had lower hip extensor moment (p<0.01) and a trend to a greater PF stress compared to control group (Table 1).

Table 1: Comparison between groups (mean ± SD)

	PFP group	Control group	Mean difference (95%CI)
Trunk flexion (deg)	10.5 ±6.7	15.2 ±9.7	-4.7 (-10.9 to 1.6)
Hip moment (Nm/kg)	0.6 ±0.3	0.9 ±0.4	-0.3 (-0.6 to -0.1)
Knee moment (Nm/kg)	1.1 ±0.7	1.1 ±0.6	-0.1 (-0.6 to 0.4)
Stress PF (MPa)	7.2 ±3.2	5.1 ±3.2	2.2 (-0.2 to 4.6)

Results indicated that a greater trunk flexion angle is related to a greater hip extensor moment, and trunk flexion angle is not related to knee extensor moment and PF stress. Besides there is no difference between groups regarding trunk flexion angle, the weakness of hip extensor muscles might induce females with PFP to perform weight bearing activities with lower trunk flexion angle in order to decrease the load on hip extensor muscles. However, this strategy does not have relation with overload on knee joint, and then, perhaps trunk position does not have relation with development or progress of PFP. Future studies with larger sample may confirm these results. Moreover, futures studies should consider postural balance as covariant.

CONCLUSIONS

Trunk position needs to be considered during physical activities and therapeutic exercises when performed to address deficits in hip extensor muscle strength.

P131 - MUSCLE CONTRIBUTION TO KNEE EXTENSION DURING EARLY STANCE PHASE IN KNEE

[1] **Shinya Ogaya**, [2] Ryo Kubota, [2] Yuta Chujo, [2] Eiko Hirooka, Kim Kwang-ho and [2] Kimitaka Hase

INTRODUCTION

Knee osteoarthritis (OA) is a major musculoskeletal disease that causes decline of physical and locomotor function. Because weakness of the quadriceps muscle is a common clinical sign associated with knee OA, the knee extension moment generally decreases in knee OA patients.

In addition, knee OA patients have a kinematic feature of knee joint excursion at the early stance. In OA patients, the knee is slightly and continuously flexed during the early stance, and there is an unclear or no peak knee flexion-angle. The kinematic feature of knee flexion in OA patients should affect the decreased knee extension moment; however, there is no evidence to clarify the relationship between knee excursion and quadriceps dysfunction.

A musculoskeletal simulation model can reveal how OA patients control the knee in the early stance phase with quadriceps dysfunction. The objective of this study was to clarify the individual muscle contributions to knee angular acceleration in the early stance phase in knee OA patients.

METHODS

Fifteen individuals with medial knee OA and 14 healthy elderly individuals were recruited. Subjects with knee OA were included if they had Kellgren-Lawrence grade 2 or greater radiographic changes in the medial tibiofemoral compartment.

Three-dimensional coordinates of reflective markers and ground reaction force were measured during standing and gait using a motion analysis system (Locus 3D MA-300, Anima, Japan). This system consists of 8 infrared cameras and two force plates. Nine markers were attached at anatomical landmarks: acromions, C7, 1st and 5th metatarsal heads, and heels. We also set imaginary markers at the medial-lateral malleolus, medial-lateral knees, and anterior-posterior superior iliac spines by using pelvic and shank devices to attach additional markers. The subjects were instructed to walk on a platform at their preferred speed. Data were low-pass filtered with a cut-off frequency of 6 Hz.

Subject-specific simulations were created by OpenSim. A simulation model was created based on a generic musculoskeletal model, comprising the lower extremities and trunk, with 92 muscle-tendon units. For consideration of varus alignment, a degree of knee adduction-abduction was added into the model. Knee adduction-abduction motion was locked after the scaling process, because this motion is very small in spite of static alignment change. Next, we processed inverse kinematics and a residual reduction algorithm, and then computed muscle control. An induced acceleration analysis was used to compute the contributions of individual muscle forces to knee angular acceleration. We divided early stance into two phases, i.e., a 5-15% stance phase (%SP) and a 15-25%SP, and an averaged contribution of muscle forces to knee angular acceleration was calculated.

T-test and chi-square were used to investigate differences in demographic data and gait speed between groups. Analysis of covariance (ANCOVA) was used to determine group differences adjusted by gait speed.

RESULTS AND DISCUSSION

There were no statistical differences between the two groups in age, height, weight, and gender distributions. Knee OA patients walked slower than control subjects, i.e., 0.90 ± 0.16 m/s in knee OA patients and 1.11 ± 0.21 m/s in controls.

Knee extension acceleration generated by lower limb muscles was observed during 5-25%SP in both knee OA and control individuals (Figure1). Major muscles used to generate knee extension in the early stance phase were the gluteus maximums and the vastus. The tibialis anterior generated large knee flexion in the early stance.

During 5-15%SP, there was no difference between groups in knee acceleration by all lower limb muscles. Patients with knee OA showed less knee extension acceleration by the vastus and greater knee extension acceleration by hip adductors than in controls.

During 15-25%SP, there was no difference after adjustment for gait speed in knee acceleration by lower limb muscles. Patients with knee OA showed significantly less knee extension acceleration by the vastus.

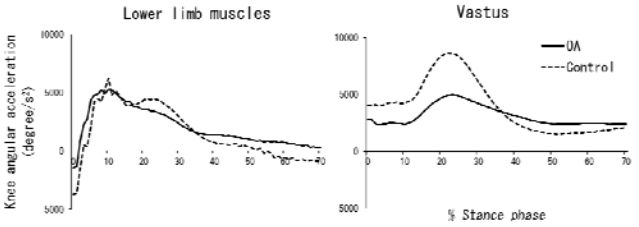

Figure 1: Muscle contribution to knee angular acceleration during the stance phase.

Our study revealed that patients with knee OA showed less knee extension acceleration by the vastus during the early stance phase. The results indicate that the generation of knee extension acceleration by the vastus muscles is impaired in knee OA patients. During 5-15%SP, hip adductor muscles, which mainly act to control medio-lateral body stability, partly compensate for the weak production of knee extension by the vastus. We could not identify a kinetic relationship between less knee extension-flexion excursion and quadriceps dysfunction during the early stance in knee OA.

CONCLUSIONS

This study revealed the important finding that patients with OA show decreased dependency on the vastus muscle for knee control during the early stance.

P132 - FUNCTIONAL MUSCLE ROLES DIFFER BETWEEN SEXES BEFORE AND AFTER ACL INJURY

[1]**Michael J Del Bel**, [1]Teresa E Flaxman, [1]Kenneth B Smale, [2]Tine Alkjaer, [2]Erik B Simonsen, [3]Michael R Krogsgaard and [1]Daniel L Benoit
[1]University of Ottawa, Canada
[2]University of Copenhagen, Denmark

Corresponding author email: dbenoit@uottawa.ca

INTRODUCTION

Injuries to the anterior cruciate ligament (ACL) are up to eight times more likely to occur in females compared to males. Neuromuscular and biomechanical differences in ACL-deficient populations have been established during a variety of tasks [1], however, it remains unclear how males and females differ in neuromuscular control following injury.This study sought to determine if injury-induced changes in neuromuscular control lead to altered functional roles of the knee joint muscles between males and females.

METHODS

A highly reliable, isometric, weight-bearing, force-matching protocol [2] required 20 ACL-deficient females (FACL), 27 ACL-deficient males (MACL), 17 healthy females (FYC) and 17 healthy males (MYC) to modulate ground reaction forces in various combinations of sagittal and frontal plane loads. Surface electromyography of 10 muscles in the lower extremity were normalized and displayed in polar plots. Ground reaction force directions and magnitudes, and 3D motion were captured. Mean activation magnitudes and patterns were quantified with an orientation analysis to determine the presence of group differences in knee stabilisation strategies and functional roles.

Watson-Williams tests (α =.05) were used to identify group differences in the mean direction of each muscle's activity (ϕ). Two-way ANOVAs (α =.05) were used to determine main effects of sex and ACL-injury in the group mean magnitudes of each muscle's activation (X_{EMG}) and variance of activation about each muscle's ϕ (specificity index: SI). The 10 muscles surrounding the knee joint were classified into 3 roles: *general stabiliser*, *moment actuator*, and *specific joint stabiliser*, using their symmetry of activation about the polar plot origin, ϕ, X_{EMG}, SI, and muscle activation profiles.

RESULTS AND DISCUSSION

The classification of functional muscle roles was different between groups, with the exception of MACL and FYC sharing the same classifications. No main effects of sex or ACL injury were found for any of the muscles' ϕ. Sex and injury effects were seen in both group X_{EMG} and SI of activations; i) FYC had higher X_{EMG} than MYC for the RF (p =0.021) and VM (p =0.009), ii) FYC and MYC had higher MG X_{EMG} compared to FACL (p =0.001) and MACL (p <0.001), respectively, iii) FACL had lower SI values for the BF than both FYC (p =0.024) and MACL (p <0.001).

Sex-related differences in neuromuscular control of the knee have been routinely cited, implying a link with increased non-contact ACL injuries among females [1]. We found that MYC had the most specific muscle activation roles, with no muscle being a general stabiliser, while FACL used the least specific muscle activation roles, with four of ten muscles being general stabilisers. Previous work shows that the vastii [3], and the MG [4] have increased activations in unstable knee joints, in an attempt to increase compression of the joint and protect the ACL from increased strain.

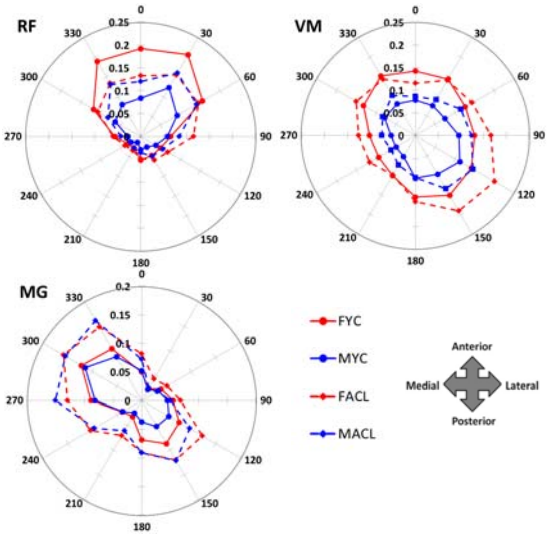

Figure 1: Mean EMG polar plots of rectus femoris (RF), vastus medialis (VM), and medial gastrocnemius (MG) muscles for FYC, MYC, (solid lines) FACL, and MACL (dashed lines). Outer numbers represent target location angle (°); inner numbers represent normalized EMG magnitude (ratio of maximum voluntary activation).

CONCLUSIONS

We deemed specificity as the ability of efficiently controlling the activation of the knee joint muscles during various loading conditions. Our results indicate a hierarchy in muscle activation strategies, in terms of specificity, when stabilising the knee joint: MYC as the most specific, FYC reflecting the strategy of MACL, and FACL as the least specific. This stresses the necessity of sex-specific patient rehabilitation management and treatment after an ACL injury.

INTRODUCTION

Ankle sprain is a common injury caused by inversion movement during the practice of exercise, sports or during daily activities. Repeated ankle sprains can lead to chronic ankle instability (CAI). Although there are many studies on this topic, doubts about how pairs of muscles are activated by Central Nervous System (CNS) still remain. One way to evaluate it is the coherence analysis electromyography-electromyography (CoAn EMG-EMG). Coherence analysis (CoAn) is a cross-correlation of frequency spectrum domain which suggests that the common oscillations of muscles are commanded by CNS. However, there are not enough studies about CoAn EMG-EMG with CAI. This study aims to evaluate the differences of CoAn EMG-EMG in females with CAI.

METHODS

Twenty four (24) female indoor football players participated and were divided in two groups: Control Group (CG) and Instability Group (IG). Ten (10) inversion movements were simulated on an inversion platform and the electrical activity of the mm. tibialis anterior, TA; fibularis longus, FL; fibularis brevis, FB; and gastrocnemius lateralis, GL were recorded by an electromyoph. The Power Spectral Density (PSD) was calculated for each muscle from two EMG epochs (the anticipatory, APA; and compensatory postural, CPA, adjustments). APA is the interval between 200 ms before and 51 ms after start of the fall of the inversion platform. CPA is the interval between 51 and 251 ms after start of the fall of the inversion platform. Platform initial movement was measured with a 3D accelerometer. Coherence analysis was applied for pair of muscles: TA-FL, TA-FC, TA-GL, FL-FC, FL-GL and FC-GL. The frequency bands evaluate were: alpha (α, 5-13 Hz), beta (β, 13-30Hz) and gamma (γ, 30-100 Hz). Raw EMG signal was demeaned, filtered (4th order 200 Hz Butterworth low-pass filter), and rectified. Two way analysis of variance (ANOVA) was applied to check the differences among the groups. The level of significance was 5%.

RESULTS AND DISCUSSION

Fatigue did not change the CoAn EMG-EMG, but the group changed some pairs of muscles. In alpha band, for APA, TA-FC, TA-GL, FC-FL, FC-GL and FL-GL ($F_{1,447}$>6.6, p<0.03) were higher within the Instability Group. For CPA, TA-FL and FC-FL ($F_{1,447}$>5.9, p<0.05) were higher within CG. In beta band, for APA, TA-GL, FC-GL and FL-GL ($F_{1,447}$>6.6, p<0.05) were higher within Instability Group. For CPA, FC-FL and FC-GL ($F_{1,447}$>4.5, p<0.05) were higher within Control Group. In gamma band, for APA, TA-FC, TA-GL, FC-FL, FC-GL and FL-GL ($F_{1,447}$>5.2, p<0.05) were higher within Instability Group. For CPA, TA-FL and TA-GL ($F_{1,447}$>7.7, p<0.05) were higher within control group. Beta and gamma band are related to voluntary contraction, and their origin can be in motor cortex [1]. Alpha can be related to balance control, natural tremor, fine motor control or global inhibition of the cortex [1]. In our results the group changed some pairs of muscles. Instability Group was able to change most pairs in APA while Control Group changed in CPA. The pairs of muscles were changed as agonist-antagonist as well as agonist-agonist. It could be understood as an attempt by the central nervous system (CNS) to avoid a possible ankle sprain in APA for IG.

CONCLUSIONS

The results suggest that CAI changed the CoAn EMG-EMG in some pairs of muscles in APA in IG. The increase of the CoAn EMG-EMG could protect the ankle against an inversion movement. The fatigue was insufficient to change the data.

P134 - IS MUSCLE CO-ACTIVATION PREFERENTIALLY DRIVEN BY OVERLAPPING CORTICAL MAP REGIONS?

Matthew J Ward, John Cirillo and **Angus JC McMorland**
University of Auckland
Corresponding author email: a.mcmorland@auckland.ac.nz

INTRODUCTION

Anatomical and functional mapping of the primary motor cortex (M1) shows overlapping representations of proximal and distal upper limb muscles. Muscle map overlap reflects structural organization of the motor system that may facilitate synergistic activation of muscles during functional tasks [1,2].

Voluntary muscle activation increases corticomotor excitability (CME) detectable using transcranial magnetic stimulation (TMS). We therefore used TMS to examine the hypothesis that CME in the known overlapping region of the muscle maps for anterior deltoid (AD) and first dorsal interosseous (FDI) was preferentially increased compared to non-overlapping regions during a task that required synergistic activation of the two muscles.

METHODS

Thirteen young, healthy right-handed individuals participated. Participants performed repeated movements of their dominant (right) upper limb for each of a thumb-index pinch task, an anterior push task against a wooden peg, or the two combined, in response to a variably-timed metronome tone. EMG was collected from AD and FDI, bandpass filtered (10 – 1000 Hz) prior to digitization at 2 kHz. Participants were instructed to generate muscle activations at 10±3% of RMS MVC when active and < 10 µV when resting.

Cortical muscle maps were collected for FDI in the pinch task, AD in the push task, and both in the combined task. To minimize map changes associated with task-learning, maps were collected using fast techniques [3] with 4–5.5 s inter-stimulus intervals using optical head and coil tracking.
TMS current flow was induced in a posterior-to-anterior direction, at 120% of active motor threshold (AMT) for each muscle. Stimulation locations were fitted to a sphere and converted to 2-D spherical coordinates for further analysis.

Peak-to-peak motor evoked potential (MEP) amplitudes were interpolated and smoothed in a grid of 750 × 750 points using a Gaussian radial basis function. Map boundaries were set to exclude any amplitudes < 10% of the maximum. From each map, centre-of-gravity (CoG), area, and volume (sum of amplitudes) were calculated. Overlapping and total area and volume were calculated for pairs of maps. Repeated measures ANOVAs and paired t-tests were used to assess changes in map metrics between individual and combined tasks.

RESULTS AND DISCUSSION

Muscle maps overlapped considerably, particularly of highly excitable areas (Figure 1). CoG of FDI (purple square) is lateral of AD CoG (green triangle) in both maps. None of the metrics measured (map areas, volumes and CoGs) showed significant differences between independent and combined tasks.

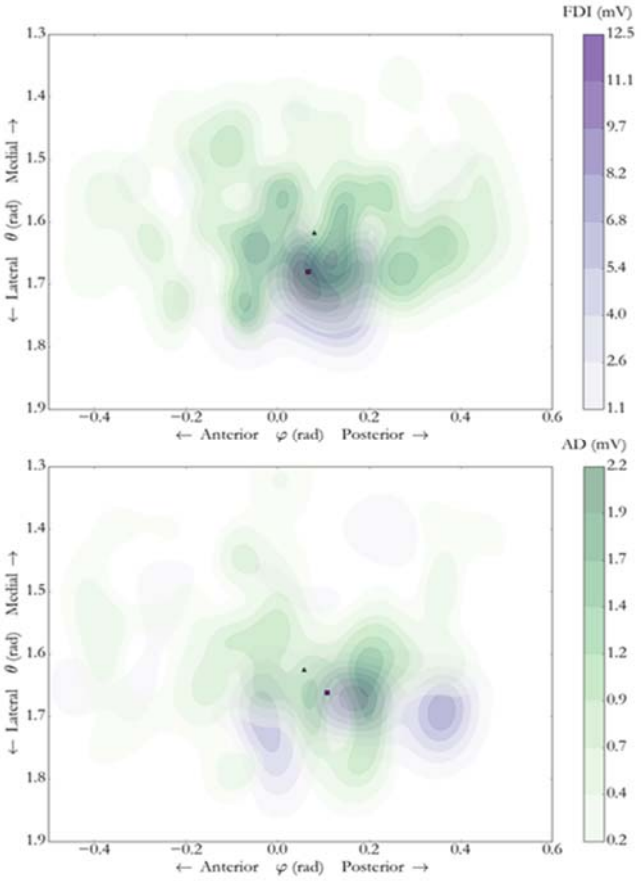

Figure 1: AD (green) and FDI (purple) muscle maps during independent (upper) and combined (lower) movements.

The lack of changes between these two tasks suggests that there is not independent regulation of the CME of the overlapping region, compared to non-overlapping regions. Overlap may still facilitate synergistic activation, but the CME of the whole maps is regulated as a single unit. Interestingly, the lack of an additive effect on total map volume suggests that, despite overlapping, the excitability of neurons related to the two muscles is independent. This finding raises the question of what connectivity exists between these co-localized neuronal networks, and what implications this has for motor control.

CONCLUSIONS

No modulation of CME in FDI and AD muscle maps was seen between independent and combined muscle activation. Synergistic activation, if present, seems not to be specific to the overlapping portion of the maps for these two muscles.

P135 - THE EFFECT OF DISTANCE RUNNING ON LATERAL POSTURAL CONTROL IN ELDERLY PEOPLE

[1] Shi-Wei MO
[1] The Education University of Hong Kong
smo@friends.eduhk.hk

INTRODUCTION

The elderly population is continually growing around the world. Each year, over one-third elders aged 65 or over fall at least one time (www.cdc.gov/ncipc/wosqars) and 70% of accidental injuries among elders are due to falls [1]. A decline of lateral postural control ability due to aging may be the primary risk factor.

Lateral postural control ability can be enhanced by physical activities. Distance running, as a life-long exercise, was recommended to maintain healthy aging. However, the increasing exposure to environment of slippery and/or uneven floor during running may increase the risk of falls and related accidents. Moreover, the effects of distance running on lateral postural control ability are unknown.

This study aimed to investigate the lateral posture control ability of the elders with regular distance running when sudden lateral perturbations were applied. The mechanics of distance running to lateral postural control ability for elders were discussed.

METHODS

Fourteen male elders (70.9±4.2yrs, 170.3±7.7 cm, 69.6±10.6 kg) with regular jogging habit composed the running group (RG) and 14 counterparts (72.4±4.1yrs, 170.0±4.5 cm, 67.5±8.8 kg) with sedentary habit composed the control group (CG). All stood (arm crossed, eyes looking forward, ear plugged) on a force platform installed in a costumed frame which can move toward different directions (0.2m/s, peak acceleration of 2 m/s/s) driven by a mechanical device and controlled using a trigger. Sudden movements with unexpected direction were applied and they were required to maintain balance without taking a step.

The displacements of center of pressure (COP), the neuromuscular reaction time of the tibialis anterior (TA), gastrocnemius (Gas), rectus femoris (RF), semitendinosus (ST), and gluteus maximus (GM) and the instant of peak pressure (IPP) in the lateral heel, medial heel, lateral mid foot, medial mid foot, 1st metatarsal (MT), 2nd-3rd MT, 4th-5th MT, hallux, and 2nd-5th toe of the dominant side from three trials were compared. Paired t-test was used to examine the differences between RG and CG. The level of significance was set at $p<0.05$.

RESULTS AND DISCUSSION

The RG displayed a larger COP area in comparison with the CG (99.1±68.5 Vs 69.9±31.9 mm^2, $p=0.002$), while no differences in the peak mediolateral and anteroposterior COP displacement. From the dynamic systems theory [2], a larger COP area may be due to coordination of multi movement control systems, which may contribute to maintain postural stability. The velocity and acceleration of COP were reported to be more sensitive to postural stability [3], but there were no related data in this study.

The pattern of muscle activity was similar between the two groups (Fig. 1a). However, the RG activated TA ($p<0.001$) and ST ($p=0.004$) earlier. It indicated that elders with regular distance running may response quickly under sudden lateral perturbations.

They also displayed smaller IPPs in the 1st MT and hallux regions in contrast to sedentary elders (Fig. 1b). The two regions played a major role in weight transference across foot [4], which may be important for maintaining stability.

CONCLUSIONS

The elders with regular distance running displayed a larger COP area, a shorter neuromuscular reaction time, and smaller IPPs in the 1st MT and hallux regions under sudden lateral perturbation condition, which demonstrated the benefits to control postural stability.

P136 - CEREBELLAR TRANSCRANIAL DIRECT CURRENT STIMULATION IMPROVES ADAPTIVE

Peter Poortvliet[1, 2], Billie Hsieh[3], Andrew Cresswell[1], Marcus Meinzer[3]
[1]University of Queensland, School of Human Movement and Nutrition Sciences
[2]University of Queensland, Queensland Brain Institute
[3]University of Queensland, Centre for Clinical Research

INTRODUCTION

Postural control is essential in daily life, but can be significantly affected by advanced age or pathological conditions resulting in injury, disability and functional dependence [1]. Rehabilitation interventions can facilitate recovery of postural control, but it remains a priority to optimize their effectiveness [2]. A promising strategy may involve transcranial direct current stimulation (tDCS) of the cerebellum, which is critically involved in fine tuning motor adaption [3]. This study, in healthy individuals, explored the potential beneficial effects of cerebellar tDCS on postural recovery from disturbance by bilateral Achilles tendon vibration during quiet standing.

METHODS

Twenty-eight healthy volunteers were recruited for this sham-tDCS controlled, randomized, double-blind study. All attended a single experimental session during which they stood blindfolded on a force platform while undergoing four trials. (A) A baseline trial that consisted of 60 sec of quiet standing, which was followed by 20 min of bilateral active (anodal-tDCS, 1 mA, 20 min, N=14) or sham (10 sec, N=14) cerebellar tDCS. (B) Subsequently, three individual experimental trials of quiet standing were performed that included 15 sec of bilateral Achilles tendon vibration (administered in the first 8 – 10 sec of each trial), followed by 25 sec of postural recovery from the disturbance. Postural steadiness during baseline and experimental trials were quantified as displacement, standard deviation and path derived from the centre of pressure, which is a surrogate for the trajectory of center of mass.

RESULTS AND DISCUSSION

Both groups were comparable in regards to demographics, baseline postural steadiness measures and fatigue and mood ratings. Although backwards displacement during vibration was similar between the stimulation groups, the active tDCS group showed significantly better postural steadiness during and following vibration, as indicated by lesser forward displacement during recovery and lower variability in centre of pressure derivatives (Figure 1).

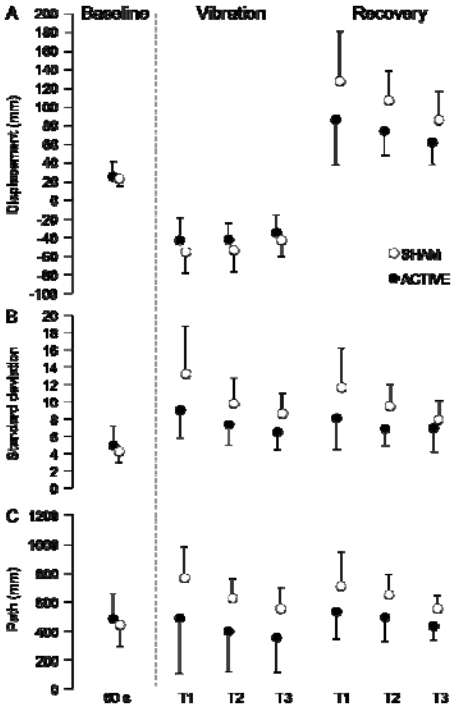

Figure 1: Postural steadiness for the sham (open circles) and active (filled circles) cerebellar tDCS groups during 60 s of baseline standing and across three consecutive experimental trials. With COP_{DISP} (A), COP_{SD} (B) and COP_{PATH} (C) for the baseline, vibration and recovery phases, respectively. Negative displacement indicates a backward shift of COP, while positive displacement indicates a forward shift of COP.

Consistent with our hypothesis, the active cerebellar tDCS group performed significantly better in regaining and maintaining standing postural steadiness compared to the sham group, both during the vibration and subsequent recovery phase. The faster and more efficient postural adaptation induced by active stimulation, warrants exploration of this type of intervention in elderly individuals or patient populations with impaired postural balance (e.g., Parkinson's disease or stroke).

CONCLUSIONS

The positive results of our study suggest that cerebellar tDCS may be a promising approach to enhance rehabilitation success in clinical populations with impaired postural balance.

P137 - EFFECTS OF TAICHI ON STATIC BALANCE AND LEG MUSCLE ACTIVITIES IN COMMUNITY MIDDLE-AGED AND ELDERLY

[1]**Kuo-Chung Tai**, [1]Kwan-Hwa Lin, [2]Jyh-Gang Hsieh, [1]Chu-Fen Chang, and [1]Yun-Ju Lee

INTRODUCTION

Aging has been considered as a crucial factor affected balance maintenance and consequent falls. Regular physical exercise has been showed that it would benefit to improvement of balance stability, particular in elderly. TaiChi is an oriental martial art and becomes popular in elderly community currently in Taiwan. Its slow and gentle movements prompt weight shifting between left and right legs anterior-posteriorly as well as medial-laterally. This weight shifting is associated with center of pressure (COP) movement. However, the mechanism of TaiChi affects the COP transformation by leg muscles for balance remains unclear. Increases challenge of balance by changes of visual and proprioceptive sensation with a narrow base of support would provide better understandings about the control of balance by the central nervous system.. The aim of the present study was designed to study effects of regular TaiChi player on challenged static balance and electromyographic (EMG) activities compared to older adults without playing TaiChi.

METHODS

Sixteen healthy middle-aged and older adults participated in the current study, included eight controls (age: 56.29±3.25; height: 162.57±7.96 cm; body mass: 60.76±15.69 kg) without regular exercises and eight participants (age: 61.71±6.85 years old; height: 156.29±8.56 cm; body mass: 61.71±11.92 kg) playing TaiChi thirty minutes per day, three days per week and more than two years.

All participants were instructed to maintain tandem stance with left leg placed backward for around 17 seconds. They performed four conditions of standing on the force platform (solid) and on the foam (foam) with eyes open (EO) and eyes closed (EC). Bilateral electromyographic activities (EMG) of tibialis anterior (TA), medial gastrocnemius (MG), rectus femoris (RF) and biceps femoris (BF) were recorded. Sway area of center of pressure (COP) was calculated within middle 15 seconds along with path and range of COP in the anterior-posterior (AP) and medial-lateral (ML) directions. For muscle activity, root mean square (RMS) values of EMG with normalization by maximum voluntary contraction were calculated for each muscle. Subsequently, magnitudes of TA and RF were summed to represent ventral muscle and magnitudes of MG and BF were summed to represent dorsal muscle for left and right legs, separately.

Mann-Whitney U tests were performed to evaluate the effects of TaiChi in four conditions (solid-EO, solid-EC, foam-EO, and foam-EC) on sway area of COP (Ae), path and range of COP in AP and ML direction (pathAP, rangeAP, pathML, and rangeML), RMS EMG of ventral and dorsal muscle on the left and right side (ventralL, dorsalL, ventralR, and dorsalR). Statistical difference was set at $p<0.05$.

RESULTS AND DISCUSSION

Figure 1 illustrates postural sway in the condition of standing on the foam with eyes closed and the similar patterns (less postural sway in the TaiChi group) were also observed in the solid-EO condition.

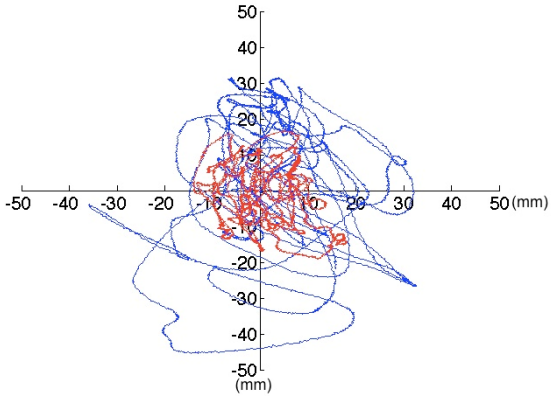

Figure 1: A typical example of COP trajectory in the condition of standing on the foam with eyes closed from two participants with playing TaiChi (red) and the other participant without regular exercise (blue).

Mann-Whitney U tests revealed that Ae, pathAP, rangeAP, rangeML, and EMG of right dorsal muscles were significant affected by regular exercise of TaiChi in the conditions of solid-EO and/or foam-EC ($p<0.05$). All magnitudes of these parameters were smaller in the TaiChi group than the non-TaiChi group. In the solid-EO condition, the rangeAP (24.0±4.1 mm) and rangeML (16.3±1.7 mm) in the TaiChi group were similar to younger adults (37.6±10.7 mm and 28.2±6.8 mm) in the 60-second tandem stance [1]. In the most challenged condition (foam-EC), the significant differences between two groups imply that the vestibular system was dominated to control postural stability and had better performances in the TaiChi group [2].

CONCLUSIONS

Older adults playing regular physical exercise, like TaiChi, have comparable postural stability with younger adults when visual and proprioceptive feedbacks are not compromised. They also have better static balance even in the situation of absent visual feedback and unreliable proprioceptive sensation by executing the vestibular system sensibly.

P138 - A COMPARISON OF THE EFFECTS OF INSOLES WITH AND WITHOUT SUBTHRESHOLD NOISE ENHANCED VIBROTACTILE SENSE DURING SINGLE LEG STANCE IN HEALTHY PEOPLE

[1]**Tan-Ling Tsao**, [1]Po-Tsun Chen, [1]Yun-Ju Lee, [1]Chich-Haung Yang

INTRODUCTION

Somatosensory function plays an important role in the postural control and contributes 70% sensory strategy in healthy people when standing on a firm base of support in a well-lighted environment [1]. Declining somatosensory feedback system will be a risk of falling to people who limited to re-weight postural sensory dependence when vision is deprived or in a dimly lighted environment [2]. Previous literature has summarized that the sub-threshold enhanced noise vibration via stochastic resonance (SR) may not only enhance the perceptive sensitivity but also improve the reaction time in static postural control [3]. Still, the effects of SR on improving balance stability in dynamic activity remains unclear. During gait, activity in daily living, and even the challenging task like single leg stance contains much single stance support. Moreover, the performance of single leg stance (SLS) served as an important predictor of falls [4]. Hence, the aim of this pilot study was to examine the effects of insoles with and without the Sub-threshold Enhanced Noise Vibrotactile Sense (SNEVS) over plantar sole during a SLS task.

METHODS

Ten healthy collegiate students (5 males and 5 females, mean age: 21±3.3 years; body weight: 56.6±10.3 kg, and body height: 167±9.4 cm) who cannot perform the SLS with their eyes closed for thirty seconds voluntarily participated in this study. They were requested to perform SLS on the dominant leg with eyes open, with and without the intervention of SNEVS from a custom-made vibrotactile insole system in a randomized order.

At the beginning of SLS task, the participants were instructed to stand on the force-plate (BP400600-2000, AMTI, USA) with weight distributed evenly on both feet. Then, they flexed the hip and knee joints to 90 degrees after hearing a computer-generated beep signal. The SLS remained as long and steady as possible until 30 seconds. Three trials in each condition were performed and a 5-min rest was permitted between conditions to avoid fatigue. The coordinates of center-of-pressure (COP) was used for further analysis. The SLS task was divided into the dynamic and static phases. The dynamic phase was defined as the process from double leg stance to SLS contains a contralateral push-off movement. The static phase was defined as the COP maintained within the base of support in the stance leg.

Outcome measures consisted of COP velocity in the mediolateral direction during the dynamic phase and COP sway area during the static phase. The COP velocity was defined as the maximal distance translation divided by the period of this translation. The middle 10 seconds of COP data was calculated for data analysis in the static phase. Wilcoxon signed ranked test was used to examine the differences between two conditions. Values of $p < .05$ were statistically significant.

RESULTS AND DISCUSSION

The COP velocity of the dynamic phase with SNEVS was significantly larger than that without SNEVS (p=0.028). The smaller COP sway area of the static phases was noticed with SNEVS than that without SNEVS (p=0.028, Figure1).

To sum up, we found that the subjects with the SNEVS, additional sensory input signals were detected from the sole, were able to achieve stability position faster in the dynamic phase. Our findings have shown that the subjects have better dynamic balance control to complete the SLS task fast but without falling. More importantly, a smaller COP sway area has implied that subjects have increased stability and better static balance control in the static phase of SLS.

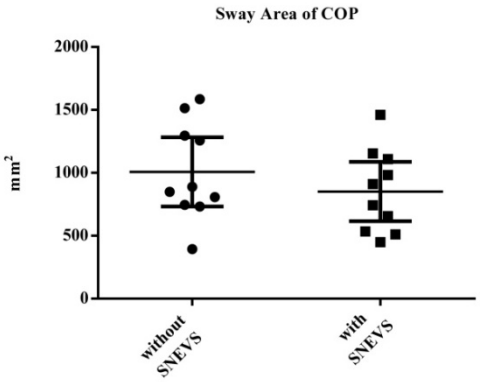

Figure 1: Significant difference in the distribution of COP sway area between with and without SNEVS intervention.

CONCLUSIONS

During a SLS task, SNEVS over plantar sole may improve balance control when performing the limb lifting as well as the maintenance of static standing in young healthy people.

ACKNOWLEDGEMENTS

We would like to thank the contribution of all participants and financial support from Ministry of Science and Technology, Taiwan (MOST 102-2410-H-320-011).

P139 - SPINE AND LOWER EXTREMITY KINEMATICS OF SURYANAMASKAR

[1] Rajani Mullerpatan, [1]Bela Agarwal , [1]Triveni Shetty , Omkar SN[2]
[1]MGM Center of Human Movement Science, MGM Institute of Health Sciences, Navi Mumbai, India
[2]Department of Aerospace Engineering, Indian Institute of Sciences, Bangalore, India

INTRODUCTION

Suryanamaskar, referred as sun salutation is one of the ancient forms of Yogasanas practiced. This yogasana is a sequence of 10 consecutive poses, producing a balance between flexion and extension, performed with synchronized breathing and aerobic activity [1]. Gentle transitions through sequences blended with breathing control have demonstrated reduction in diastolic blood pressure. Additionally, positive benefits for weight and physical fitness management; improving cardio-respiratory fitness, upper limb muscle endurance and body flexibility are known [1]. However limited information is available on biomechanical exploration of suryanamaskar.

Motion analysis of suryanamaskar using magnetometer and accelerometer revealed kinematic component of transition from one posture to another [2]. Further Omkar *et al* (2011) evaluated effects of suryanamaskar on wrist, elbow, shoulder, hip, knee and ankle joints using mathematical model and reported dynamic moments with high magnitudes and rates, applied with unusual distribution patterns, optimal for osteogenesis and sub-maximal loading ensuring none of the joints were overstressed [3]. However further exploration of joint angles of spine and lower extremity joints would enhance kinematic understanding of surya namaskar. Therefore present study was aimed to explore spine and lower extremity kinematics of suryanamaskar.

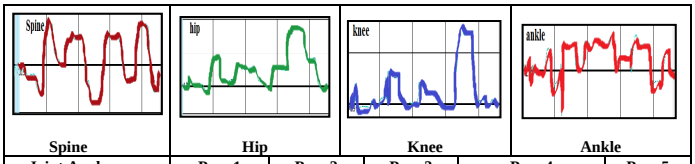
METHODS

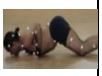
3D motion capture was performed on five healthy trained yoga practitioners. The 10 pose sequence of suryanamaskar, performed gracefully, was captured with 12-camera Vicon system (Oxford Metrics Group,UK) at a sampling frequency of 100Hz using 39 reflective markers. Data were processed using plug-in-gait model. Analog data was filtered at 6Hz. Joint angles during 10 subsequent poses were computed within Vicon Nexus.

RESULTS AND DISCUSSION

Joints of spine (C7-L5) and lower extremity are observed to move through nearly full range of motion in sagittal plane (refer to Table1). Movements were largely symmetrical in all poses except pose 4 and 9 which were reciprocal. Spine moved through a range of 56^0 flexion to 47^0extension alternating between flexion and extension exerting a stretch on posterior structures such as dorsolumbar fascia, hamstrings and tendoachilles during pose 3. Hip moved from 148^0 flexion to 15^0 extension applying a stretch on quadriceps bilaterally. Knee flexed upto140^0 and ankle moved in a closed kinematic chain through 40^0 dorsiflexion effectively stretching the tendoachilles.

Principal motion in sagittal plane is reported with a limitation to report cervical spine motion. There is further scope to discuss coupled minimal motion in coronal and transverse plane. Varying base of support during the complete sequence of 10 poses is likely to challenge the postural control of the body.



Joint Angle (degree)	Pose 1	Pose 2	Pose 3	Pose 4		Pose 5
						Spine	-19.46	-44.9	56.9	21		33.2
Hip flexion	6.43	-8.9	85.7	144.1	-4.4*	53
Knee flexion	-2.38	3.5	12.9	118	35.3*	2
Ankle dorsiflexion	5.5	17.1	1	25.8	27.8*	25.1
	Pose 6	Pose 7	Pose 8	Pose 9		Pose 10
						


Spine	-20.3	-47.9	39.7	13.2		54.1
Hip flexion	46.7	-12.5	65.9	144.2	-4.7*	81.6
Knee flexion	35.5	19.3	4.3	138.7	38.4*	3.4
Ankle DF	31.1	24.6	33.7	39.2	23.5*	-4.7

Pose 9- Ashwa sanchalanasana , Pose 10 - Hastapaadasana
*joint motion of contra-lateral extended leg in the pose

CONCLUSIONS

Suryanamaskar is a yogasana largely symmetrical in pattern following a graceful sequence of poses that move the spine and lower extremity joints through a near complete range of motion predominantly in the sagittal plane. It holds huge potential as a single complete exercise to enhance flexibility and postural control of the body in a closed kinematic chain to impart benefits of weight bearing.

P140 - MUSCLE LENGTH-DEPENDENCE OF RESIDUAL FORCE ENHANCEMENT IN THE KNEE EXTENSORS

INTRODUCTION

Residual force enhancement (RFE) describes the phenomenon where the isometric steady-state force following a lengthening contraction remains elevated above the force of a purely isometric contraction at the same final muscle length [1]. Previously, RFE has been observed *in vivo* at long, but not short muscle lengths, for the knee extensors [2]. This finding is in contrast to other research in the same muscle group that has shown RFE on the ascending limb of the force-length (FL) relationship [3]. The discrepancy between these studies may be due to differences in muscle lengths or the muscle-specific force capacities of the knee extensors for the tested knee angles, since only knee joint angle was standardised across participants. Also, the amount of muscle fascicle stretch may have differed, which could have influenced the magnitude of RFE [4]. Therefore, the aims of this study were to (1) match the muscle-specific force produced by the vastus lateralis (VL) at the final muscle length on the ascending and descending limbs of its FL relationship, and (2) to quantify the amount of fascicle stretch during the lengthening contractions at short and long muscle lengths with ultrasound imaging.

METHODS

Subjects were sitting with a hip angle of 70° and their right or left shank fixed to the lever arm of a dynamometer (IsoMed2000, Ferstl GmbH, Germany). In this position, participants performed maximum voluntary isometric knee extensions at knee angles ranging from 40° to 100° with 10° increments. Following this session, the individual force of VL was estimated by multiplying the net torque produced at the knee by the estimated physiological cross-sectional area of VL [5]. VL torque was then divided by the estimated moment arms of the VL determined in OpenSim [6] at the respective joint angles, to determine the VL force-angle relationship. A third-order polynomial was fitted to this relationship and one knee angle at both a short and long muscle length, where the VL produced the same estimated muscle force, was selected. Following this, participants performed purely isometric contractions and eccentric-hold contractions over a 20° range that finished at the two predetermined knee angles. Eccentric contractions were performed at 60°/s and the experimental setup was identical to the first session. The order of the contractions and the knee angles tested was randomised.

Muscle fascicles of VL were imaged with B-mode ultrasonography using a 60 mm transducer with an image depth of 65 mm and a frame rate of 60Hz (LogicScan 128 CEXT-1Z Kit; Telemed, Vilnius, Lithuania). Fascicle lengths were later calculated using a semi-automated tracking algorithm implemented in Matlab [7]. Muscle activities of VL, vastus medialis (VM) and rectus femoris (RF) muscles were assessed using surface electromyography (sEMG) and sampled at 2000 Hz. Knee torque was recorded from the dynamometer at 200 Hz and synchronized with EMG and ultrasound data using a 16-bit A/D card within a Power 1401 data acquisition interface and Spike2 data collection software (Cambridge Electronic Design, UK).

RESULTS AND DISCUSSION

Preliminary results (n=3) indicate that VL muscle forces were similar on the ascending (2520 ± 371 N) and descending limbs (2507 ± 361 N) of the FL curve, with mean knee angles of 68 ± 3° and 98 ± 2°, respectively. RFE was observed on the descending limb of the FL relationship with 147.7 ± 7.31 Nm of torque for the eccentric-hold contractions and 127.0 ± 11.7 Nm for the purely isometric contractions at the same muscle length. However, on average, no RFE was observed on the ascending limb of the FL curve with 245.3 ± 50 Nm of torque for the eccentric-hold contractions and 248.6 ± 32.2 Nm for the purely isometric contractions. The differences in RFE observed at short and long muscle lengths may be explained by greater fascicle stretch on the descending limb (10 ± 2 mm) versus the ascending limb of the FL curve (6 ± 1 mm). Differences in normalized sEMG root-mean-square amplitudes between participants may also explain the variable RFE, since there were reduced muscle activations from 2.5-3.0s following the stretch (VL 82%, VM 87%, RF 88%) versus the purely isometric contractions at the short muscle lengths in two of the participants. In the participant with no activation reduction, RFE was observed at the short muscle length. Therefore, reduced fascicle stretch and/or potential inhibition of the knee extensors at short muscle lengths may explain the differences in RFE between subjects.

CONCLUSIONS

Preliminary results of the present study confirm that RFE occurs on the descending limb of the FL relation and that RFE on the ascending limb is possible, but may not occur in all participants. Currently, it is difficult to infer why there was activation reduction at the shorter muscle lengths in two of the subjects tested and it may indicate that additional familiarisation or electrical stimulations are required to activate the knee extensors. Also, it would be worth standardising the amount of fascicle stretch during the eccentric-hold contractions at short and long muscle lengths to determine if this factor influences RFE *in vivo*. Certainly, more participants will need to be tested and we are confident that results from a greater sample size will help to confirm some of the factors responsible for RFE in human muscle.

P141 - BIOMECHANICAL INVESTIGATION OF A BRACED ARM-TO-THIGH LIFTING TECHNIQUE FOR OCCUPATIONAL TASKS, WITH KINEMATIC ANALYSIS AND COMPUTER MODELING APPROACHES

[1,2,3] **Erica Beaucage-Gauvreau**, [2,4]Dominic Thewlis, [1]William S P Robertson, [3]Robert D Fraser, [2,3]Brian J C Freeman, and [1,2,3]Claire F Jones

INTRODUCTION

Low back pain (LBP) is a common and costly health condition that is related to occupation and activities of daily living [1, 2]. Despite the common use of one-handed lifting techniques for activities of daily living, they have received little attention in the biomechanics literature. The braced arm-to-thigh technique is a one-handed lifting method, where the dominant hand is used to pick up low-to-moderate mass objects from ground level, while the free hand supports the trunk by applying a bracing force on the corresponding thigh. This technique reduces compression forces in the lumbar spine of young healthy males, compared to unsupported lifting methods [3]. The specific aim of this study is to perform a biomechanical analysis of the braced arm-to-thigh bending and lifting technique in 20 healthy and 20 LBP participants and compare the results to two-handed or unsupported one-handed lifts. This abstract presents the data that has been collected to date for one male LBP participant.

METHODS

Three repetitions of four different lifting techniques with a load of 5 kg were performed by one male participant (age 30, body mass 81.9 kg): two-handed squat, two-handed stoop, one-handed stoop, and braced. Kinematic and kinetic data were collected with a 12-camera Vicon motion analysis system (Oxford Metric, UK) and two force platforms (AMTI, USA), with sampling rates of 100Hz and 2kHz, respectively. A switch plate was used to determine when the load was lifted from the ground. A three-axis load cell (Kistler, SUI) secured to the thigh directly above the knee measured the bracing forces applied by the hand, with a sampling rate of 2kHz. Four reflective markers were rigidly fixed to the load cell assembly to determine the location and orientation of the bracing force applied to the thigh.

A modified version of the Raabe et al., [4] full body OpenSim model with a detailed lumbar spine, was used to determine the trunk angles, lumbar spinal joint loads, and muscle activation for the different lifting techniques.

RESULTS AND DISCUSSION

The peak trunk flexion was lower for the braced technique (45°) than for the other three lifting techniques (one-handed stoop: 62°; two-handed stoop: 60°; and, squat: 52°).

The estimated compression and shear forces at L5/S1 were both reduced by the support of the hand on the thigh. Compressive forces at L5/S1 were reduced by 12%, 15%, and 19%, while the shear forces were reduced by 57%, 58%, and 52%, when compared to the one-handed stoop, two-handed stoop, and squat, respectively. Kingma et al. [3] observed similar compressive force reductions in healthy males. The peak resultant hand support force ("bracing force") for the braced technique was 127N, which is within the 110-218N range reported by Kingma et al. [3] for a similar supported lifting technique.

The muscle activation for both the right and left erector spinae (ES) were reduced during the braced technique, when compared to the other techniques. ES forces were lower on the right; this participant applied the bracing force to the left thigh.

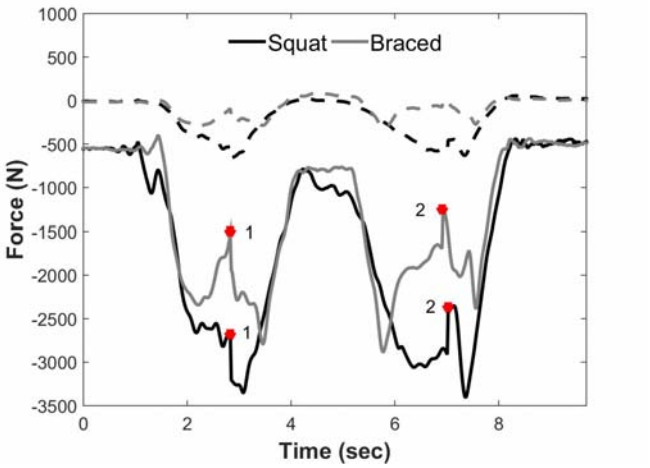

Figure 1: Compression forces (solid lines) and shear forces (dashed lines) at L5/S1 for squat (black) and braced (grey) lifts. The instants of load pick-up (1) and put-down (2) are indicated by the filled circles.

CONCLUSIONS

Applying a bracing load to the thigh via the hand/arm, to support the trunk, led to reduced lumbar spine loading and ES muscle activations during lifting for this participant. The total trunk angle was reduced during braced lifting.

P142 - IN-VITRO STUDY OF 3D BIOMECHANICAL FEATURES OF SUBOCCIPITAL LIGAMENTS DURING AXIAL ROTATION AND FLEXION EXTENSION OF THE UPPER CERVICAL SPINE

[1] Pierre-Michel Dugailly, [1]**Benoit Beyer**, [2]Stéphane Sobczak and [1]Véronique Feipel [1]Université Libre de Bruxelles, Belgium
[2] Université du Québec à Trois-Rivières, Canada

INTRODUCTION

Several studies have focused on kinematics analysis and musculoskeletal modeling of the UCS[1,2]. However, integration of motion and suboccipital ligaments data into specimen-specific 3D UCS models is not reported. The aims of this study were to assess alterations of ligament length and moment arm and to create anatomical modeling with motion representation including musculoskeletal biomechanical features.

METHODS

The present investigation was conducted on the basis of a previous in-vitro study on 3D kinematics of the UCS[3]. Motion data (i.e. flexion extension and axial rotation) were collected from eight anatomical specimens, and integrated into subject-specific 3D model to provide anatomical motion representation. Kinematics outputs consisted in lateral bending, axial rotation and flexion extension motion components obtained from helical axis rotation.

Ten UCS ligaments were identified on each specific 3D model using virtual palpation: anterior and posterior atlantoaxial ligaments (AAA; AAP), alar ligament (AL), anterior and posterior occipito-atlantal ligaments (OAMA; OAMP), tectorial membrane (TM), transverse ligament (TR), apical ligament (APIC), cruciform ligament inferior (XI) and superior (XS) parts. The line of action of each ligament was computed as a straight line between the origin and the insertion attachments. Moment arm (MA) computation was based on the direct method for calculating lever arms, i.e. the perpendicular distance between the helical axis (e.g. MHA) and the action line vector of ligaments. Figure 1 represents a 3D anatomical model including AL ligaments and their respective moment arm for axial rotation.

RESULTS AND DISCUSSION

In general, results showed three categories of length and moment arms variations. First, ligaments with both negligible length and moment arm variations, second ligaments with simultaneous length and moment arm variations of an identical sign, and a third category of ligaments that demonstrated length and moment arm variations of an opposite sign. Table 1 depicts length in UCS neutral position and relative length at maximal amplitude.

Larger MA magnitude was observed for posterior ligaments (AAP and OAMP) for both motions of interest. Moreover, changes of moment arm during motion were mostly found for AAA and AAP in FE and AR, and for OAMA and OAMP in AR only. In contrast, apical, cruciform, alar and transverse ligaments displayed small moment arms.

These outcomes are consistent with previous studies and supply additional data regarding posterior UCS ligaments.

XS	18.80	1.7	1.11	0.05	0.96	0.03

CONCLUSIONS

The present investigation is the first comprehensive description of the biomechanical characteristics of the UCS ligaments during both flexion extension and axial rotation. These outcomes may improve our understanding of functional anatomy of the UCS using specific 3D-model including musculoskeletal and motion representation.

P143 - CO-CONTRACTION KNEE INDEX BEFORE AND AFTER OF STOPPING OF A GAIT CYCLE IN AMATEUR SOCCER PLAYERS

[1]**Gabriel Carreño-Zillmann**, [2]Ivo García and [3]Patricio Pincheira, [2]Pedro González
[1]Universidad de Viña del Mar.

INTRODUCTION

Football is the most popular sport in the world with more than 260 millions of amateur players and they suffer about 670,000 injuries per year [1. The most common location of injuries is in the lower limb (67-88%). Meniscal rupture and partial or complete ligament sprain are about 19% of the injuries. The normal knee function includes a co-contraction between agonist and antagonist muscle of flexors and extensors to protect the anterior cruciate ligament (ACL) from a sprain or complete rupture [2,3]. The aim of this study was to characterize the co-contraction index of normal amateur football players by the controlled reproduction of the flexor-extensor component of the injury mechanism of ACL.

METHODS

Twenty male amateur football players (age: 24±2.14years, height: 1.73±0.04m, weight: 68.58±3.94kg, and BMI: 22.89±1.32) volunteered to take part in the study after signing informed consent forms. The subjects had a training background of almost 5 years and had no health problems (including absence of pain and sprain or knee surgery). This study was approved by the local University Ethics Committee. The subjects walked on a treadmill (PowerJog JW160) for 5 minutes before the test to stablish a comfortable normal speed (3.22±0.20km/h with treadmill slope of 2%). The EMG activity was recorded sampling at 2000Hz with eight bipolar surface electrodes (Myomonitor® Delsys Inc.) placed bilaterally over vastus medialis oblicous (VMO) and vastus lateralis (VL) of quadriceps femoris and biceps femoris (BF) and semitendinosus (ST) according to SENIAM recommendation. During 10s the speed was maintained and before 60s the treadmill was stopped. The limb on which the treadmill would stop was randomly assigned prior to the test and was established between the heel strike and foot flat of human gait. The EMG raw data were full-wave rectified, low pass filtered at 6Hz and normalized expressed as percentage of EMG value during stand at rest. The Co-contraction index (CCI) was calculated using the method of Winter [4]:

$$CCI = \frac{2I_{ant}}{2_{Total}} \times 100$$

where I_{ant} is the area of total antagonist activity and is calculated by:

$$I_{ant} = \int_{t1}^{t2} EMG_{agon}(t)dt + \int_{t2}^{t3} EMG_{ant}(t)dt$$

where $t_1$and t_2 denote the period where the EMG agonist is less than EMG antagonist, whereas t_2 and t_3 denotes the period where the EMG antagonist is less than EMG agonist during the windows analysis:

$$I_{Total} = \int_{t1}^{t3} [EMG_{agon} + EMG_{ant}](t)dt$$

The windows analysis corresponds to the 20% of the Stance Phase of the Gait. We established two relations for agonist and antagonist: (1)VMO/ST and (2)VL/BF and these were compared before treadmill stop (CCI) and after treadmill stop (CCIA). To evaluate data distribution the Schapiro-Wilk normality test was applied and for the tuples agonist/antagonist before the treadmill detention and after treadmill detention (not before vs after) the Mann-Whitney U test ($p<0.05$) was applied.

RESULTS AND DISCUSSION

The mean values were similar for the four groups and were not statistically different (figure 1) but the variance before treadmill detention the VMO/ST (2.60.42) was 2.21 times greater than VL/BF (117.47) and after treadmill detention this relation was 4.05 times greater (VMO/ST: 249.39, VL/BF: 61.48). These phenomena are interesting because the function of the chosen pairs is different. The VMO/ST in addition to flexion and extension control have a role over the control of knee rotation during human gait. For this reason, we believe that a high variability was found. In comparison with other studies we obtained different values of CCI. One of the problems in finding similar values lies in the difference in the windows of analysis and in the choice and allocation of the agonist and antagonist muscles. Many studies use windows of analysis that are larger than ours and include the complete human gait cycle or an entire phase or are not associated with dynamic events.

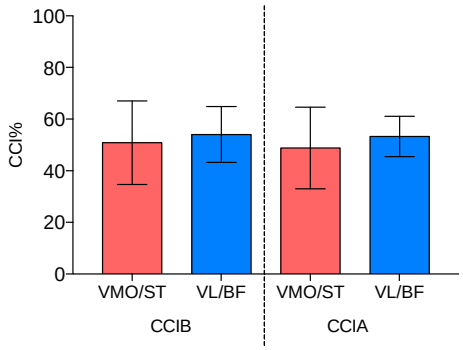

Figure 1: Co-contraction index (CCI) before (CCIB) and after (CCIA) detention of treadmill.

CONCLUSIONS

The knee flexor-extensor muscles play a fundamental role in the protection of ligamentous injury of the anterior cruciate ligament. Currently, there are no reference values for CCI. In this study, we establish specifically values for the normal knee in amateur football players.

P144 - 3D-DIGITIZATION OF THE CERVICAL SPINE BY CT AND IN-VITRO: APPLICABILITY ON ARTICULAR TROPISM

Nicolas Van Vlasselaer, A. Scafoglieri, J. Tuynman, E. Cattrysse
Vrije Universiteit Brussel
Corresponding author email: nicolas.van.vlasselaer@vub.ac.be

INTRODUCTION

The objective of this study was to verify if dimensions of the facet joints measured on in vitro cervical spines can be compared with measurements from 3D-digitized CT-scans. Facet tropism and asymmetry of the cervical spine was investigated both on the in vitro bones as well as on the CT-images. At the mid- and low-cervical spine, asymmetry of the articular surface of the joint facets occurs frequently [1,2] and asymmetry regarding the orientation of these facets is also found regularly on macerated bones [1-3]. In order to determine if these asymmetries effect our movement, it must be measured accurately in vivo.
Segmentation of CT-images and using algorithms to obtain a 3D model is a technique that has been commonly used [4-6], but the existing algorithms for automatic or semi-automatic segmentation can't be used for the spine and as a consequence each slide has to be segmented manually.
So far the validity and applicability of this technique has not been sufficiently studied.

METHODS

CT-scans of three cervical spines, at three different slice-thicknesses and kVp's, were manually segmented and 3D-models were reconstructed. A list of landmarks were marked using 3D Slicer 4.4.0 open source-software. The spines were macerated and the same list of landmarks were marked with the Microscribe G2X digitizer (Immersion Co., San Jose, CA). A bone- and a joint- embedded reference frame were created according to the ISB recommendation on definitions of joint coordinate systems [7] and a mathematical routine (Mathcad 14®) calculated the morphological characteristics. Bootstrapped descriptives, paired samples t-tests, intra-class correlations (ICC) and a Bland–Altman plot were made using SPSS 23.

RESULTS AND DISCUSSION

Intra- and inter-observer reliability of the Slicer CT-model scored well with ICC of respectively: 0.84 and 0.81. Morphological characteristics included the facet dimensions (height, width and surface area), curvature, orientation and implantation of the facets. The specimen with slice thickness 2 mm in het sagittal view and 100 kVp, showed good results demonstrating only a significant difference between the Microscribe and Slicer 3D-model for 'the distance of the facets the transversal plane' (n: 12, p: 0,007). Also the specimen with slice thickness 0,32 mm and 120 kVp showed only a significant difference for the angle to the frontal plane (n: 12, p: 0,016). The third specimen (0,22 mm and 100kVp) showed slightly more significant differences in morphology between the Microscribe and the Slicer data.
Comparing each left and right superior facet for asymmetry, only one significant difference was found (Facet distance to the sagittal plane), for all other measurements the average difference approximated 0 mm but with a large range in Standard Deviations.
When redistributing the data in maximum and minimum values regardless of the side, a lot more significant left-right differences were found. Which indicates that asymmetry occurs frequently, but in this study no preference for one side or the other was demonstrated.

Figure 1: (a) Macerated bone, (b) 3D digitalized model, both with the list of landmarks added.

CONCLUSIONS

Taking in consideration that the number of slices and the quality could influence the results, as well as the stability of the bone embedded reference frame, CT 3D-modeling by manual segmentation might be used for morphological research of the cervical facet joints. These 3D-models could also be used for a reliable and accurate visualization of the vertebrae during biomechanical movements of the cervical spine. This research provides a good protocol for measuring the asymmetry of the cervical spine using 3D-models. We propose to use a slice thickness between 0,3mm and 0,5mm in the sagittal view and a kVp between 100 and 120 for manually segmenting the cervical spine and rendering usable and reliable 3D-models of the cervical spine, including the articular surfaces.

INTRODUCTION

Cervical Spine Intervertebral discs diseases have received more and more attention in recent years. Currently, there are two common surgical options for treating this disease, fusion surgery and non-fusion surgery. Although, fusion surgery can restore the height of discs and relieve pain from patient. However, this method will limit the motion of the implanted levels and cause a compensation of motion in adjacent levels. This result will speed up the degeneration of adjacent levels. In recent years, there have been many studies on artificial cervical disc replacement surgery, because it has an active joint surface which will provide range of motion in the operated level, but there exists wearing problems in the joint surface. The effect of combing fusion and non-fusion surgery in the cervical spine has not been investigated. In the current study, we conducted a biomechanical study of three different surgical methods on the cervical spine based on finite elements (FE) analysis.

METHODS

An intact C2-T1 spine FE models was created from the cervical spine CT images of a male subject from the Visible Human Project(National Library of Medicine, USA). Then three models with interbody fusion cages(Wiltrom Co., Taiwan) and/or artificial discs(Mobi-C, Zimmer Biomet, USA) were created. The implants are implanted into the discs between C4-C5 and C5-C6 to simulate non-fusion (with both mobi-C discs in C4-C5 and C5-C6), fusion(with both fusion cages in C4-C5 and C5-C6) and hybrid(with fusion cage in C4-C5 and mobi-C in C5-C6) surgeries. The material properties used for the FE models were adopted from previous literatures [1,2]. The four models were analyzed under 50 N axial load and 1 N-m pure moment loading in flexion, extension, lateral bending, axial rotation, respectively. By using finite element analysis software (Abaqus, Simulia, USA), we are able to investigate the range-of-motion (ROM) patterns of each motion segments, as well as the compression stress in the nucleus, the von Mises stress distributions on the implant and the facet joint.

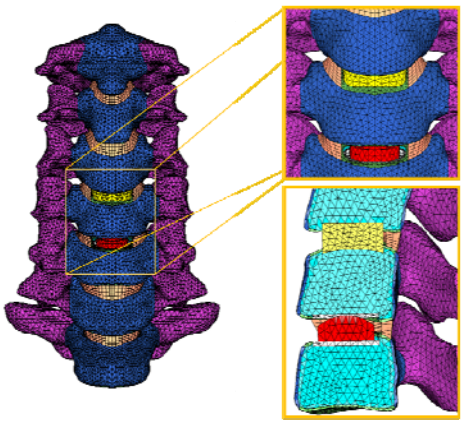

Figure 1: Finite element model of the C1-T1 cervical spine with hybrid surgery(fusion cage in C4-C5, mobi-C in C5-C6).

RESULTS AND DISCUSSION

The results showed that when bi-level interbody fusion cages were implanted into the discs under the four types of loading, the ROM's of the operated levels are the lowest. Moreover, the compensation effects in the adjacent levels become more significant. Due to the compensation effects, it leads to the increase of the stress in the nucleus and higher stress in the facet joints of adjacent levels. As compared to the non-fusion and hybrid models, the stresses in the implants of the fusion model are the highest. When a single fusion cage and an artificial disc were implanted, lower adjacent level motion was found. As for the stress in the nucleus and the facet joint stress stay closer to the intact model. Because the artificial disc is designed with movable joint surfaces, it is able to reduce the maximum stress in the implant. We could conclude that when bi-level artificial discs were implanted under the loadings of flexion, lateral bending, and axial rotation, the ROMs in the operated levels are closer to that of intact model. However, under the extension loading, the range of motion is much higher, it might cause the loading in the facet joint to increase and the stress in the adjacent nucleus and facet joint to be reduced. This results showed the alleviation of degeneration in the adjacent discs when bi-level non-fusion or hybrid fusion and non-fusion surgeries were performed.

CONCLUSIONS

According to the simulation results, bi-level non-fusion surgery possesses better biomechanical performance on the treatment of cervical spine degeneration disease. However, there are still concerns such as the increase of the facet joint load at the operated level that might speed up the facet joint degeneration. Therefore, the hybrid surgery with cage and artificial disc has the benefit of closer stress values in the adjacent level nucleus and facet joint load as compared to those of the intact spine. It might be an alternative choice besides bi-level fusion and bi-level non-fusion surgeries.

P146 - PREDICTION OF THE PARASPINAL MUSCLE ACTIVITY AND THORACOLUMBAR FASCIAL TENSION IN ACCORDANCE WITH THE MECHANICAL RESPONSE IN THE INTERVERTEBRAL DISC

INTRODUCTION

Spinal stability is controlled by two inter-related systems: the spinal column including ligaments and the muscular control system. Instability results when single or multiple components fail or when there is a malfunction in either of the two systems. The spinal column has a structural function and a transducer function; the former provides stiffness to the spine and the latter, in the spinal components, provides the information needed to characterize the spine posture, vertebral motion, and spinal loads. This information can be acquired through the innumerable mechanoreceptors present in the ligament, facet capsules, and disc annulus fibrosus. Paraspinal muscles could activate to execute the task while taking into account the information given by the stress sensors. This notion forms the basis for a hypothesis that there is a sensor driven control mechanism in the musculoskeletal system of the spine and the paraspinal muscles would be activated in such a way as to maintain spine stability [1]. In this study, we calculated the paraspinal muscle activity during erect standing and forward flexed postures based on this hypothesis.

METHODS

Newly developed musculoskeletal model was used for this analysis. The model consisted of a validated finite element lumbar spinal column model, trunk and pelvis modelled as a rigid body, and 114 of muscle fascicles [2]. In addition to the muscle fascicles, effect of abdominal muscle and abdominal pressure was replaced with tensioning of thoracolumbar fascia. Finite element method combined with the optimization method was used to obtain the response in the spine and muscle activity. The muscle forces and fascial tension were the independent unknowns in the optimization steps, which were calculated by minimizing the cost function. The standard deviation of the hydrostatic pressure in the ground matrix of the outermost layer of annulus fibrosus in each disc was chosen for the cost function because intervertebral discs contain the mechanoreceptors in the outer two to three lamellae of annulus fibrosus [3]. The trunk movement while maintaining the prescribed posture was chosen as the constraint. The analyses were conducted in the erect standing and isometric 60º flexed posture with 400 N of upper body weight.

RESULTS AND DISCUSSION

The activity of each muscle group maintained the posture while reducing the pressure and stress difference in the disc. The muscle activities (% of MVC) of iliocostalis lumborum, longissimus thoracis, and multifidus were 12.7%, 13.0%, and 12.1% in erect standing posture and 9.2%, 21.4%, and 31.6% in 60º flexed posture, respectively. (Figure 1) The iliocostalis lumborum, longissimus thoracis, and multifidus show the similar % of MVC to resist the flexion moment generated by the trunk weight in the erect posture. The flexed motion markedly increased the activities of the longissimus thoracis, and multifidus, while the muscle activities of rectus abdominis decreased to 6% from 10% in the erect standing posture. Noticeable change was calculated in the tension of the fascia and ligaments. The total fascial tension of 9.55 N and 91.92 N was calculated in each side during the erect standing and 60º flexed posture, respectively. The ligamentous tension attached to the posterior element was markedly increased (e.g. 0 N of supraspinous ligament force at L3-L4 level in the erect standing posture increased to 22.9 N in the 60º flexed posture). The calculated nucleus pressure at the L4-L5 level in the erect standing posture was 0.55 MPa, which was very closed to the 0.5 MPa value measured in-vivo [4]. The pressure increased to 0.98 MPa in the 60º flexed posture.

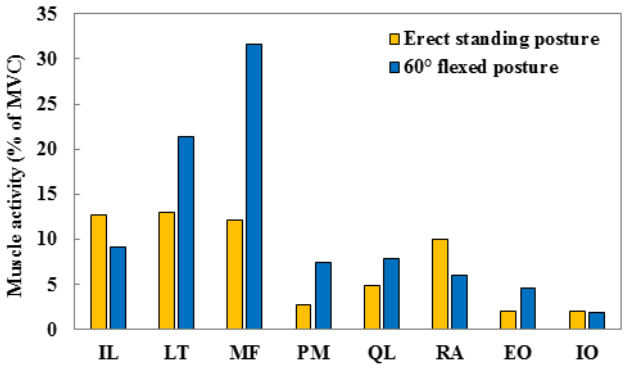

Figure 1: Muscle activities in each muscle group. It was normalized with respect to the maximum voluntary contraction. (IL: iliocostalis lumborum, LT: longissimus thoracis, MF: multifidus, PM: psoas major, QL: quadratus lumborum, RA: rectus abdominis, EO: external oblique, IO: internal oblique)

CONCLUSIONS

This study confirmed the changes of muscle activity and thoracolumbar fascial tension for spinal stability during the flexed posture. This analysis will lead to a better understanding how spinal stability is maintained under different trunk posture.

P147 - MULTI-SEGMENT KINEMATIC MODEL TO ASSESS THREE-DIMENSIONAL MOVEMENT OF THE SPINE AND PELVIS DURING TWO VARIANTS OF ONE-LEG STANDING

[1,2] **S. De Mits,** [1] M. Dolphens, [1] T. Palmans, [3] R. Needham, [3] N. Chockalingam, [1] L. Danneels & [1] T. Willems

INTRODUCTION

A three-dimensional (3D) cluster spine model has been shown to provide clinically relevant kinematic data of spine motions during gait [1]. The current pilot study is aimed at investigating the usability of this model for other clinically relevant movements, such as one-leg standing.

METHODS

After necessary ethical approval, nine healthy subjects, (6 men, 3 female, 22±2.0 years, 177±7.4 cm, 69±8.7 kg) were recruited to participate in the study. The marker configuration was in accordance with Needham et al.[1].
Subjects were instructed to complete 2 variants of a one-leg standing task. In both tasks they stood relaxed on both feet and were either instructed to flex the knee (90°) without hip extension (backward lifting) or to flex both hip and knee to 90° (forward lifting), starting with the right leg and followed by the left leg. The rhythm was verbally guided by the investigators.
Data were collected with an 8 camera opto-electronic system (Oqus, Qualisys, Göteborg, Sweden) at 100 HZ and processed in Visual3D (C-Motion Inc., Germantown, MD, USA) using a low-pass Butterworth filter with a cut-off frequency of 6 Hz. Motion from the upper (T3) versus lower thoracic spine (T8), from lower thoracic versus lumbar spine (L3) and between the lumbar spine and the pelvis was analyzed for 3 valid trials per subject.

RESULTS AND DISCUSSION

Figure 1 shows the mean spine kinematics for the 3 planes when performing both tasks. In the sagittal plane the main differences are seen in the lumbar spine versus the pelvis, while at the higher regions, the spine is quite stable only showing minor differences. In the frontal plane the upper thoracic region shows hardly motion, where the lower thoracic and the lumbar regions bend to the opposite side of the lifted leg. This is more pronounced during forward lifting. Rotational movements are seen in all three regions. The direction of rotation for forward leg lifting is opposed to the one during backward lifting.
To our knowledge this is the first study to document the spine kinematics of different regions during clinical tasks, e.g. two variants of one-leg standing.
Future research should aim at testing more subjects, other clinically relevant movements and comparing healthy subjects with patient populations.

CONCLUSIONS

The 3D cluster spine model seems to be a useful tool to document the spine kinematics during clinically relevant tasks such one-leg standing. This will aid effective clinical management.

P148 - TOO MUCH WORK: REVISITING ULTRASOUND-BASED ESTIMATES OF ACHILLES TENDON ENERGY STORAGE AND RETURN

Jason R. Franz[1] and Karl E. Zelik[2]

INTRODUCTION

Ultrasound imaging is increasingly used with motion and force data to quantify tendon dynamics and to understand the functional role of tendons during human and other animal movement. Frequently, tendon dynamics are estimated indirectly from measures of muscle kinematics (by subtracting muscle length from muscle-tendon unit length), but there is mounting evidence that this approach, which we term the *Indirect* method, yields implausible tendon work loops (tendon force vs. elongation) [e.g., 1-2]. Since tendons are passive, viscoelastic structures, they should exhibit negative work loops (i.e., net negative work over a loading-unloading cycle). However, prior studies using Indirect estimates of tendon kinematics report large positive work loops, estimating that tendons return 100-400% more energy than they store [e.g., 1-2]. More direct ultrasound methods have emerged that estimate tendon elongation by tracking either the muscle-tendon junction (termed the *Direct MTJ* method) or localized tendon tissue stretch (termed the *Direct Tendon* method) [3]. However, it is unclear if these Direct estimates yield more plausible tendon work loops. Here, we estimated tendon work loops and hysteresis using these two Direct tendon kinematics estimates during human walking compared to previously reported values based on Indirect kinematics estimates.

METHODS

We reanalyzed human walking data from our prior work (N=8, mean ± standard deviation, age: 23.9 ± 4.6 years) [3]. Subjects completed two 2-minute walking trials at three walking speeds (0.75, 1.00, and 1.25 m/s) - one trial for each of two probe locations. We collected human motion and force data using standard gait analysis procedures. Simultaneously, we collected raw radiofrequency (RF) data from longitudinal cross-sections through the right plantarflexor MTU using a 10-MHz, 38-mm linear array transducer (L14-5W/38, Ultrasonix, Richmond, BC) secured using an orthotic. For the Direct MTJ estimate, we recorded (128 frames/s) through a 3 cm depth from a probe centered on the distal lateral gastrocnemius (LG) MTJ, from which we estimated local MTJ displacements. For the Direct Tendon estimate, we recorded (155 frames/s) through a 2 cm depth from a probe on the distal free Achilles tendon. Custom 2D speckle-tracking estimated longitudinal free Achilles tendon tissue displacements [3]. Achilles tendon elongations were then derived by co-registering local LG MTJ (Direct MTJ) and Achilles free tendon (Direct Tendon) displacements with the calcaneus marker position. Finally, we estimated Achilles tendon force as the net ankle moment divided by subject-specific measures of the Achilles tendon moment arm to create stance phase tendon work loops (tendon force vs. elongation). We integrated tendon work loops to calculate: (i) net stance phase work (J) and (ii) hysteresis (%), defined as one minus the positive work (energy returned during tendon unloading) divided by negative work (energy stored during loading). Tendon hysteresis from Direct MTJ and Direct Tendon methods were compared to Indirect values from literature [e.g., 1-2]

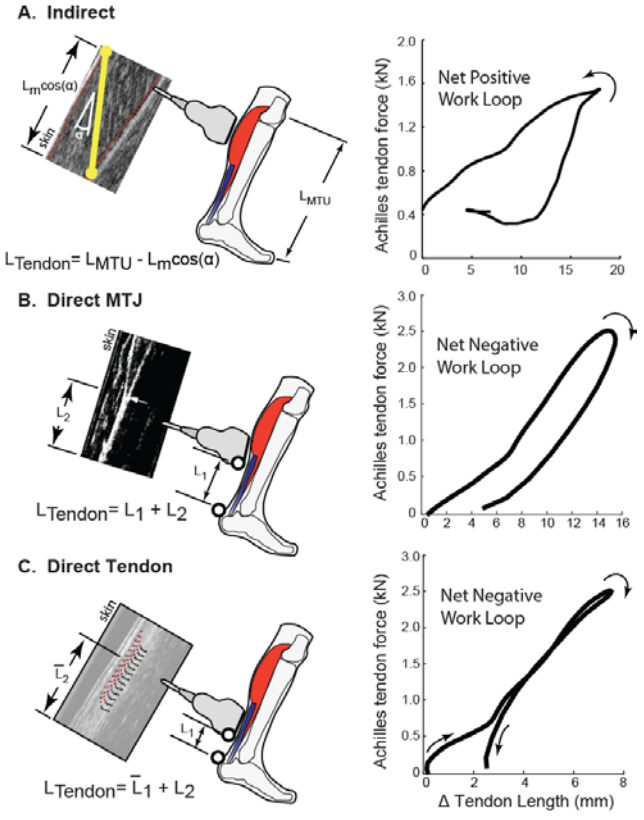

Figure 1. Tendon kinematic measurements and group-average tendon work loops during walking.

RESULTS AND DISCUSSION

Based on digitized data from literature, Achilles tendon hysteresis during walking derived indirectly from soleus and gastrocnemius fascicle kinematics elicited values of approximately -130% and -200%, respectively, indicating considerable but physiologically implausible positive work performed by the tendon (Fig. 1A) [1]. In contrast to Indirect estimates, we found that both Direct methods yielded, on average, negative tendon work loops and thus positive tendon hysteresis values during the stance phase of walking. Direct MTJ tendon hysteresis (net work) averaged 49.7% (-8.9 J), 37.9% (-8.2 J), and 9.2% (-5.1 J) for walking at 0.75, 1.00, and 1.25 m/s, respectively (Fig. 1B). Direct Tendon estimates averaged 32.9% (-3.4 J), 11.0% (-2.0 J), and 2.1% (-1.2 J), respectively (Fig. 1C).

CONCLUSIONS

As we advance our scientific understanding of movement biomechanics, it is important to continue advancing and validating our experimental methods. Compared to Indirect tendon estimates, Direct estimates may be preferable for understanding tendon dynamics such as energy storage and return, especially during dynamic activities such as walking.

P149 - A PRIMATE MODEL FOR THE STUDY OF PARASPINAL MUSCLE WEAKNESS USING BOTULINUM TOXIN ON DISC DEGENERATION

[1] **Sang Kuy Han**, [2]Youngjeon Lee, [2]Jung-Joo Hong, [2]Hyeon-Gu Yeo, [2]Jincheol Seo, [2]Chang-Yeop Jeon, [2]Kang-Jin Jeong, [2]Yeung Bae Jin, [2]Philyong Kang, [2]Sangil Lee, [3]Young Eun Kim, [1]Keyoung Jin Chun, [2]Kyu-Tae Chang, [2]Sang-Rae Lee

INTRODUCTION

The spine is a complex anatomic structure and provides mobility and strength. The health of the spine depends on the integrity and proper function of structural components. Since the paraspinal muscles and spine are mutually dependent in a functional manner, it has been generally accepted that paraspinal muscle dysfunction including muscle weakness is related to the spinal degeneration such as intervertebral disc (IVD) failure [1-2]. Our previous study of paraspinal muscle weakness using the lapine model suggested that muscle weakness can lead to degeneration of the lumbar spine manifesting itself in decreases in disc height and degeneration of spinal alignment [3]. However, the quadripedal lapine model is not a suitable model of upright stance and two legged locomotion. Therefore, the purpose of this study was to investigate the effects of paraspinal muscle weakness induced by the botulinum toxin type-A on the degeneration of the lumbar spine in a primate model.

METHODS

One young cynomolgus monkey (Macaca fascicularis, aged 9 years, at 3.37 kg body weight) was used for in this study. All procedures were approved by the KRIBB Institutional Animal Care and Use Committee (Approval No. KRIBB-AEC-15031). Botox was injected into the paraspinal muscles, i.e., erector spinae and multifidus muscles, at 6 different sites from the level of the spinous process of L3 to L5 vertebra (about 60 µl per site) in both left and right sides for a total of 2U/kg. Botox injections were conducted biweekly up to 19 weeks after the first botox injection for a total of 10 injections in order to maintain paraspinal muscle atrophy. MRIs were performed for measurement of muscle cross-sectional areas and evaluate intervertebral disc integrity right before the first botox injection and then every two weeks up to 21 weeks post initial injection (3T Achieva scanner, Philips Medical System, Best, Netherlands)). For MRI data acquisition, the monkey was anesthetized with 2% isoflurane in 99.9% oxygen (2 L/min) and immobilized in a supine position in a custom-made bed holder.

RESULTS AND DISCUSSION

Botox injections produced significant paraspinal muscle atrophy. The cross-sectional areas of the paraspinal muscles at L2-L3, L3-L4 and L4-L5 decreased by 7 %, 20 % and 11 % at 15 weeks post the initial Botox injection, respectively. Grey muscle area increased within the muscle, which indicates non-contractile elements, such as fat or connective tissue. The lumbar spinal discs appeared normal throughout the entire 21 week experimental period. Disc thickness at L2-L3, L3-L4 and L4-L5 increased by 2 %, 1 %and 1 % at 15 weeks post initial Botox injection, respectively.

Locomotion activity was more static post compared to pre-Botox injections. The duration of sit increased from 21 % to a maximum of 97% at 9 weeks post initial Botox injection, and stance times decreased from 9% to a minimum of 1% in week 11 post initial Botox injection. Furthermore, pace time decreased from 66 % to a 143 minimum of 1% in week 9 post Botox injection, and hang time increased from 4% to a maximum of 70% in week 20 (Figure. 1).

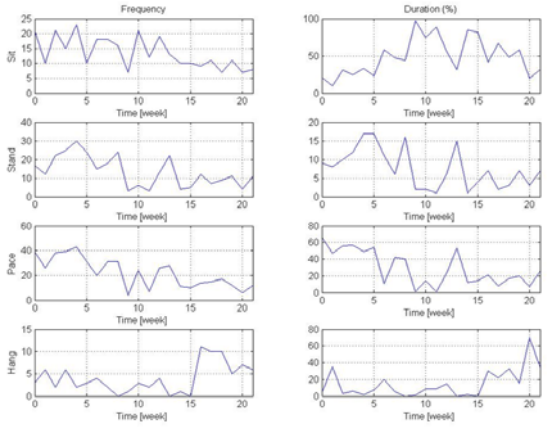

Figure 1: Behaviour pattern before and after botulinum toxin injection.

We did not observe disc degeneration in this study which might have been related to the lower dosage of Botox (2U/kg in this study vs. 4U/kg in the rabbit study), the animal model, the difference in mechanical loading of a four legged vs. two legged animal, and many other factors. The trunk muscles in primates, like in humans, contribute significantly to the stability of the spinal column [4]. Therefore, the effect of the back side paraspinal muscle weakness, which is induced by botox injection on IVD degeneration, in quadrupedal animals may be different from that of upright animals.

CONCLUSIONS

This study demonstrated the feasibility of a primate model as an alternative approach to understand spinal mechanics and adaptation of the upright spine. The findings of this study revealed that paraspinal muscle atrophy affects locomotion activity of a primate and may lead to a reduced level of mechanical stimulation of the IVDs.

P150 - MORPHOFUNCTIONAL ANALYSIS OF THE HUMAN FOOT USING THREE DIMENSIONAL FINITE ELEMENT MODEL

[1] **Kohta Ito**, [1]Ryo Suzuki, [2]Koh Hosoda, [3]Takeo Nagura, [3]Hiroyuki Seki, [3]Masateru Kitashiro, [3]Nobuaki Imanishi, [3]Sadakazu Aiso, [3]Masahiro Jinzaki and [1]Naomichi Ogihara

INTRODUCTION

Human walking is a mechanical phenomenon to move the center of body mass forward by appropriately generating the ground reaction forces onto the foot. Therefore it is anticipated that mechanical characteristics of the human foot embedded in its anatomical design may greatly contribute to realize appropriate mechanical interactions between the body and the ground to facilitate generation of robust bipedal walking. Detailed understanding of the behavior and internal loading of the human foot is crucial to elucidate such structural adaptations, but it has not been fully investigated due to the difficulty of measurement.

In the present study, we developed a three-dimensional (3D), anatomically detailed finite element (FE) model of the human foot and quasi-statically simulated mechanical interactions of the foot with the ground during walking gait to investigate structural adaptations of the anatomical structure of the human foot bipedal locomotion.

METHODS

Figure 1A shows a 3D human foot FE model. Each bone and the whole foot surfaces were extracted from computer tomography images. The volume enclosed by each surface was meshed with tetrahedral elements and its outside was meshed with shell elements. The contact between the articular surfaces was considered. The encapsulated soft tissue and the skin were defined as a hyperelastic Ogden material. The material parameter of the soft tissue is identified by a spherical indentation [1]. Ligaments and plantar fascia were represented by tension-only spring elements. The foot-ground contact was modeled using rigid contact surfaces.

To evaluate the predictive ability of our proposed FE model, the model was validated by comparing with a cadaver experiment of the human foot under axial loading. Paired radiographic images of five cadaver feet (68-90 years) under different axial loading conditions were obtained using the biplanar fluoroscopic system (Shimadzu, Kyoto, Japan). We determined the motion of the tarsal and metatarsal bones by a model-based registration technique [2]. We also reproduced the same loading condition using proposed FE model then calculated and compared the change in the relative positions and orientations of each of the bones due to axial loading. We confirmed that predicted bone movements are roughly consistent with that of the cadaver experiment.

To investigate the human foot bone kinematics and internal loading during walking gait, the mechanical interaction of the foot with the ground at the 20, 50 and 80% of stance phase were simulated by explicit finite element analysis such as to reproduce the measured kinematics of walking gait. Figure 1B shows a behavior of the foot FE model during the simulated walking gait. The predicted ground reaction forces, tension of the plantar fascia and foot bone motions were reasonably in good agreement with corresponding measured data.

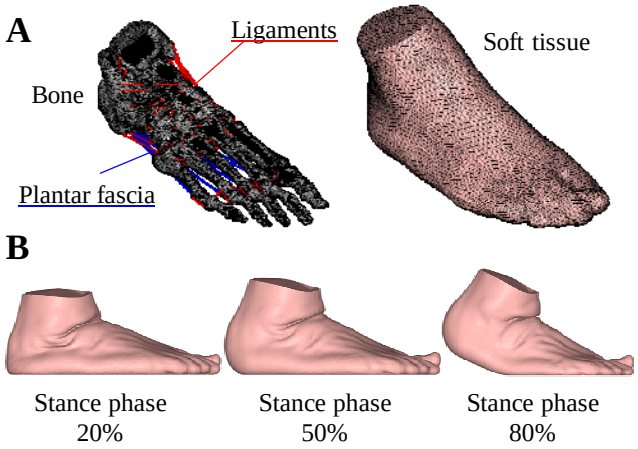

Figure 1: (A) 3D human foot FE model, (B) the behavior of the human foot FE model during simulated walking gait.

RESULTS AND DISCUSSION

The present study demonstrated that the plantar aponeurosis stored larger elastic energy as the foot approaches to the late stance phase due to the so-called windlass mechanism [3]. Furthermore, the stiffness of the foot increased in the late stance phase to act as a stiff lever because of the relative inversion of the calcaneus and cuboid. The present study also demonstrated that the talus is adducted with respect to the calcaneus as the calcaneus is everted due to loading, causing anterolateral movement of metatarsals and generation of medial rotation moment around the vertical axis of the foot during walking.

CONCLUSIONS

We reported quasi-statistic human gait analysis based on a 3D anatomical human foot FE model. The present simulation framework may be effective to identify morphofunctional relationships between the foot architecture and human bipedal walking.

P151 - EVALUATION OF KNEE JOINT EXTENSION IN ELDERLY PERSON WITH THE USE OF WAVELET ANALYSIS FOR SEMG AND MMG SIGNALS

[1] **Kenichi Kaneko**, [2]Hitoshi Makabe, [3]Kazuyuki Mito and [3]Kazuyoshi Sakamoto
[1]Fuji University

INTRODUCTION

Japan has the highest proportion of elderly citizens in the world. It is called a "super-aging society". Falls and bone fracture are some of the main causes for requiring care. The ability of knee joint extension play a key role in preventing falls. The purpose of this study was to evaluate the function of knee joint extension on elderly persons from the viewpoint of frequency components of surface electromyography (SEMG) and mechanomyogram (MMG) [1] activities for lower limb muscles. The frequency of EMG and MMG activities were evaluated by using of Wavelet Transform (WT). The WT of SEMG is informative in understanding the characteristics of muscle activity, which include the motor unit (MU) firing frequency, number of recruited MUs, and fiber type. In this study, we compared the SEMG with the MMG about frequency components to estimate the function of knee joint extension in elderly persons.

METHODS

The study was carried out on five healthy elderly subjects and three healthy young subjects. All participants provided written informed consent before participating in the study as approved by the University Institutional Review Board. Subjects sat on a lower body exercise machine (ISOFORCE GT-330, OG Wellness, Japan). SEMG and MMG signals were recorded simultaneously form m. quadriceps femoris during the knee joint extension with 50% of the maximal voluntary contraction (MVC). The low cut filter was set at 5.3 Hz for SEMG, 1 Hz for MMG, respectively. The both SEMG and MMG signals were stored on a personal computer through an A/D converter (PowerLab, ADInstruments, New Zealand) with a sampling frequency of 1000 Hz.

As a wavelet analysis, a discrete wavelet transform (DWT) was applied to the SEMG and MMG data. In this study, the wavelet transform coefficients were estimated by using the Daubechies-4 wavelet algorism. SEMG and MMG data of 1024 points in relation to the knee joint extension were used for the analysis of frequency components. The data were decomposed into six separate scales for the SEMG, seven separate scales for the MMG. Finally, to examine the mean power of each frequency band, E*j* was calculated and compared in each frequency band [2].

RESULTS AND DISCUSSION

The mean power of wavelet decomposition (E*j*) made comparison between the elderly group and the young group in the figure1. Firstly, for SEMG, the highest value of E*j* was at j = -2 (125-250Hz) in the elderly group, at j = -3 (62.5-125Hz) in the young group. The analysis of variance (ANOVA) revealed a significant effect of Frequency-band ($F_{5,36}$ = 2.675, p<0.05), however there was no significant effect of Aging ($F_{1,36}$ = 1.756, *n.s.*). Secondly, for MMG, there were main effects of Frequency-band ($F_{6,42}$ = 5.920, p<0.01) and of Aging ($F_{1,42}$ = 18.627, p<0.01), respectively. These effects were limited by the significant interaction ($F_{6,42}$ = 5.657, p<0.01). The E*j* of higher frequency bands (31.25-250 Hz) were smaller for the elderly group than for the young group with the significant difference of 5% (Figure 1).

Orizio indicated that the MMG frequency content seemed to be strongly influenced by the global motor units' firing rate, contrary to EMG [1]. The results of this study agreed with Orizio' opinion.

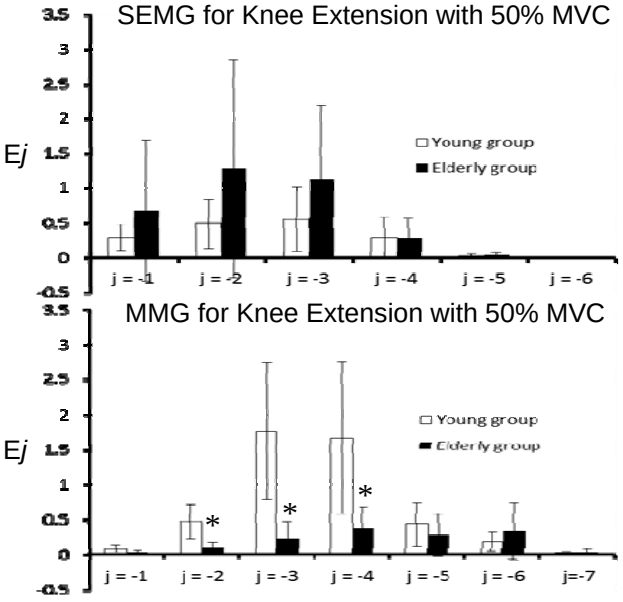

Figure 1: Comparison of mean power E*j* between elderly group and young group during the knee joint extension. The j = -1, -2, -3, -4, -5, -6, and -7 indicate the frequency band as 250-500Hz, 125-250Hz, 62.5-125Hz, 31.25-62.5Hz, 15.625-31.25Hz, 7.8125-15.625Hz, and 3.906-7.8125Hz respectively. The marks * show a significantly different level of 5%.

CONCLUSIONS

The characteristics of knee joint extension in elderly persons were estimated by the DWT of SEMG and MMG signals within m. quadriceps femoris. The values of E*j* of MMG were a useful index to evaluate the function of knee joint extension in elderly persons.

P152 - INTERRELATIONSHIPS AMONG DEFORMABILITY, ELASTICITY, AND SIZE OF THE UPPER- AND LOWER-LIMB MUSCLES IN THE ELDERLY

INTRODUCTION

Skeletal muscles demonstrate strikingly large inter-individual variability with respect to size and architecture [1]. As typical biological soft tissues, muscles possess elasticity that is demonstrated in their deformability especially at rest [2]. Not much is known however, about the interrelationships between the size, deformability and elasticity of skeletal muscles. These properties are important especially in the elderly population where age-related muscle loss (sarcopenia) is prevalent, and noncontractile tissues within a muscle increase [3]. We tested the hypothesis that such age-related characteristics of muscles might be associated with their deformability upon mechanical loading, in a cross-sectional study design.

METHODS

One hundred and sixty-nine healthy men and women (82 men [66.2 ± 10.7yr] and 87 women [62.9 ± 11.2 yr]) participated. Cross-sectional images of the triceps brachii (TB) and rectus femoris (RF) were taken with B-mode ultrasonography (SSD900, Aloka, Japan) at the site distal 60% of the upper arm and at the midthigh respectively, while a participant stood at rest. An ultrasonic probe was applied onto the skin in the transverse direction to TB and RF in 2 conditions, 1) without any compressive force (N) and 2) with pushing force in the direction from the mediolateral center of TB and RF to that of the femur, up to when no more muscle deformation occurred (P). The muscle thickness was measured as the distance from the deep fascia to the humerus for TB and the antero-posterior distance between fascial borders for RF. For RF, the width (mediolateral distance between fascial borders) was also measured. The ratio of the two conditions (P/N) was calculated both for thickness and width as an index of deformation. In addition, among the subjects, shear-wave elastogram (Aixplorer 2, SuperSonic Imagine, France) was further taken from the same site for TB and RF (n=29 men and 53 women), and shear modulus was determined for the muscle belly in the longitudinal direction. Pearson product-moment correlations and unpaired t-tests (between genders) were performed with the level of statistical significance at p<0.05.

RESULTS AND DISCUSSION

As for TB, muscle thickness was larger in men (28 ± 5 mm) than in women (23 ± 4 mm). In each gender, there was a significant correlation (r=-0.31 and -0.46 in men and women respectively) between muscle thickness and the deformation ratio (P/N), i.e., thicker muscles deformed more (Figure 1). Shear-modulus of TB (3.6 ± 1.1 and 4.0 ± 1.4 kPa in men and women, no significant difference) was negatively correlated with muscle thickness (r=-0.27, men+women). As for RF, muscle thickness (43 ± 7 mm [males] > 37 ± 7 mm [females]) was not correlated with P/N although the shear modulus (5.0 ± 1.8 kPa [men] < 6.3 ± 2.7 kPa [women]) was negatively correlated with muscle thickness in both genders (r=-0.39 [men] and 0.63 [women]). For RF, muscle width was negatively correlated with its P/N (r=-0.66 [men] and 0.55 [women]), i.e., wider muscles widened less.

The results suggest that muscle deformability at rest is related to the size of TB but not of RF, while elasticity is related to the size for both muscles. In RF, its deformation might have been limited in the direction of the circumference of the thigh, possibly due to the well-developed deep fascia covering the whole quadriceps.

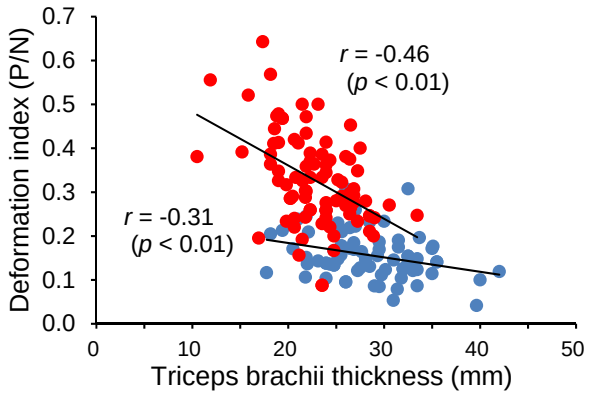

Figure 1: The relationship between muscle thickness and deformation index (ratio of thickness with pressure/without, P/N)

CONCLUSIONS

The triceps brachii and rectus femoris deform under pressure, the amount of which is related to their size in the former but not in the latter. In both muscles, shear modulii are related to their sizes. Rectus femoris deformability is related to its mediolateral width.

P153 - RELATING THE BIOMECHANICS AND METABOLOMICS OF A FOCAL CARTILAGE DEFECT POPULATION

INTRODUCTION

Focal cartilage defects (FCDs) of the smooth hyaline cartilage in human knee joints often progress to osteoarthritis (OA), due to altered joint biomechanics and changes in the biological environment of the joint in response to damage. There is a deficit of research characterizing the relationship between biomechanical and biological mechanisms of FCDs in affected knees, which needs to be addressed to further understand progression of FCDs and optimize surgical intervention. Quantifying knee synovial fluid (SF) metabolites by nuclear magnetic resonance (NMR) spectroscopy is an emerging area of research, and has shown promise. In this study, knee gait biomechanics and SF metabolic profiles from the same knees are measured and related in a small cohort of symptomatic FCD subjects, in an effort to elucidate the interplay between knee function and metabolic changes in the microenvironment.

METHODS

5 subjects with confirmed ICRS grade III+ FCDs of the femoral condyle (due for microfracture surgery) were consented, and subjected to 3D gait analysis and synovial fluid analysis within a 5 day period. Bare foot, level gait analysis was carried out using a 9 infra-red camera (Qualisys, Sweden), 4 force-plate (Bertec, US) motion capture set-up. Discrete gait parameters found in previous literature that showed the largest variance in 'moderate OA' gait relative to 'normal' gait [1] were calculated using Visual 3D (C-motion Inc) software, which included: knee abd/adduction moment (KAM) mid-stance value and second peak value, peak flexion/extension (KFM/KEM) moments, knee adduction angular impulse (KAAI) and the peak knee flexion angle (KFA). Synovial fluid (SF) was extracted from the affected knee at time of surgery. 1H NMR spectroscopy was performed on acellular SF samples (Bruker DPX 500 spectrometer, 298K) and intensities of spectra signals were measured (TopSpin 2.1, Bruker Corp) and normalised to a reference peak (TSP). Nine metabolites shown to change in progressive OA in previous literature [2] were chosen for comparative analysis: Glutamate, Glutamine, Creatine, Glucose, Alanine, Lactate, Phenylalanine, Proline and 3-hydroxybutyrate (identified using the BMR Data Bank). Pearson's correlations with p-values were computed (SPSS) to assess the relationship between biomechanical parameters of gait and SF metabolite concentrations.

RESULTS AND DISCUSSION

It was interesting to find that declining knee function was strongly associated with higher glucose levels, consistent with another human OA vs healthy SF metabolomics study conducted by Mickiewicz et al. [1]. This suggests there may be a mechanism yielding increased glucose levels in subjects with increasing OA-like knee function. However, this contradicts another report [3] who suggest that increased hypoxic, acidotic conditions in OA joints would lead to a decline in SF glucose. Higher glucose, higher lactate, and lower 3-hydroxybutyrate levels altogether in response to declining baseline knee function indicates there may be dysregulation in energy utilization involved with progression of cartilage damage, which could be associated with higher energy demands of the defected tissue [1].

Relationship	R^2	Sig.
KAM peak 2 & Glucose	0.94	<0.006
KAAI & Glucose	0.94	<0.006
Peak KFA & Glucose	-0.77	<0.049
KAAI & Glutamate	0.81	<0.037
Peak FKA & Glutamate	-0.77	<0.049
Mid-stance KAM & Lactate	0.79	<0.043
Peak KFM & 3-hydroxybutyrate	0.92	<0.027

Table 1 – Summary of significant relationships between knee function gait parameters and SF metabolite conc.'s

Glutamate is a mechano-responsive metabolite and neurotransmitter that has been found to increase up to 67-fold in the osteoarthritic knee in comparison to healthy knees, and is associated with bone resorption, inflammatory processes and pain [4]. Our subjects experiencing higher KAAIs presented higher glutamate concentrations, suggesting that increased cumulative loading of the knee resultant of declining knee function could be subsequently increasing mechano-sensitive upregulation of glutamate. We propose that decreased peak-KFA in relation to higher glutamate could be resultant from compensatory gait mechanisms in response to pain, to avoid over-loading the defective area at full knee flexion, in which could be heightened by the increased glutamate levels in the joint.

CONCLUSIONS

Knee functional and metabolic factors play a vital role in disease development and progression. We find that declining knee function may be associated with higher musculoskeletal tissue energy demands. We also find increased levels of Glutamate, a pain inducing mechano-responsive neurotransmitter levels are increased with cumulative knee loading, suggesting OA-like gait may directly influence joint pain.

P154 - THE EFFECT OF CHAIR'S LEVEL ON KNEE EXTENSORS FORCES DURING HORIZONTAL LEG PRESS MOTION

INTRODUCTION

Horizontal leg press (LP) motion is a multi-joint and closed kinetic chain exercise that biomechanically resembles to jumping and running. This movement is used to enhance performance in sport activities and for rehabilitation purposes especially for patients with patellar chondromalacia or after anterior cruciate ligament (ACL) surgery [1, 2]. This exercise has potential to be performed in various techniques including alterations in the distance between the plate and chair.

People with musculoskeletal disorders of the lower limb are advised to perform LP motion with specific protocols that lead to some basic questions; how different is the muscles forces in the variety of foot placement in up, down and center on the plate [3]. Furthermore, how effect is depicted about the muscles forces in the distance's change between feet and the plate. Comprehension of these changes from biomechanical point of view may suggest new training programs. Our hypothesis was the more close distance between feet and plate, the more forces generates by the knee extensors muscles.

METHODS

Previously-collected kinematic data was used for this study [3]. Briefly, kinematic data was acquired from 6 healthy subjects (Age: 25.5 ± 3.9, Height: 173.5 ± 10.1, Weight: 65.83 ± 7.96) with no previous pain in lower extremity by attaching reflective markers on anatomical reference. Before starting the trials, maximum permissible weight (MPW) of the extensors of the knee was obtained by each subject. Then, each participant performed the trials with 30% and 70% of MVC. The study was based on changing the chair's level; level *I* indicated the further distance than level *VI*. A recursive Newton-Euler algorithm was implemented on a 3-segments mechanism with 3 degrees of freedom to obtain the differential equations of motion. A phenomenological Hill-based musculotendon model was employed. To calculate the forces of 40 lower limbs muscles through optimization, the computed muscle control algorithm was used with considering the sum of squared muscle activation as cost function. All programs were written in MATLAB software.

RESULTS AND DISCUSSION

The effect of chair's level changes on the forces exerted by quadriceps muscles was of the interest. A paired t-test was utilized to investigate any significant difference during performing the LP motion from chair's level *I* and *VI*. To implement this test, the average of muscles forces through time was computed using numerical integration. In each MPW, all forces increased from level *I* to *VI* except vastus intermedius. Furthermore, quadriceps forces showed a great jump from performing 30% to 70% MPW. (Table 1) However, an increase found with increasing the load on the plate and decreasing the initial distance between the chair and the plate, no significant differences illustrated (p <0.05). At the equal effort (.e.g. 70% MPW), moment arm of external force is the influential factor and may be the reason of increasing muscles forces from level *I* to *VI*.

Table 1- The mean of muscles forces (%BW)

Muscle	External forces (30% MPW)		External forces (70% MPW)	
	Level *I*	Level *VI*	Level *I*	Level *VI*
Rectus femoris	43.03	70.49	67	88.34
Vastus intermedius	205.3	181.7	326.4	302.3
Vastus lateralis	204.1	235.6	349.5	406.2
Vastus medialis	71.53	98.7	133.4	175.3

CONCLUSION

The result confirmed the hypothesis that closer interval from feet to plate (level *VI* than level *I*) led to great forces of knee extensors. The observation suggests level *VI* for performing LP motion if strengthening the knee extensors is desired.

P155 - LUMBAR MOMENT MESUREMENT OF DRIVING POSTURE USING SEPARATED SEAT

[1]Dong Hyun Kim, [1]Seo Hyun Kim, [1]Young Jin Jung, [1]Dong Hyun Hwang, [1]Ye Eun Song, [1]Seong Guk Kim, [1]Bokku Kang, [1]Han A Lee, [2]Young Keun Cho, [2]Hyung Joo Kim and [1]**Han Sung Kim**

INTRODUCTION

Recent trends in auto industry has led the higher vehicle seat comfort, which is one of the most important factors in selecting a car. In addition, customers' demand for reliable vehicle seat has increased although low-priced vehicles have been constantly released.

Previous studies have suggested that driving posture is a key factor determining drivers' comfort.[1] Also, a number of researchers have reported that an inappropriate driving posture of the individual could cause biomechanical load to spinal column, especially to L5/S1.[2] Similarly, extensive research has shown that an ideal driver`s posture is possible to reduce the load to L5/S using lumbar supporter.[3] However, no equipment has been found that measured lumbar moment in real time as driving posture changes. Therefore, the aim of this study is to find the proper lumbar moment for the ideal driving posture through analyzing the changes in lumbar moment as driving posture changes.

METHODS

All 25 participants have never suffered from musculoskeletal disorders. All participants should have acquired driver's licenses at least 2 years before the experiment. The participants were between the ages of 27 and 46. The weight of them be in the range of 73.5 ± 11.5 kg and the height be in the range of 1.74 ± 0.11 m.

The separated seat which is divided into two parts is consisted of seat pan and seat back. Each seat pan and seat back was connected with two force plates. Reaction forces were collected with each force plates (Advanced Mechanical Technologies, Inc., Newton, MA, USA) and these data were captured at 1000 Hz (Figure 1).

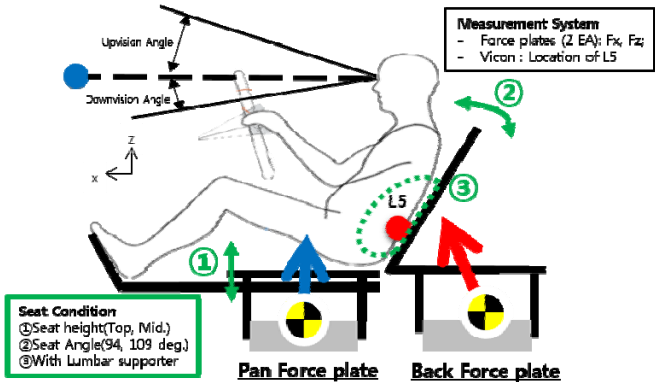

Figure 1: Mimetic diagram of separated Car Seat and experiment process.

Lumbar moments were calculated from moment arm between lumbar center and reaction force of seat pan and seat back. (①)

$$M_{Lumbar} = Ar_{Pan} \cdot F_{Pan} \quad \cdots\cdots ①$$

All participants took a seat on the seat which was adjusted for seat back angle (94/109 degrees from the ground) and height (Top/ Mid.) with lumbar support (presence/absence) in order to analyze various driving posture. All participants were requested to maintain their hands to grip at 2 and 10 o`clock of steering wheel and stare at the painted point on the wall in order to simulate the actual driving situation.

The lumbar moments for each seat condition were performed unpaired t-test to acquire statistical significance ($P < 0.05$).

RESULTS AND DISCUSSION

Each car seat adjustment alternating driving position were collected to measure lumbar moments. (Table 1).

Seat condition	Average(N·m)	SD	P-value
109deg. Top	30.14	2.719	0.0433
94deg. Top	37.64	2.381	
109deg. Top, with LS	25.76	2.445	0.0005
94deg. Top, with LS	39.95	2.945	
109deg. Mid.	25.44	2.826	0.0159
94deg. Mid.	35.40	2.809	
109deg. Mid., with LS	29.91	2.933	0.0227
94deg. Mid., with LS	39.81	3.016	

Table 1: The average of collected lumbar moments, standard deviation and P-value according to the changes in car seat adjustment.

These results indicate that the seat back angle may be the main cause of decreased driver's lumbar moment. However, other car seat adjustment factors, except seat back angle, for lumbar moment does not have any significance (P>0.05). Also, these results are accorded with the result from Hirao, which suggests that driving position is similar to the neutral body posture in the aspect of physical fatigue reduction.

CONCLUSIONS

This study suggests that car drivers should lean their back against seat back in order to decrease lumbar moment. Also, further studies are required to find other factors diminishing lumbar moment although seat back plays a key role.

P156 - TWO-DIMENSIONAL KINEMATIC AND BIOMECHANICAL ANALYSES OF SWIMMING IN PACIFIC WHITE-SIDED DOLPHINS

[1] **Aya Kurita**, [2]Kenji Okutsu and [1]Naomichi Ogihara
[1] Department of Mechanical Engineering, Keio University
[2] Hakkeijima Seaparadise
Corresponding author email: ogihara@mech.keio.ac.jp

INTRODUCTION

After the proposal of "Gray's paradox" that a swimming dolphin experiences drag power larger than its estimated muscle power, mechanics of high-speed swimming in dolphins has received considerable attentions. Therefore, many studies have been conducted to elucidate mechanisms underlying the high-speed swimming in dolphins. However, detailed kinematics and dynamics of dolphin swimming have yet to be fully elucidated.

In the present study, we quantified kinematics of steadily swimming movements in dolphins to estimate propulsive and drag forces based on the hydrodynamic theory of the oscillating wing.

METHODS

A total of 4 adult pacific white-sided dolphins (*Lagenorhynchus obliquidens*) swimming in a large marine pool were filmed sagittally at the Hakkeijima Sea Paradise Aquarium, Yokohama, Japan. A high-speed camera with 512 x 384 pixels was used to record the movements at the frame rate of 240 Hz through an underwater viewing window. Dolphins were trained to swim fast by a trainer's instruction, and to swim slowly by following a trainer walking beside the pool, to obtain variability in swimming speed. Only recorded sequences in which the animals swam straight and steadily were selected for further analysis. A total of seven characteristic points on the dolphin body (Figure 1a) were manually digitized frame-by-frame using digitizing software (Frame DIAS4, DKH, Japan). In addition, the midpoint between the base of dorsal fin and the base of flipper was calculated as the center of body.

Spatiotemporal and kinematic parameters such as swimming velocity, frequency, and time changes in peduncle angle (α) and fluke angle (β) (Figure 1a) were calculated based on the digitized coordinates. A swimming cycle is defined as the time period in which the body angle (φ) reaches to the minimum value to when the angle again reaches to the minimum value. Therefore, the first half of the swimming cycle is upstroke whereas the second half is downstroke.

The propulsive force of swimming dolphin is basically generated by simultaneous vertical and rotational oscillation of the fluke [1]. In the present study, we calculated forces acting to the fluke during dolphin swimming by using the measured kinematic data based on the hydrodynamic theory of an oscillating wing. Specifically, the dolphin was modeled as a two-hinged oscillating wing in the sagittal plane. We calculated the lift force F_L and drag force F_D applied to the fluke due to the measured oscillation of the fluke. The thrust force F_T was estimated as the sum of the horizontal components of F_L and F_D. The cross-sectional shape of the fluke was approximated by a NACA0015 aero foil. The lift and drag coefficients were determined as functions of the angle of attack which can be obtained experimentally.

RESULTS AND DISCUSSION

A total of 14 cycles which dolphins swam faster than 4 m/s were analyzed. The mean (and standard deviation) velocity measured in the present study was 5.7 ± 0.7 m/s. We found that there was a significant correlation ($p < 0.01$) between the velocity and frequency in dolphin swimming.

The time change in the calculated thrust force along with the horizontal components of the lift and drag forces were presented in Figure 1b. We found that the dolphins generate thrust force during both downstroke and upstroke in high-speed swimming, although it was previously reported that the thrust force was generated only during the downstroke when the velocity was slow [2]. Furthermore, we also found that the drag forces applied to the fluke were very small, indicating that the movement of fluke was chosen such as to reduce the drag force. We need to measure drag force acted on body surface in future studies to completely understand the force balance of high-speed swimming dolphins.

P157 - INDEXING THE FUNCTION OF LOWER LIMB MUSCLES DURING STEADY-STATE RUNNING

[1] **Adrian Lai**, [2] Andrew A Biewener and [1] James M Wakeling
[1] Simon Fraser University
[2] Harvard University
Corresponding author email: adrian_lai@sfu.ca

INTRODUCTION

The functional role of muscles is to generate force and energy needed to produce and control movement. Two critical factors that determine a muscle's functional role is muscle-tendon unit (MTU) design and the mechanical demands of a movement task. Previous studies have quantified the mechanical function of muscles to satisfy the mechanical energy demands during dynamic movements in-vivo in animals (e.g. [1]) as well as in humans through inference of joint mechanics (e.g. [2]). In general, more proximal human lower limb muscles (e.g. gluteus medius) consist of long, parallel muscle fibres connected to a short, stiff tendon. This configuration favours the modulation of mechanical energy of the body by utilising muscle fibre shortening, which results in the muscle functioning in a motor-like manner [3]. While more distal muscles (e.g. soleus) consist of short, highly pennated muscle fibres connected to a long, compliant tendon; a configuration that favours force economy and elastic energy savings, which results in the muscle functioning like a spring. However, there has yet to be an approach that characterizes the function of multiple muscles in the human body that takes into account the MTU design and the mechanical demands of the measured movement task.

This study adapts a previous approach that used joint work to characterise joint function during a movement task. We extended the approach to characterize the functional role of muscles using predictions from a musculoskeletal model. We tested the approach by characterizing a subset of proximal and distal lower limb muscles during steady-state running.

METHODS

Ground reaction force and 3D kinematic data were taken from a subject who ran on an instrumented treadmill at a steady-state speed of 4 m s^{-1}. Five complete gait cycles were collected and analysed. The skeleton of the subject was represented by a scaled musculoskeletal model (22 segment, 37 degrees-of-freedom) and was actuated by 80 lower limb MTUs. OpenSim™ was used to compute joint angles and net joint torques. MTU length was calculated at each discrete time-step using the origin and insertion sites of the MTU and the joint orientation. Static optimisation was used to decompose the joint torques into a set of muscle forces. We calculated MTU power as the product of muscle force and instantaneous MTU velocity and MTU work as the integral of MTU power over the entire gait cycle.

We adapted the index-based approach by Qiao and Jindrich to characterize MTU function during steady-state running [2]. This approach uses joint-specific energetics – joint moment, power, positive work and negative work – to characterize joint function during walking into four indices: strut-, spring-, motor-, and damper-like mechanical behaviour. We converted the joint-specific parameters to MTU parameters (i.e. joint moment to muscle force, joint power and work to MTU power and work). The four indices were normalised to sum up to 100% and the largest index was considered the "primary" function of the MTU. In addition, we estimated the contribution of the muscle fibre and tendon components to the overall MTU function by using a ratio of the optimal fibre length (in the line of action of the MTU) to tendon slack length obtained from the musculoskeletal model. For illustrative purposes, we selected four representative single-joint muscles that absorbed and generated substantial mechanical energy during steady-state running and had different muscle-tendon designs: two proximal muscles spanning the hip (gluteus medius and psoas) and two distal muscles spanning the knee (vastus lateralis) and ankle (soleus).

RESULTS AND DISCUSSION

We found that the two proximal muscles, gluteus medius and psoas functioned in a motor-like manner (Fig. 1), consistent with previous observations that muscles spanning the hip modulate positive work during walking [2]. Furthermore, the muscle fibres were the major contributors to the motor-like behaviour, consistent with the MTU designs of the muscles.

The two distal muscles absorbed and generated greater energy than the two proximal muscles and thus met a greater proportion of the mechanical demands of steady-state running (Fig. 1). Both distal muscles functioned in a spring-like manner with the tendon component contributing the majority of spring-like function; again, being consistent with MTU design of the distal muscles, which favour tendon elastic energy storage.

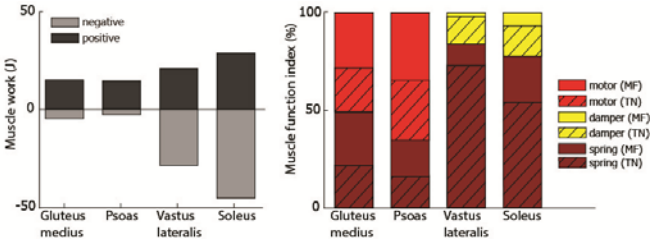

Figure 1: Muscle work and index for the selected lower limb muscles during running. MF and TN represent muscle fibre and tendon, respectively.

CONCLUSIONS

The index-based approach used in this study provides a springboard for future exploration into characterising the function of major lower limb muscles according to their muscle-tendon design and the mechanical demands of the movement task. This information can assist in a range of applications such as examining the shifting roles of muscle groups across motor tasks.

P158 - EFFECTS OF AGE ON FLUCTUATION OF SUSTAINED SUB-MAXIMAL GRIP CONTRACTION

[1]**Ke Li**, [2]Na Wei, [3]Shouwei Yue
[1]Department of Biomedical Engineering, School of Control Science and Engineering, Shandong University
[2]Department of Geriatrics, Qilu Hospital, Shandong University
[3]Department of Physical Medicine and Rehabilitation, Qilu Hospital, Shandong University
Corresponding author email: kli@sdu.edu.cn

INTRODUCTION

Sustained sub-maximal grip contraction (SSGC) is a grip-strength measurement that requires subjects maintaining a stable grip at a certain percentage of maximal grip strength (MGS), with protocols lasting from a few seconds to a few minutes [1].

SSGC provides valuable information for fatigue resistance, tremor, and risk of falling [2, 3].Age is an independent factor that affects the muscle tolerance and power generation in evolution of neuromuscular function [4, 5].Although it has been found the MGS can be influenced by geriatric frailty and adolescents' growth, little is known whether the age affects the fluctuation of SSGC.

This study aims to investigate the effects of age on the force fluctuation during SSGC. We hypothesized that the ageing subjects have lower structural variability in their grip forces during SSGC than the subjects in middle age. The adolescents have lower force structural variability by SSGC than the middle-aged subjects.

METHODS

Grip force was measured using a MIE Grip Analyzer (MIE Medical Research Ltd, Leeds, UK) with resolution 1 N/0.1 kg and accuracy of >1% of full scale output (1000 N). Each subject was tested only for their dominant hand.

The MGS values were evaluated as the maximal value of three maximal voluntary contractions lasting about three seconds, with one minute rest between trials. To evaluate the SSGC, subjects were required to maintain, as stable as possible, an isometric contraction at 70% of their MGS for 30 s within an acceptable region (±3% MGS) displayed on the screen.

A one-way ANOVA was used to test for differences of DFA exponents across the age groups ($p<0.05$).

RESULTS AND DISCUSSION

Group 7 had significant higher DFA values than the Group 2, Group 4 and Group 5, but the Group 7 had no significant differences between Group 1, Group 3, and Group 6.
The average DFA values of all the groups were less than 1, which indicated persistent long-range correlations (0.5<DFA exponent <1) for the force fluctuation.

The DFA exponents of SSGC have a curvilinear relationship to age. The higher DFA of the elderly supports the previous findings that the behavioral complexity decreased with ageing [6]. The grip force by SSGC of all the groups exhibited fluctuations with persistent long-range correlations (0.5<mean α <1).

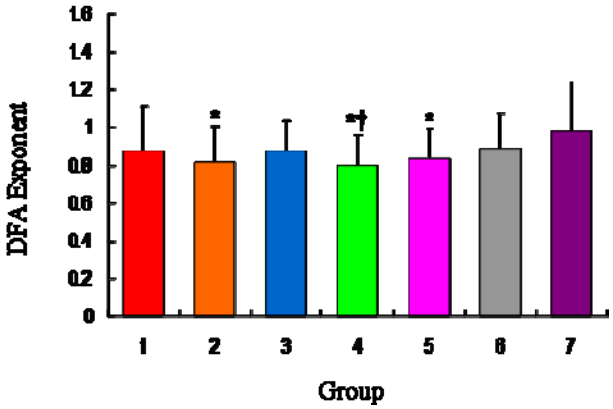

Figure 1. Mean and standard deviations of DFA exponent for the seven age groups. * Significant differences from Group 7. † Significant difference from Group 6.

DISCUSSION

The decreased structural variability in the elderly appears with a reduction in muscular strength, fiber type distribution changes, or a reduction in potential movement/neural control speed [7]. Lower force structural variability of adolescents are probably related to their immature neural system, different muscle fiber types, body mass and skin fold thicknesses [8].

CONCLUSIONS

This study demonstrated that the structure of grip force by SSGC varies with age. Grip force reaches to the highest structural variability at the middle age. DFA provides novel metrics in analysis of force signals during SSGC.

P159 - CHARACTERISTICS OF ANKLE STRATEGY FOR RESPONDING TO DYNAMIC TILTING PERTURBATION

[1] **Hansol Seo**, [1] Leila Alizadeh Saravi [2] Hohyun Jung and [1] Dohyung Lim
[1]Department of Mechanical engineering, Sejong University

INTRODUCTION

Maintaining balance is a critical factor to influence the functional performance during daily life. Balance is maintained by the sensorimotor control systems. In motor output, ankle strategy is the most first activated parameter to maintain balance [1]. However, few studies evaluate the characteristics of ankle strategy to maintain balance caused by tilting perturbation. The aim of the study was to identify the characteristics of the ankle strategy in response to the dynamic tilting perturbations.

METHODS

Following Institutional Review Board approval (IRB No. SJU-2015-002), seven healthy males (aged 25.5±1.7 years, average height of 173.9±6.4cm, average body mass of 71.3±6.5kg) participated. The customized tilting perturbations simulator generated 8 tilting perturbations around 4 axes (Coronal, 45° Clockwise rotated coronal, Sagittal, 45° Clockwise rotated sagittal axes). At this time, the ankle joint motions were measured using a 3D motion capture system (VICON Motion System Ltd., UK). Peak value of the foot pressure and COP trajectory were measured by using a pressure sensor (Novel GmbH, Germany), and 4 main muscles' activations related to the ankle joint motions were measured by using a wireless EMG system (DELSYS, USA).

RESULTS AND DISCUSSION

The overall ranges of motion (ROMs) were 8.1±3.5°/-6.3±2.8° in dorsi/plantar flexion, 4.4±2.9°/-4.7±4.0° in inversion/eversion and 0.4±0.2°/-0.4±0.1° in abduction/adduction in response to 8 dynamic tiling perturbations ($p<0.05$). ROMs of the dorsi/plantar flexion and the inversion/eversion were the highest for the perturbation around the 45° clockwise rotated coronal axis. The overall peak value of the foot pressure was from 76.3KPa to 113.8KPa for 8 dynamic tiling perturbations. The COP trajectories were generally located in the midfoot and small changed (Figure 1). The similar pattern has been observed in overall muscle activation for each perturbation ($p>0,05$). The activity of soleus (SOL) was, however, generally highest in the dynamic tilting perturbations, among the all muscles (Figure 2).

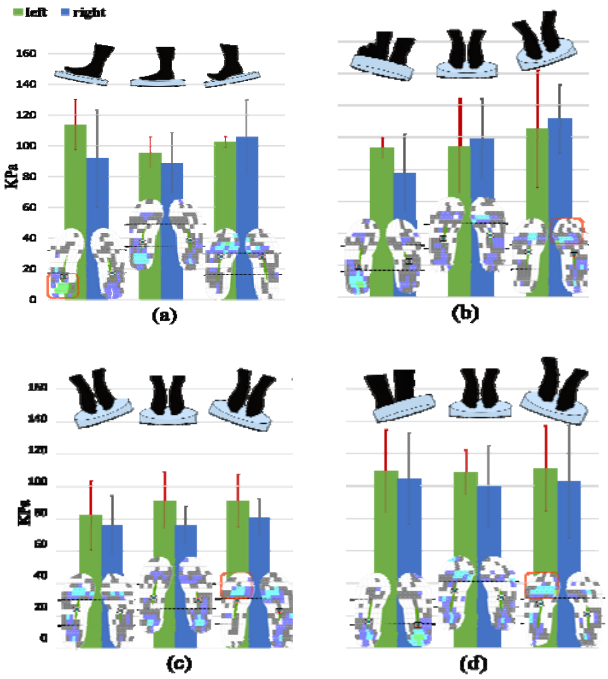

Figure 1: Peak foot pressure and COP trajectory caused by the tilting perturbations around (a) coronal, (b) 45° clockwise rotated sagittal, (c) sagittal and (d) 45° clockwise rotated coronal axes.

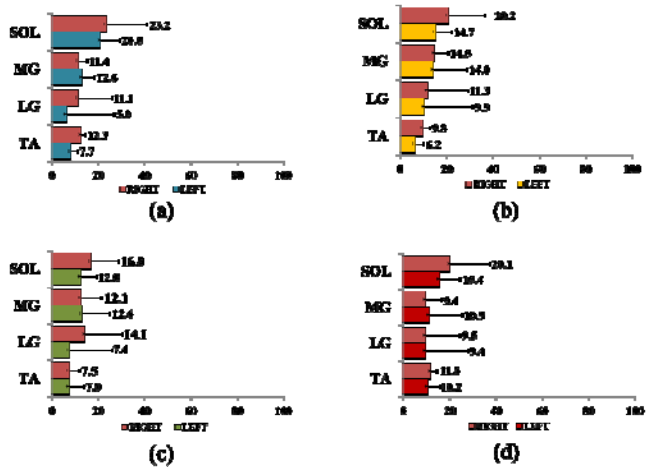

Figure 2: Muscle activity responses to the tilting perturbations around (a) coronal, (b) 45° clockwise rotated sagittal, (c) sagittal and (d) 45° clockwise rotated coronal axes.

CONCLUSIONS

This study may be, valuable to utilize the ankle strategy to prevent imbalance due to dynamic tilting perturbations.

P160 - COMPARISON OF HIP MUSCULOSKELETAL CHARACTERISTICS IN DANCERS WITH ANKLE-FOOT INJURY

[1] Chi Tzu Liu, [2]Yi Fen Shih
[1,2]National Yang-Ming University
Corresponding author email: yfshih@ym.edu.tw

INTRODUCTION

Ballet movement requires a great movement range and control of the hip joint. It has been shown that hip joint control bears an important role in balance strategy, and is associated with lower extremity injuries. Researchers showed hip muscles was highly associated with ankle-foot injuries, they found the muscle onset timing of gluteus medius muscle and gluteus maximus muscle delayed and the muscle activity duration decreased in patients with chronic ankle instability. Past studies mentioned that subjects with insufficient hip muscle strength had a higher risk of ankle sprain during landing. However, few studies have assessed the differences in hip musculoskeletal characteristics between the injured and non-injured legs in dancers with unilateral ankle-foot injury. So the aim of this study was to compare hip musculoskeletal characteristics between the affected side and non-affected side in young dancers with unilateral ankle-foot injury. We hypothesized that there were significant differences in hip musculoskeletal characteristics between the affected side and the non-affected side in young dancers with unilateral ankle-foot injury.

METHODS

We recruited 8 young dancers with unilateral ankle-foot injury. All participants received the measurement of muscle activation, lower extremities muscle length and lower extremities muscle strength. The muscle activity of the lower extremity major muscles were assessed using an electromyography (EMG) system (TrignoTM Wireless, DELSYS., USA) during ballet jumping movement which called "Grand Jeté". The EMG data were collected during landing phase of Grand Jeté. The muscles assessed included: fibularis longus, soleus, tibialis anterior, quadriceps, hamstring, and gluteus muscles. An independent t-test was used to compare the differences between affected side and non-affected side. A statistical significance was set at $P < 0.05$.

RESULTS AND DISCUSSION

Eight participants aged 17-22 years, 5 female and 3 male, with unilateral ankle-foot injury in dominant side were recruited for the study. The results showed that there were no significance in muscle strength and muscle length between affected side and non-affected side. Also, there was no significant difference in muscle activity (Table 1). However, the muscle activity of hamstring showed a trend to be higher in non-affected side than affected side (P=0.058) during landing phase of Grand Jeté.

Muscle activation (% of MVC)	Non-affected side	Affected side	P value
Gluteal maximus	17.573±6.033	13.910±4.829	0.201
Gluteal medius	18.012±5.395	20.814±3.993	0.257
Hamstring	20.821±4.886	16.071±4.313	0.058
Quadriceps	18.449±6.496	15.471±5.741	0.348
Tibialis anterior	19.268±2.686	21.254±9.819	0.614
Peroneal longus	18.168±8.801	18.777±7.581	0.884
Soleus	16.228±4.313	16.694±4.958	0.844

Table 1: Muscle activity of lower extremity muscles during landing phase of Grand Jeté.

CONCLUSIONS

There were no significant difference in muscle strength, muscle length and muscle activity between affected side and non-affected side. A trend toward higher muscle activation of hamstring in non-affected side was identified. However, this study was limited by the sample size; nonetheless, the results produced were interesting. In the future, we will recruit more ankle-foot injured dancers to participate this study.

ACKNOWLEDGEMENTS

We would like to thank professor Yunyu Wang, Dean of School of Dance of National Taipei University of the Arts, and lecturer Chiou-O Chiang for their assistance. We would also like to thank their dancers for their participation.

P161 - EFFECTS OF PELVIS FORWARD TILTING ON LATERALLY ASYMMETRIC THORACIC SHAPE AND TRUNK ROTATION

[1] **Tetsuya Mamizu**, [2,3]Tetsuro Hirayama, [3]Yuuki Homma, [2]Kazuya Tame, [2]Tomoko Kawasaki, [3]Ayumi Mohara, [4]Yukisato Ishida, [4]Fujiyasu Kakizaki

INTRODUCTION

Thorax and pelvis interact in chain movements through lumbosacral and sacroiliac joints. Pelvis forward tilting elicits trunk rotation and changes in thoracic shape. Previously, we showed that the pelvis forward tilting produced the unidirectional rotation of lower thoracic vertebra and predominantly hemi-activation of lumber erector spinae muscles [1]. This specific pattern of movements is dependent on the asymmetry of thoracic shape [2], and possesses the few variation in movements, In the present experiments we aim to investigate the typical pattern of thoracic shape change and trunk movement induced by the pelvis forward tilting in healthy subjects, thereby providing the standard kinematic chain between pelvis and trunk movements applicable for instable trunk movements of patients.

METHODS

Subjects were healthy adult males 14 people (26.3 ± 2.9 yo). The posture was sitting square with raising hands. The task was the tilting lumber region forwards by 10° against the pelvis and monitored pelvis and trunk movements using a 3-D motion analysis (VICON-MX, VICON Inc.). Trunk segment was extracted with 4 markers placed on the midpoint of the 3rd sternocostal joint (center of upper thorax), the xiphoid process (center of lower thorax) and respectively projected levels of spinous processes on the back. The trunk was divided into 4 parts, left and right halves of upper and lower thoraces. For each part, additional 3 markers with even space were placed on the front of the upper thorax or on the back of the lower thorax at the same horizontal level of each center of thorax. The sum of three distances from the center of thorax to 3 markers was regarded as the anteroposterior diameter of the thorax. The pelvis segment was made with 4 markers on both sides of anterior and posterior superior iliac spines. Then, horizontal angles of the trunk segment against the pelvis segment at the initial position and the forwardly tilted (10°) position of the pelvis were measured. The task was repeated three times and average values were regarded as the representative value. Statistical analysis was performed using paired *t*-test.

RESULTS AND DISCUSSION

When anteroposterior diameters between left and right halves of thorax were compared at the normally sitting posture, the diameter was bigger in the left side than in the right at the upper thorax ($p<0.05$), and was bigger conversely in the right than in the left at the lower thorax ($p<0.01$) (Fig. 1.).

When the pelvis was tilted forwards, the lateral difference in the anteroposterior diameter was kept nearly constant at the upper thorax, but was significantly reduced at the lower thorax ($p<0.01$). The pelvis forward tilting elicited a rightward rotation of the trunk segment by ~0.4° ($p<0.01$).

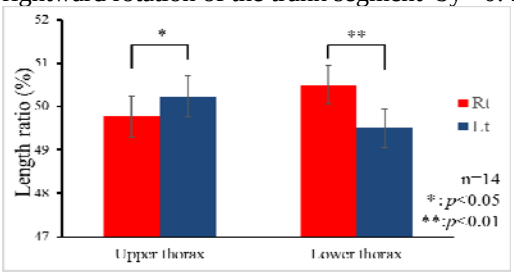

Figure 1: Bilateral anteroposterior diameters of upper and lower thoraces at the normal sitting posture. Ordinate: lateral length (%) of thorax; the sum of left and right half lengths of upper or lower thorax was regarded as 100% of area.

These results suggest that the bilateral difference in the anteroposterior diameters of thorax at the normal sitting posture is dependent on the rotation direction of ribs: the right half of upper rib cage may relatively rotate forwards compared with the left half, and the right half of lower rib cage may rotate backwards. The asymmetry in the thorax may elicit the relatively unilateral activation in muscles, leading to the respective unidirectional rotation of upper and lower thoraces. For this movement, dominancy in the activation of left low back muscles associated with the trunk extension may produce the rightward rotation of the trunk. Since left low back muscles insert at left lower ribs, the activation of these muscles rotates lower ribs backwards, thus leading to the reduction in the asymmetry of the lower thorax.

CONCLUSIONS

The present experiments show the association between pelvis forward tilting and trunk-segmental rib cage motion, specifically focused on the asymmetry in the shape of upper and lower thoraces. The measured anteroposterior distance of thoracic segments revealed the opposing directions in the bilaterally asymmetric pattern between upper and lower thoraces. Pelvis forward tilting elicited the rightward rotation of the trunk and selectively reduced the asymmetry in the lower thorax, presumably due to the relatively predominant activation in the left low back muscles. These results may be regarded as a standard for understanding instable movements of trunk in patients, and for quantitative assessments of trunk instability at clinical settings.

P162 - EFFECT OF LATERAL WEDGED INSOLES ON THE MEDIAL KNEE COMPRESSIVE FORCE IN MEDIAL KNEE OSTEOARTHRITIS

[1] **Marco Mannisi**, [1]Andrea Dell'Isola, [2]Michael Skipper Andersen and [1]James Woodburn

Corresponding author email: marco.mannisi@gcu.ac.uk

INTRODUCTION

Medial compartment Knee Osteoarthritis (KOA) is commonly treated with Lateral Wedge Insoles (LWI). The aim of LWI is to unload the medial compartment during the gait. However, the effectiveness of LWI is still unclear. Targeting this treatment to patients with biomechanical phenotype characterised by varus malalignment and medial disease may improve treatment efficacy [1]. Moreover, subject-specific musculoskeletal modelling allows the Medial Compressive Force (MCF) to be accurately estimated [2]. The MCF may provide new insights on the mechanism of action of LWI to alter knee joint loads.

Therefore, the purpose of this study was to investigate the mechanical effect of LWI on knee MCF in participants with medial KOA and varus malalignment.

METHODS

Five volunteers with clinical or X-Ray evidence of medial KOA and varus malalignment (age 64.2 ± 6.14 years, BMI 31.8 ± 1.8 $Kg \cdot m^{-2}$) and four healthy subjects (age 56.5 ± 1.5 years, BMI 25.3 ± 2 $Kg \cdot m^{-2}$) were recruited through National Health Service – Greater Glasgow and Clyde.
Three-dimensional kinematic data were collected using a 14 Qualysis Oqus camera system sampling at 120Hz. Ground reaction forces were measured with a Kistler platform.
Participants' feet were 3D surface scanned and custom LWI with 0°, 5° and 10° degrees of lateral wedge were designed in CAD and manufactured using 3D printing.
Each participant performed four gait conditions at preferred speed: a) with standardised sports training shoes only (SO), b) with SO and 3D printed insoles at 0°, 5° and 10° of lateral wedge.
The most symptomatic leg was included in the analysis for KOA patients, the dominant leg (defined as the leg used to kick a football) was selected for the control group.

A subject-specific musculoskeletal model (MS), adapted from Lund et al. [2], was developed in the AnyBody Modeling System (AMS, AnyBody Technology A/S). The model was used to estimate the MCF using an inverse dynamic analysis. The MCF for the four gait tasks was corrected for body weight and presented as %BW (Figure 1). The mechanical effect of the LWI, during the stance phase, was estimated by the relative difference of impulse and peaks values of MCF of the three LWI conditions with respect to the SO condition. Given the sample size and subject-specific nature of the study, formal statistics testing was not employed.

RESULTS AND DISCUSSION

As shown in Figure 1, the KOA group had a higher load during the single support phase in all the conditions compared to the controls. These findings suggest the inability of KOA subjects to unload the medial compartment during the midstance phase.

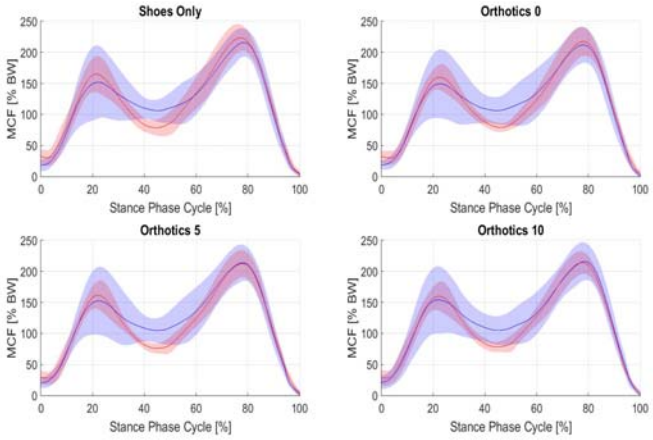

Figure 1: Knee Medial Compressive Force (MCF) for control (red) and medial KOA with varus malalignment (blue). Shaded areas indicates ± 1 standard deviation.

The KOA group showed an average limited reduction of the impulse of the MCF for the three LWI conditions compared to SO. The MCF impulse had a reduction by -2% (range +5%, -12%), -3% (range +4%, -11%) and -0.3% (range +5%, -6%) for the 0°, 5° and 10° conditions, respectively.
The peaks value did not change significantly.
For the control group, in comparison to SO condition, the MCF impulse had a variation by +2% (range +7%, -0.2%), +0.2% (range +5%, -3%) and -1% (range +3%, -1%) for the 0°, 5° and 10° conditions, respectively.

CONCLUSIONS

In this present study employing patient-specific MS model, a highly variable LWI response was demonstrated in patients with biomechanical phenotype, characterized by varus malalignment and medial disease. The MCF was reduced and increased in participants across the range of LWIs investigated and no overall dose-response trend, according to the degree of lateral wedging, was observed. Further analysis based on an extended dataset and more precise participant classification based on MRI confirmation of medial knee compartment disease is warranted.

P163 - RELATIONSHIP BETWEEN STEADINESS OF SUBMAXIMAL CONTRACTION FORCE AND AGE IN FOREARM AND LOWER-LIMB MUSCLES

[1] **Kazuyuki Mito**, [1]Aya Shirai, [2]Satoko Soga and [2]Noriyasu Ota
[1]The University of Electro-Communications
[2]Kao Corporation
Corresponding author email: mito@inf.uec.ac.jp

INTRODUCTION

The steadiness of the submaximal contraction force which is an index of evaluation for a neuro-muscular function decreases with age [1, 2], but difference in steadiness among muscles with different innervation ratio have not been studied. In this study, the relationship between steadiness of submaximal contraction force and age was examined in both the grip force and the knee extension force.

METHODS

The subjects were 117 healthy volunteers 22-79 years of age (60 females and 57 males), and they provided a written informed consent to participate in this study after a detailed explanation including the purpose and procedures of the experiment.

The subjects were seated in a chair and performed isometric contraction for two tasks of grip and knee extension. The contraction levels were 20% and 40% of maximum muscular contraction (MVC) in the two tasks. Force signals were detected by a stain gauge force transducer, and its signal was indicated in real-time on a screen of a digital indicator. Subjects controlled the force level displayed on the screen by visual feedback for about 6 seconds. The force signal was stored in a PC through an A/D converter with a sampling frequency of 2,000 Hz.

The coefficient of variance (CV) was calculated from the force signal for about 5 seconds. The initial position of the analysis was set to be 80% of the target value.

Comparisons of groups for age and contraction level were performed by two-way ANOVA.

RESULTS AND DISCUSSION

In both tasks of grip and knee extension, the maximum muscular contraction (MVC) significantly decreased with age. Coefficient of variance (CV) values of force in grip and knee extension are shown in Figure 1. In the grip task (Figure 1 (a)), CV values increased with age ($p<0.01$). Particularly, CV values of 60s and 70s were significantly higher than those of 20s, 30s, 40s and 50s. However, no significant difference of CV was recognized in contraction level. In the knee extension task (Figure 1 (b)), CV values did not change with age ($p=0.51$) although significant difference of those were recognized between contraction levels. It is known that the innervation ratio of finger and arm muscles is smaller than trunk and foot muscles. The steadiness of the submaximal contraction force might be closely related to innervation ratio.

CONCLUSIONS

In this study, we examined the relationship between steadiness of the submaximal contraction force and age in the grip and knee extension muscles. The coefficient of variance (CV) of the submaximal contraction force was significantly changed with age in the grip task that uses muscles of small innervation ratio. The steadiness of the submaximal contraction force might be closely related to innervation ratio.

P164 - GAIT KINEMATICS OF INDIAN CLASSICAL BHARATNATYAM DANCERS

[1] Rajani Mullerpatan, [1]Juhi Bharnuke
[1]MGM Center of Human Movement Science, MGM Institute of Health Sciences
Corresponding author email: rajani.kanade@gmail.com

INTRODUCTION

Bharatanatyam is an ancient Indian classical dance form which originated in temples of South India. It is the most widely performed Indian dance form across India and globe, encompassing all traditional aspects of Indian classical dancei.e.*mudras*(hand gestures),*abhinaya*(facial expressions to depict emotions) and *padams*(narrative movements). Bharatanatyam movements are characterized by *adavus*(intricate footwork) performed in *sausthav*(ears and waist in one line, shoulder and head in one line, hips in and body leaning forward), flexed knee postures like *ayatamandalam*(semi-sitting) and *swasthasthana*(full sitting position with heels raised) with co-ordinated hand-eye movements to depict *bhava*(emotions).

Kinematic demands placed by Bharatnatyam dance on spine and lower extremities due to sustained postures warrant investigation to understand whether reflections of dance training are observed in common weight-bearing activity of daily living such as gait. Therefore present study aimed to explore pelvis and lower extremity kinematics during gait with an objective of exploring cause for commonly reported low back and knee joint pain in Bharatnatyam dancers.

METHODS

Following ethical approval, signed, informed consent was sought from 28 healthy female volunteers aged 18-25 yr. Fourteen formally trained active Bharatanatyam dancers performing for an average of 14 years (10-18yr) were matched with 14 non-dancers on age, weight, height. None of the participants were engaged in training for any other physical activity. Females with neuro-musculoskeletal injury (<3 months) were excluded.

Three trials of gait at natural walking speed were captured with 12-camera Vicon system (Oxford Metrics Group, UK) with sampling frequency of 100Hz. Full body plug-in-gait marker model was used with 39 markers at predetermined anatomical positions. Data were processed within Vicon Nexus 2.4. Mid-gait data were used to obtain spatio-temporal variables of gait. Kinematics was studied with joint angles of pelvis, hip, knee and ankle in sagittal, coronal and transverse plane. Spatio-temporal variables and joint angles during gait were compared using Mann-Whitney U test, $p \leq 0.05$. Dancers were instructed to report joint pain using a body chart.

RESULTS AND DISCUSSION

Spatio-temporal variables of dancers and non-dancers were not different ($p \geq 0.05$). Consistent dance training over 14 years reflected in joint angles. Bharatnatyam dancers walked with 26% greater anterior pelvic tilt, approximately thrice greater pelvic obliquity, 15% greater hip flexion, 82% greater hip abduction and approximately twice the knee extension compared to non-dancers. Low back pain was reported by 64% dancers whereas knee pain was reported by 21% dancers. Greater anterior tilt and medio-lateral obliquity of pelvis is likely to cause excessive compressive stress at lumbo-sacral spine resulting in spine pain. Similarly excessive knee hyperextension observed in dancers may increase tibio-femoral joint stress and cause knee pain. It is interesting to note that increased pelvic tilt, pelvic obliquity, hip abduction and knee extension during gait are also reported among ballet dancers (1).

Joint angles	Dancers (n=14) Mean(SD)	Non-dancers (n=14) Mean(SD)	p value
Anterior pelvic tilt	11.15(1.28)	8.82(1.92)	0.00*
Pelvic obliquity	6.46(3.87)	2.58(1.67)	0.00*
Pelvic rotation	13.64(4.06)	10.83(1.75)	0.10
Hip flexion	26.05(4.02)	22.26(3.58)	0.01*
Hip extension	-17.87(5.09)	-20.4(4.75)	0.16
Hip abduction	-8.85(2.78)	-4.84(2.55)	0.00*
Hip adduction	7.94(1.82)	9.30(6.35)	0.28
Hip external rotation	-14.61(6.92)	-21.62(12.94)	0.35
Knee flexion(stance)	25.88(7.43)	27.27(5.42)	0.15
Knee flexion(swing)	56.9698.01)	53.82(6.56)	0.54
Knee extension (stance)	-5.61(3.54)	-2.70(1.51)	0.03*
Knee extension (swing)	-3.60(2.70)	-2.50(2.27)	0.21
Ankle plantarflexion (stance)	13.95(4.02)	14.89(2.48)	0.32
Ankle dorsiflexion (stance)	-10.32(3.88)	-9.79(3.81)	0.70

Table 1: Lower extremity joint angles during gait and typical Bharatnatyam postures

CONCLUSION

Present study is a first report on gait characteristics of Indian classical Bharatnatyam dancers. Kinematic demands placed by typical dance postures due to sustained excessive motion at pelvis, hip and knee were reflected in gait kinematics of dancers. Higher kinematic demands placed by typical Bharatnatyam postures at pelvis and knee explain low back pain and knee pain reported by dancers.

Although such a gait pattern was a result of kinematic demands placed by Bharatnatyam dance, implementation of a specific exercise program targeted towards neutralizing excessive deviations at pelvis and knee may reduce likelihood of low back and knee pain reported by dancers.

P165 - COMPARISON OF MOTOR UNIT FIRING PROPERTIES OF VASTI MUSCLES DURING LOW LEVEL, ISOMETRIC KNEE EXTENSION CONTRACTIONS

[1]Hélio da V Cabral, [1]Leonardo M L de Souza, [1]**Liliam F de Oliveira**, [2]Taian M Vieira
[1]Universidade Federal do Rio de Janeiro
[2]Politecnico di Torino
Corresponding author email: heliocabral@peb.ufrj.br

INTRODUCTION

Motor unit (MU) firing properties, as firing rate and recruitment threshold, have been widely investigated to clarify motor control strategies. The effect of interventions, such as stretching [1] and resistance training [2], on these MU properties are some examples of researches in this field. Furthermore, the MU firing characteristics may assist to better understand the muscle functional roles during voluntary contractions.

The vastus medialis (VM) and vastus lateralis (VL) muscles perform important functions in knee joint. Specifically, evidences suggest that VM distal region would be related to patella alignment whereas VM proximal region and VL to knee extension. Several researches using distinct methodologies attempted to figure out the VM and VL functional relation [3-4]. However, investigations of MUs firing properties of these muscles during a knee extension task is currently unavailable to our understanding. Therefore, here we investigate the mean firing rate of VM proximal and distal regions, and VL motor units during torque-varying, knee extension task.

METHODS

Ten healthy, male subjects (range: 24-32 years; 168-182 cm; 70-85 kg) were seated comfortably on a dynamometer chair, with the knee held flexed at 80 deg. Then, with a visual feedback assistance, they were asked to successfully modulate their knee extension force from 0% to 20% of their maximal voluntary contraction (MVC) in 5 s, hold at 20% MVC for 10 s and then back to 0% MVC in 5 s. Three arrays of eight electrodes were used to acquire electromyograms (EMGs), each aligned parallel to VM proximal, VM distal and VL fibers.

EMGs were decomposed into motor unit action potentials trains [5]. The smoothed firing rate of each motor unit were obtained and from these signals, the mean firing rate were calculated considering the central 5s of constant force phase. Kruskal-wallis and Dunn-Sidak post-hoc tests were performed to compare MU mean firing rate of the three muscle regions.

RESULTS AND DISCUSSION

A total of 56 motor units were analysed for the ten participants: 21 of VM distal region, 17 of VM proximal region an 18 of VL muscle.

Dunn-Sidak post-hoc analysis revealed a significant difference in mean firing rate values between VL and VM regions. As shown in Figure 1, the VL motor units reached lower mean firing rates (interquartile interval: 8.36-12.26 pps) than VM distal motor units (10.28-20.36 pps) and VM proximal motor units (10.32-21.21 pps; Kruskal-wallis test; $P = 0.0133$).

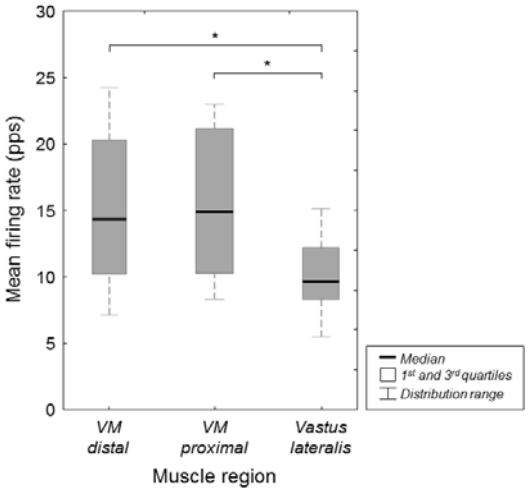

Figure 1: The distribution of mean firing rate values computed for vastus medialis (VM) distal, VM proximal and vastus lateralis motor units. Asterisk denotes statistical significance ($P < 0.05$).

Considering that vastus lateralis muscle has higher capacity in force production due to it greater physiological cross-sectional area in relation to the other quadriceps muscles [6], our finding suggests that nervous system benefits from this VL muscle architecture characteristic to fine tuning of vasti muscles activity. Thus, in low level contractions, VL MUs achieve lower firing rates in comparison to MUs of distinct VM regions, that need higher firing rates to counterbalance VL forces and consequently perform their functions. Moreover, the muscle architecture seems to be a key role in the capability of the nervous system controls distinct muscles and different regions within a muscle.

CONCLUSIONS

Our results suggest that, in low level knee extension contractions, the mean firing rate of VL motor units are lower in relation to VM distal and proximal motor units. This finding contribute to the advance of understanding in how the nervous system regulates the MUs of vasti muscles.

P166 - DOES FATIGUE INFLUENCE MUSCLE SYNERGIES DURING AN ISOMETRIC TASK?

INTRODUCTION

A prevailing theory of movement control is that mechanisms exist to reduce the dimensionality of the control problem, allowing for less demanding control from the CNS. Muscle synergies are fixed patterns of muscle activation with a lower dimensionality than the number of effectors. If individual synergies are linearly combined they can recreate complex motor behavior. This theory has shown to be consistent in natural movements in animal and human models [1].

Fatigue is generally defined as a use-induced decrease in muscle force that will ultimately lead to task failure. Fatigue affects muscle activation and movement performance by changing the relationship between activation and force production in muscles. In response to muscle fatigue, the neuromuscular system adapts by changing performance parameters such as activation levels, motor units' discharge frequency or recruitment [2]. The effect of these changes on the weights and coefficients of muscle synergies has not previously been examined. Study of these effects will contribute to the body of evidence of synergies as the building blocks of human movement. Our aim is to determine if synergies are consistent through time during a fatiguing isometric task of the upper limb.

METHODS

Ten healthy subjects participated. The experiment was divided in two segments, during which the participants remained seated with the same posture. The experimental task consisted of an upper limb isometric contraction exerted at 40% of the shoulder's external rotation maximal force (MVF). To perform the isometric trials the participants held the handle of a robotic arm instrumented with a 6-axis force-torque transducer. A custom virtual reality feedback (VRF) consisting of a user-movable sphere and a fixed target sphere was used to show the real-time 3-D force vector applied to the transducer. The displacement of the movable sphere was proportional to the force exerted at the handle, and the target position had a vector length of 40% MVF.

In the first segment, the participant executed 26 isometric trials in directions evenly distributed within a sphere from the starting position. The goal was to match the VRF targets and maintain the force level for four seconds. During the trials, force and surface EMG signals were recorded continuously from 14 muscles of the shoulder, arm, and forearm. EMG signals were band pass filtered (5 - 400 Hz), demeaned, full-wave rectified, normalized, converted to unit variance, and low-pass filtered (5 Hz) to obtain an envelope. From this segment, muscle synergy weights and their preferred direction tuning were determined. In the second segment, the participants performed isometric contractions at 40% MVF until fatigue, determined by perceived exertion, in the preferred direction of each synergy extracted during the first segment.

Synergies were calculated using non-negative matrix factorization [4]. The synergy extraction algorithm identified only synergies that accounted for 90% of global, and 80% of local variance. EMG data were extracted from five epochs throughout each fatigue trial, at 0-5%, 20-25%, 45-50%, 70-75%, and 95-100% of the total duration. Data in these epochs were resampled to obtain 100 data points, to extract a single synergy from each fatigue trial epoch.

A repeated measures ANOVA was performed to compare the scalar product between the five time epochs of the matched synergies' weights from the fatigue trials.

RESULTS AND DISCUSSION

Four synergies were sufficient to represent the data from the majority of the participants (3.9±0.4). This is in agreement with previous research that reported four synergies as representative for upper limb motor behaviors in a variety of experimental paradigms.

No significant changes were found between the synergy weights extracted from the epochs of the fatigue trials. Subtle changes of synergy weights and variation on the synergy coefficients, were the main mechanism of adaptation of the neuromuscular system to fatigue (Figure 1). These synergy changes might correspond to previously described mechanisms such as muscle alternations [4].

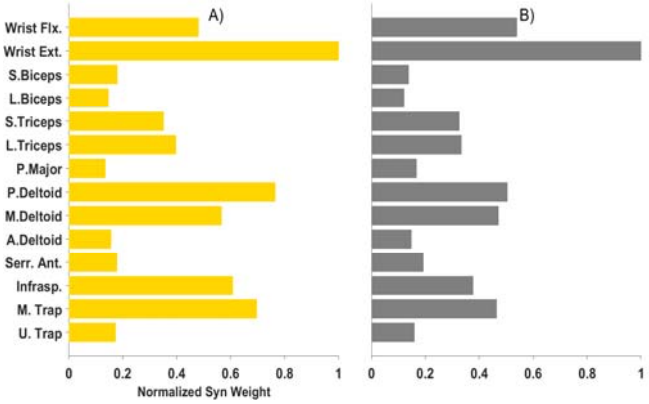

Figure 1: Individual synergy weights from a random participant during the performance of an isometric contraction until fatigue. A) 0-5% and B) 95-100%, of the time series.

CONCLUSIONS

These findings suggest muscle synergy weights are maintained through isometric contractions until fatigue. Our research supports the notion of synergies as stable building blocks of human movement.

P167 - ASSESSMENT OF MEDIAL COLLATERAL LIGAMENT BUNDLES ON ELBOW STABILITY

INTRODUCTION

In the elbow joint, the most important ligamentous structure in terms of avoiding dislocation caused by valgus forces, is the Ulnar Medial Collateral Ligament (UMCL) [1]. UMCL complex is divided into bundles with different anatomical and functional features. Anterior Medial Collateral Ligament (AMCL) bundle is a primary constraint for valgus stress, internal rotation and it prevents the joint opening at all angles of flexion [2]. On the contrary Posterior Medial Collateral Ligament (PMCL) bundle role in preventing posteromedial dislocation and joint subluxation in case of compressive load is still debated.

In this study we present an elbow stability analysis using a video stereo-photogrammetric system, on a cadaveric arm in order to evaluate UMCL bundles functionality.

METHODS

All the muscles of a cadaveric elbow were resected and the UMCL was exposed. Three clusters of reflective markers were used: one fixed, one on the humerus and one on the ulna. Markers positions were acquired with two cameras (100 fps) during supination valgus stress (SV_{stress}) and pronation varus stress (PV_{stress}) maneuvers. Maneuvers were exerted for 3 different UMCL bundles statuses in sequence: 1) intact ligament (baseline dislocation); 2) AMCL dissection; 3) AMCL & PMCL dissection. Optimal Common Shape Technique [3] was then applied to minimize artifacts and markers tracking errors. The poses of the clusters were processed to define the trajectory of the forearm with respect to the arm.

Considering the maneuvers exerted on the intact elbow, the regression plane (RP_I) of the origin of the ulna (O_U) reference frame trajectory with respect to the humerus reference frame was calculated. The axis of the elbow flexion has been assumed perpendicular to RP_I. Regression planes perpendicular to the elbow flexion axis had been calculated considering maneuvers after AMCL or AMCL & PMCL dissections. Regression planes are RP_A and RP_{AP} respectively. The deflection *d* of the elbow was measured as the distance of O_U from RP. Mean value and standard deviation of *d* were calculated for all UMCL bundles statuses. Comparisons of these values are used to characterize elbow stability.

RESULTS AND DISCUSSION

Figure 1 shows the trajectories of O_U with respect to the humerus reference frame, with intact elbow, AMCL and AMCL & PMCL dissections. x-axis is the elbow flexion axis, while plane yz is the RP_I. With the dissectioned elbow SV_{stress} and PV_{stress} maneuvers were compared.

An increasing envelop of the O_U trajectory can be noticed, considering the different statuses. Furthermore the distance of RP_{AP} with respect to RP_I is greater than the distance of RP_A with respect to RP_I. An increasing of the mean values and standard deviations of the deflection *d* can be observed. In particular with AMCL dissection d=1.7±2.1 mm and d=0.1±1.7 mm for SV_{stress} and PV_{stress} respectively. With AMCL & PMCL dissection d=7.6±11.6 mm and d=4.5±7.7 mm for SV_{stress} and PV_{stress} respectively.

CONCLUSIONS

These findings, although limited to one case, highlight the role of PMCL into the elbow biomechanics. Results suggest that a dissection of PMCL causes varus and rotation instability of the elbow.

P168 - EFFECT OF ECCENTRIC CALF RAISE ON FASCICLE LENGTH OF GASTROCNEMIUS MEDIALIS

INTRODUCTION

Plyometric training (PT), which features stretch-shortening cycle (SSC) typified by eccentric training, is primarily prescribed to improve performance. Many researchers explained that PT not only improves performance but also increases muscle strength and the cross-sectional area of the muscle [1] and increases the tendon stiffness and elastic energy storage [2]. SSC possesses characteristics that utilize elastic energy and stretch reflection due to the stretching of both muscle and tendon. Therefore, PT can possibly affect the lengthening of the fascicle length (FL). Fouré et al. reported that no significant difference could be found in the FL of the triceps-surae muscle before and after PT. However, their programs consisted of whole-body training, which could easily compensate for weak muscles, and it was unclear whether there was an effect on the triceps-surae muscle. We learned that the eccentric calf raise (ECR) exercise possesses the characteristic of PT [3]. The purpose of the present study is to clarify the effects of ECR exercise on the FL of the gastrocnemius medialis (GM) muscle.

METHODS

Twenty-one healthy normal volunteers with no injuries in the lower limb and who provided their informed consent participated in this study. Their 42 legs were categorized into 22 legs of 11 volunteers in the ECR group (eight males and three females; mean age = 21.2 ± 3.9 years) and 20 legs of 10 volunteers in the normal calf raise (NCR) exercise group (six males and four females; mean age = 19.6 ± 0.7 years). To equalize the total works in each training, the ECR group was set to perform 15 repetitions daily in two sets, seven days/week, and the NCR group was set to perform 20 repetitions daily in two sets, seven days/week for 12 weeks based on our pilot study. The calf-raise rhythm was 60 beats per minute. Ultrasound images of the GM muscle were recorded at a height that was 25% of the proximal length of the lower leg at 0° position of the ankle in the prone position using the B-mode 12-MHz linear transducer ultrasonograph (My Lab. 25, Esaote Corporation). The pennation angle and muscle thickness of the GM muscle were determined using Image-J (NIH, Washington, DC, USA) [3], and extended lines that delineate the deep aponeurosis and visible fascicle on each images were used to determine the FL [4]. The maximum dorsiflexion angle of the ankle was determined with the knee in fully extended position on supine posture using a goniometer. All measurements were performed three times, namely, before training and training after 3, 6, 9, and 12 weeks. The mean values were calculated. In each group, all measurements were examined at each time point using the multiple comparison test ($p<0.05$)

RESULTS AND DISCUSSION

In the ECR group, the FL significantly increased after six weeks compared with those of the baseline and after three weeks: baseline: 68.3±8.1 mm, 3 weeks: 70.5±9.2 mm, six weeks: 73.2±8.8 mm, nine weeks: 74.5±8.3 mm, and 12 weeks: 74.2±8.0 mm (Figure 1).

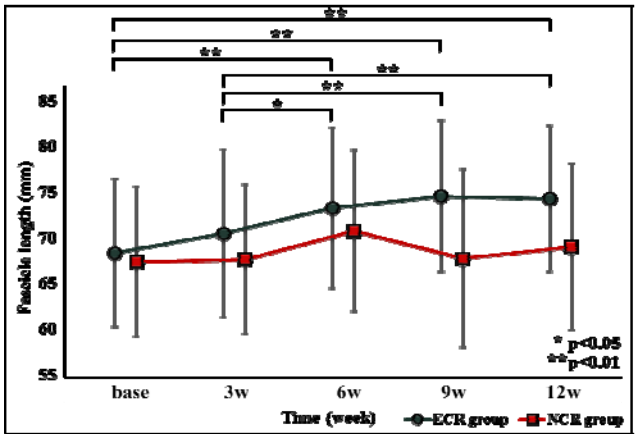

Figure 1: Changes of fascicle length in the ECR and NCR group.

The dorsiflexion angle and muscle thickness after three weeks significantly increased compared with that of the baseline. In the NCR group, the FL, pennation angle, dorsiflexion angle, and thickness of the GM muscle showed no significant difference among all data. Evidently, static stretching can improve the excursion of the muscle-tendon complex [5]. However, no evidence appeared to show that the FL can be increased by static stretching. In the present study, the dorsiflexion angle was increased by the improvement in the muscle sliding property until three weeks. Thereafter, we considered that lengthening of the FL occurred by further continuing the muscle contraction through stretching stimulation. Our results revealed that the FL of the GM muscle in the ECR group succeeded to lengthen after six weeks, and the extensibility of the GM muscle was improved.

CONCLUSIONS

We have shown that the FL of the GM muscle lengthened by continuous ECR for six weeks. This result provided evidence that PT can lengthen the FL.

P169 - COMPARISON OF TWO METHODS TO DIFFERENTIATE SITTING AND LYING USING ACCELEROMETER-BASED ACTIVITY MONITORS

INTRODUCTION

High levels of sedentary time (sitting or lying during waking hours with low energy expenditure) has now been detrimentally linked to several health outcomes. Differentiating sitting from lying may help to further understand the mechanisms associated with the health impacts. Sensors worn on the thigh can identify when the thigh is horizontal, which is used to define 'sedentary' behavior, or vertical, which defines an 'upright' position. However, as the thigh is horizontal in both sitting and lying, differentiation between those two positions is not straightforward. Laboratory validation has shown that with a second sensor on the trunk [1], lying can be accurately distinguished from sitting by the horizontal (versus vertical) trunk position. An important drawback to this method is the inconvenience of wearing a second sensor on the trunk. As an alternative, Lyden et al. [2] developed a method using a single thigh-worn sensor that differentiates sitting from lying based on the degree of thigh rotation (expected to be greater in lying than sitting). The method showed good accuracy against diary-reported criterion that treated sedentary behavior during sleep time as lying down and during waking time as sitting.

The aim of this study was to test the agreement in sitting/lying classification between the single- and two-sensor methods in free-living conditions.

METHODS

The study involved fifteen participants (mean(SD) age=32(7) years; 8 females) who were randomly selected from a larger ambulatory monitoring study. Physical activity was measured using activPAL3 sensors that were worn on the thigh and the trunk. The first full day of data when the monitors were worn, from midday to midday the next day, was selected for analysis. Only participants who had complete data, i.e. who did not report removal of sensors during the first full day of measuring, were selected. Both waking hours and sleep were included.

The two-sensor method used the posture (sitting/upright) that occupied most of each time-matched 15-second epoch to make classifications. Sitting/lying time as identified by the thigh monitor was classed as lying when the trunk monitor also registered sitting, or as sitting when the trunk monitor registered upright posture. The single-sensor method estimated the angle of rotation of the y-axis of the thigh sensor from the raw acceleration signals. Each sitting/lying event that included a rotation of the thigh of more than 65 degrees was classified as lying and all other events were classed as sitting.

The total duration of time spent lying and sitting (in hours) was calculated for both methods. Agreement between the two methods was determined using Bland-Altman methods.

RESULTS AND DISCUSSION

Overall, the two-sensor method identified a larger amount of time spent lying than the single-sensor method. The mean differences (95% limits of agreement) were 0.5 (-4.2, 3.2) hours for lying time and 0.6 (-3.0, 4.3) hours for sitting time. The difference in lying time was within 0.6 hours for most participants with two outlying cases, which can be seen in Figure 1.

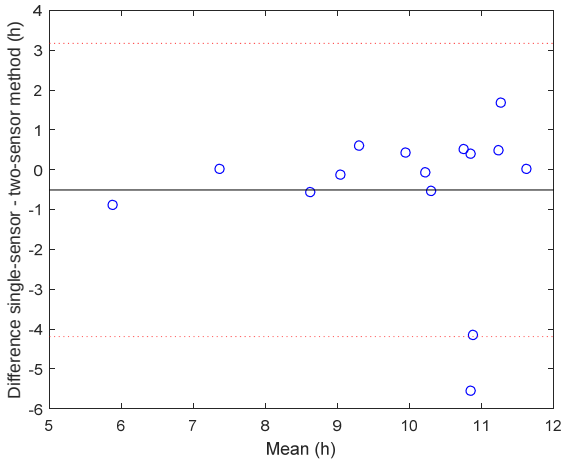

Figure 1: Bland-Altman plot showing agreement in time spent lying. The black horizontal line is the mean difference and the two red dotted lines show the upper and lower 95% limits of agreement.

One explanation of this underestimation by the single-sensor method relative to the two-sensor method could be that lying periods without movement, such as lying on a couch, are not classified as lying, because there was no rotation of the thigh. This is consistent with the initial development targeting sleep time as lying down. Although the two-sensor method had good accuracy in its laboratory validation [1] it may have had errors in free-living conditions that contributed to disagreement.

CONCLUSIONS

This study shows that the single and two-sensor methods have some differences in their estimation of the extent in their daily sitting and lying time identification. Wearing a single sensor on the thigh is sufficient to broadly differentiate active and sedentary behavior, however, improvements may be required to distinguish sitting from lying.

P170 - GENERATION OF 3-D PRECISION GRIP MOVEMENT BASED ON A NEURO-MUSCULOSKELETAL MODEL

Yuki Tanaka, Yuki Moritani, Naomichi Ogihara
Department of Mechanical Engineering, Keio University
Corresponding author e-mail: ogihara@mech.keio.ac.jp

INTRODUCTION

Humans can stably hold and skillfully manipulate an object by coordinated control of hand musculoskeletal system. However, computing the muscle activation patterns that realize stable precision grip of an object is not straight forward because of the complexity and the inherent redundancy in the musculoskeletal system. How the nervous system spontaneously controls such dexterous movements still remains unclear.

In present study we proposed a recurrent neural network model which can spontaneously generate muscle activations with no prior planning of trajectories and force/moment equilibrium. The proposed neural network model was integrated with a 3D three-finger hand musculoskeletal model to simulate precision grip movement of an object.

METHODS

We constructed 3D musculoskeletal model of the human hand with a thumb, an index finger and a middle finger. Each finger consists of three rigid links with proximal, middle, and distal joints having 2 (flexion-extension and adduction-abduction), 1 (flexion-extension), and 1 (flexion-extension) DOF, respectively. The dimensions and inertial parameters were determined by reference to literature [1]. A total of eight muscles were attached to each of the finger model. Muscle parameters such as maximum forces were determined by reference to literature [2]. In this study, moment arms were assumed to be constant regardless of the joint angles.

The nervous system was modeled as a recurrent neural network (RNN) model [3] consisting of reciprocally connected neuronal elements that can prescribe kinematic and kinetic conditions must be satisfied in precision grip tasks in the form of energy functions. The RNN autonomously behaves such as to decrease the energy functions. Therefore, given the target fingertip positions, the estimated mass and the location of the center of mass of the target object, the nervous system model can spontaneously generate muscle activation signals that realize stable precision grips. In the proposed nervous model, there are three RNN models: 1) a RNN model to estimate joint angles to bring the fingertips to the target positions, 2) a RNN model to estimate fingertip force vectors that can satisfy force and moment equilibrium of the grasped object, and 3) a RNN to estimate muscle activation signals that can realize generation of a given joint torque patterns. In addition, information about local slip between fingertips and object surfaces was utilized to adjust forces to be generated at the fingertips.

We constructed the hand neuro-musculoskeletal model using the rigid body physics library, Open Dynamics Engine with C++. As an example of precision grip task, here we simulated hand movements to pinch a 3-cm cube (0.1 kg) and lift it to a height of 1 cm. Parameters in the nervous system were determined arbitrary so that the model can accomplish precision grip tasks.

RESULTS AND DISCUSSION

Fig. 1 shows the generated precision grip movements of the three-finger hand model. The proposed neural network model could stably pinch and successfully hold up the object while avoiding the motor redundancy problem due to the dynamic relaxation of the energy functions embedded in the nervous system.

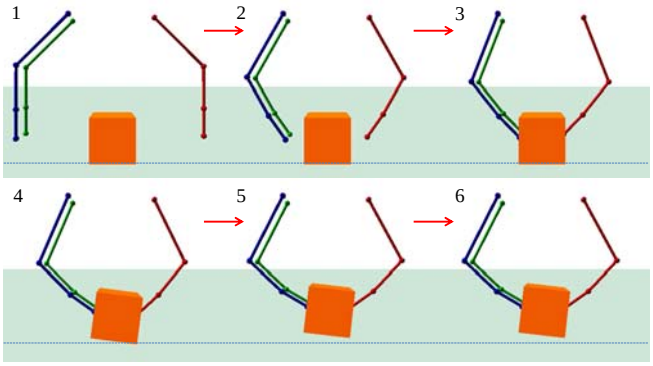

Figure 1: Stick diagram of generated precision grip

The simulated fingertip force profiles were qualitatively similar to the data obtained in human physiological experiments [4]. The proposed neuro-computational framework may actually be implemented in and utilized by the central nervous system for precision grip tasks in humans.

CONCLUSIONS

Our results demonstrated the proposed neural network could stably grasp an object without pre-planning trajectories.The proposed neuro-musculoskeletal model may possibly explain fundamental control strategy of precision grip in humans.

P171 - EFFECTS OF PHOTOBIOMODULATION IN THE ACTIVATION OF QUADRICEPS FEMORIS MUSCLE AFTER 8 WEEKS OF STRENGTH TRAINING - PRELIMINARY RESULTS

Helga Tatiana Tucci[1], Raquel de Paula Carvalho[1], Danielle Figueiredo[1], Ana Cláudia Muniz Rennó[1]
[1]Universidade Federal de São Paulo
Corresponding author email: helgatucci@gmail.com

INTRODUCTION

Aging is responsible for several changes in the body, and the musculoskeletal system is one of the most affected tissue. The photobiomodulation associated with strength training has been effective in reducing muscle fatigue [1]. However, there is no evidence that this therapeutic resource increases muscle activation after strength training. The objective of this study was to analyze whether the photobiomodulation associated with quadriceps femoris strength training increases the activation of this muscle. The hypothesis is that the subjects who receive active photobiomodulation associated with training have a increase in the activation of the quadriceps femoris after training compared to subjects who received sham photobiomodulation.

METHODS

This is a prospective, crossover, randomized, double-blinded study approved by the University Ethical Committee (n°1.681.982). Sixteen females [mean (standard deviation) 65,6 (3,7) years; body mass 66,9 (8,2) kg; and height 1,51(2,4) m] were randomized in Active Laser Group (ALG; n=08): strength training associated with active photobiomodulation; and Sham Laser Group (SLG; n=08): strength training associated with placebo photobiomodulation. The study had 4 Stages (S-1 to S-4). S-1: initial evaluation of 1-Maximum Repetition (1-RM); S-2: surface electromyography signal sampling (SEMG) from the vastus medialis (VM), rectus femoris (RF), and vastus lateralis (VL) for 10 seconds of maximum voluntary isometric contraction (MVIC); S-3: Quadriceps femoris strength training (8 weeks, 2 weekly sessions, 5% of load increasing every two weeks, start at 65% of initial 1-MR). The 1-MR was reevaluated every 2 weeks and at the end of training [2]. After each session of training, photobiomodulation was applied over the quadriceps femoris of the dominant lower extremity, according to randomization, using a cluster with 7 diodes of 850nm wavelength (GaAlAs), 100mW output power, 4J per diode, totaling 28J in 40 seconds. Due to cluster´s size, 4 applications were necessary to cover the muscle, totalizing 112J in 120 seconds. S-4: The S-2 was repeat 24 hours after the last training session. Before placing the electrodes, skin was shaved and cleaned with alcohol. Myoelectric signals from the VL, RF, and VM were sampled with disposable bipolar electrodes (Ag/AgCl, 20 mm inter-electrode distance) made of polyethylene foam and medicine hypoallergenic adhesive gel, connected to a sensor. Electrodes were placed according to SENIAM recommendations [3]. Sensors have input impedance of 10 GΩ, Common Mode Rejection Ratio of 130 dB and gain of 20 times. A circular disposable reference electrode was fixed in the tibial plateau of dominant lower extremity for reducing the acquisition noise. SEMG signals were sampled simultaneously by a 16-bit A/D converter board with 2 kHz frequency (Miotec®, Rio Grande do Sul, Brazil). The raw 10-seconds of MVIC SEMG signal (RMS) was digitally filtered at frequency bandwidth of 20-500Hz, and posteriorly normalized by the RMS obtained from the initial 3-seconds of MVIC of the same SEMG signal. This data analysis was done before and after the strength training. Hence, the normalized SEMG signals and 1-MR were compared between groups before and after training. T-Student test for independent samples to analyze demographic variables and repeated measure (ANOVA) to analyze SEMG and 1-MR variables were used as statistical analysis, with level of significance set at $p<0.05$.

RESULTS AND DISCUSSION

There were no significant differences between groups for age ($p=0.31$), body mass ($p=0.15$) and height ($p=0.87$). There were no significant differences between groups and interaction groups vs training. Thus, significant results were only due to training. Values of 1-MR were greater after training for ALG [mean (standard deviation); 15,85 (8,29); $p<0.01$], and SLG [mean (standard deviation); 15,85 (8,29); $p<0.01$]. The normalized SEMG were lower after training for VL in ALGroup [mean (standard deviation); 15,85 (8,29); $p=0.28$] and SLG [mean (standard deviation); 15,85 (8,29); $p=0.28$], for RF in ALG [mean (standard deviation); 15,85 (8,29); $p=0.28$] and SLG [mean (standard deviation), and for VM in ALG [mean (standard deviation); 15,85 (8,29); $p=0.28$] and SLG [mean (standard deviation)]. Literature has been shown that photobiomodulation has positive effect on muscle performance based on several types of analysis[1]. So, preliminary results of our study could be justified to the small sample size, and also by the fact that phototherapy parameters of this research could not be the best choice to improve muscle performance in elderly women.

CONCLUSIONS

To use of photobiomulation after each session of quadriceps femoris strength training was not effective in increasing the activation of evaluated muscles after the strength training. Although limited, this preliminary finding suggests that a study with larger sample size should be done to assess the benefits of this resource.

P172 - GLENOHUMERAL JOINT MOTION WITH ARM ELEVATION IN THE FRONTAL AND SAGITTAL PLANES AT COMMON CLINICAL EVALUATION BODY POSITIONS

[1,2]**Vassilios G. Vardaxis**, [3]Michael E. Maiden, [2]David Stapleton, [4]Dimitra Blana, and [1]Traci A. Bush

INTRODUCTION

Arm elevation is routinely used for clinical evaluation purposes and upper-extremity rehabilitation exercise programs for glenohumeral dysfunction [3, 5]. For specific shoulder dysfunctions such as rotator cuff syndrome, there is no consensus on the ideal protocol in terms of tests, measurements, and therapeutic exercises [2]. Existing protocols often incorporate the placement of the body in various positions to assess function and alter the intensity of rehabilitation [8]. Furthermore, glenohumeral muscle activation patterns were shown to vary with body position and glenohumeral orientation [1, 7]. Therefore, a detailed examination of the glenohumeral joint motion during different active arm elevation tasks in the frontal and sagittal planes, performed at various common clinical evaluation positions, may help clinicians standardize assessment and design optimized rehabilitation protocols.

METHODS

Eighteen (18) male participants without injuries or ROM issues participated in the study. Participants completed 5 trials of arm elevation (dominant side only) in the sagittal and frontal plane to ~110 degrees, in 4 different body positions: seated, sidelying, prone and supine. During arm elevation in all positions/tasks the palm of the hand was faced medially. A motion analysis system with 10-cameras (Motion Analysis Corp.) running at 120 Hz was used to capture 3D data of reflective markers attached to the upper-limb and torso. Euler angles were used to compute scapula relative to the thorax, humerus relative to the scapula, and humerus relative to the thorax 3D rotations, per ISB recommendations [9]. The glenohumeral joint location was calculated using a regression method [6]. The glenohumeral, humerothoracic, and scapulothoracic motion was assessed at 15° increments between 15° and 90° elevation angle. Statistical analysis of glenohumeral plane of elevation, elevation angle, and axial rotation was performed using 3-way RM-ANOVA (task-by-position-by-elevation angle). Greenhouse-Geisser degree of freedom adjustment was used when the sphericity assumption was violated.

RESULTS AND DISCUSSION

The plane of elevation with respect to the thorax was -12.3° (±2.6) for the frontal plane and 60.2° (±4.3) for the sagittal plane and was not different across body positions. The average (pooled across body positions and elevation angles) glenohumeral plane of elevation was -37.2° (±9.8) and 30.9° (±3.5) for the frontal and sagittal planes, respectively. There were no significant differences in the arm elevation ROM between body positions or between tasks. The average arm elevation was 100.1° (±4.2) from the initial resting position relative to the thorax (humerothoracic), 68.1° (±4.1) was contributed from glenohumeral and 33.4° (±7.2) from scapulothoracic motion, when pooled across body positions and tasks. Across all humerothoracic elevation angles, there was a significantly lower glenohumeral elevation in the frontal plane compared to sagittal in seated and supine positions (mean difference: 2.3° and 2.8°, respectively; $p < 0.03$). However, there was significantly greater glenohumeral elevation in the frontal plane in sidelying and prone positions (mean difference: 12.6° and 8.9°, respectively; $p < 0.001$).

Table 1. Glenohumeral Axial Rotation (°) Internal (+) / External (-)

		Humerothoracic Arm Elevation (°)					
		15	30	45	60	75	90
FRONTAL	SEATED	-3.2	-11.9	-19.4	-24.7	-28.6	-30.4
	SIDELYING	30.7	8.8	-1.0	-6.8	-10.9	-15.1
	PRONE	54.0	29.9	15.3	2.8	-9.5	-18.0
	SUPINE	84.9	63.8	31.8	14.9	3.4	-4.9
SAGITTAL	SEATED	-47.5	-58.7	-64.6	-67.2	-66.8	-63.3
	SIDELYING	-28.4	-44.1	-52.1	-55.4	-57.2	-58.5
	PRONE	-9.1	-26.0	-35.2	-41.4	-46.2	-47.5
	SUPINE	-57.6	-66.7	-69.3	-68.8	-67.4	-64.8

Note. Average values shown, SD range 6.2° - 17.8°, higher values at 15° elevation.

There was a significant ($p < 0.001$) 3-way interaction effect for glenohumeral axial rotation (Table 1). The glenohumeral joint remained significantly ($p < 0.001$) more externally rotated during elevation in the sagittal plane compared to frontal plane, opposite to current literature findings [4], most likely due to discrepancies in task performance. The axial rotation ROM in the external rotation direction was significantly greater during arm elevation in the frontal plane and it was different across body positions (27.2°, 45.8°, 71.9°, and 89.1°, respectively for seated, sidelying, prone, and supine; $p < 0.001$).

CONCLUSIONS

The overall glenohumeral motion as reflected by 3D kinematics varies with the plane of elevation and body position. The findings of this study add to the understanding of the normative motion of the shoulder during arm elevation and can be used to aid in the assessment of patients with glenohumeral dysfunction and the planning of rehabilitation interventions.

INTRODUCTION

Humeral elevation as related to the thorax is a complex motion that requires scapular stability and mobility for normal shoulder function [1, 4]. Scapular motion facilitates glenoid fossa orientation to allow for proper glenohumeral joint function without impingement [4]. Alterations in scapular kinematics have been shown to be related to shoulder dysfunction [3]. There is no consensus in the description of the normal scapular kinematics in asymptomatic individuals [5, 6]. Findings on scapular motion in asymptomatic individuals have shown that dominance may have an effect on the upward/downward rotation and anterior/posterior tilt during humeral elevation [2]. Hence, the primary aim of this study is to compare the dynamic 3D kinematics of the scapula between various common clinical evaluation positions for the dominant arm of healthy controls while performing the task of arm elevation in the frontal and sagittal planes.

METHODS

Eighteen (18) healthy male participants with normal shoulder clinical exams and without any musculoskeletal problems volunteered for the study. Participants completed 5 trials of each task, arm elevation (dominant side only) in the sagittal and frontal planes to ~110 degrees, in 4 different body positions: seated, sidelying, prone and supine. A motion analysis system with 10-cameras (Motion Analysis Corp.) running at 120 Hz was used to capture 3D data of reflective markers attached to the upper-limb, and torso. Reference frames were defined for the thorax, scapula and humerus. Euler angles were used to compute 3D rotations of the scapula relative to the thorax, humerus relative to the scapula, and humerus relative to the thorax per ISB recommendations [7]. The scapulothoracic motion was assessed at 15° increments between 15° and 90° of humerothoracic elevation angle. Statistical analysis of the scapulothoracic motion in 3D was performed using 2-way RM-ANOVA (position-by-elevation angle), separate for each task. The Greenhouse-Geisser degree of freedom adjustment was used when the sphericity assumption was violated.

RESULTS AND DISCUSSION

The average age, height, and weight of the participants were: 24.0 ±1.7 years, 1.73 ±0.39 m, and 85.5 ±15.1 kg, respectively. For all participants the scapular kinematics for internal-external rotation and anterior-posterior tilt while performing arm elevation in the different body positions are illustrated in Figures 1A and 1B. The 2-way RM-ANOVA on the scapular motion during arm elevation in the frontal plane revealed significant interaction effect between arm elevation angle and position for all three scapulothoracic motions (minimum F=5.84, p=0.001). Overall the scapula moved towards external rotation, upward rotation, and posterior tilt during arm elevation in the frontal plane. In the sidelying position the scapula started in a more externally rotated position and then moved towards the internal rotation direction with arm elevation (Figure 1A). The scapular posterior tilt ROM was the greatest overall in the supine position; with limited ROM in sidelying and an anterior tilt trend in the prone position (Figure 1B).

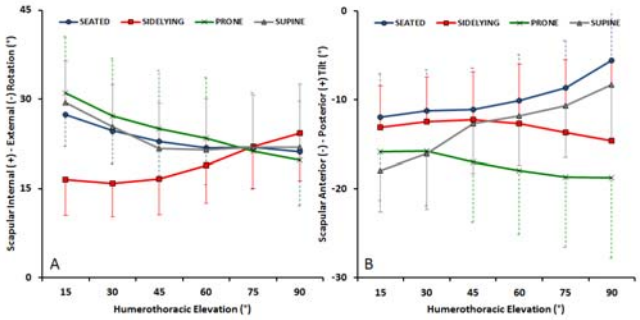

Figure 1: Scapular int/ext rotation (A) and ant/post tilt (B) during arm elevation in the frontal plane in the different body positions. Mean and Standard Deviation.

Significant interaction effect was also found for the scapular motion between arm elevation angle in the sagittal plane and body position (minimum F=4.96, p=0.002). The sagittal plane arm elevation effect on scapular motion was similar to that of the frontal plane, with one difference: there was an internal rotation trend with arm elevation in this case. Limited scapular ROM in the internal/external rotation and anterior/posterior tilt directions were observed with arm elevation in the sagittal plane in the prone position. Significant elevation angle and body position main effects were also found for both tasks.

CONCLUSIONS

Differences in the scapular kinematics were observed, in non-symptomatic adults, between common body positions used for clinical tests, measures, and exercises to assess function and alter intensity of rehabilitation. When restoration of altered scapular kinematics is the therapeutic goal, body position effect as determined by these findings should be taken into account as biomechanical consideration for shoulder assessment purposes.

P174 - VASTUS MEDIALIS AND LATERALIS ACTIVITY DURING VOLUNTARY AND STIMULATED CONTRACTIONS

INTRODUCTION

The vastus medialis (VM) and lateralis (VL) muscle heads are part of the quadriceps femoris, and are responsible for extension at the knee joint [1]. Alterations in VM electromyographic (EMG) activity have often been associated with patellofemoral pain syndrome [2]. Therefore, maximizing VM muscle activity, particularly with respect to the VL, has long been the challenge of physical therapists and the aim of a multitude of methodological studies.

Despite the common belief that the relative activation of the VM is greater at short muscle lengths, particularly in the field of rehabilitation, the EMG VM/VL ratio has often been found to decrease proportionally with decreasing knee flexion angle in both healthy individuals and patellofemoral pain syndrome patients [3], therefore suggesting a greater relative activation of the VM at long rather than at short muscle length. Therefore, the purpose of this study was to re-examine the relative activation of VM and VL muscles during voluntary and stimulated isometric contractions at different joint angles.

METHODS

Sixteen healthy men (mean age: 26 years) completed maximal voluntary and stimulated contractions of the knee extensor muscles at 30°, 65°, and 100° of knee flexion, while seated in the chair of an isokinetic dynamometer with a trunk-thigh angle of approximately 90°. VM/VL ratios were calculated from voluntary EMG and evoked torque recordings. The relative contributions of VM and VL muscles to evoked knee extension torque were calculated (peak twitch torque evoked by VM or VL stimulation/peak twitch torque evoked by femoral nerve stimulation) as a percentage.

Normal distribution of data was verified with the Shapiro-Wilk test. For further statistical analysis, parametric or non-parametric (Friedman) 1-way repeated measures ANOVA followed by Student-Newman-Keuls post hoc analyses were used. Significance was set at $\alpha<0.05$.

RESULTS AND DISCUSSION

The main findings of this study were that both EMG and VM/VL torque ratios obtained during voluntary and stimulated isometric knee extensions were smaller at extended (30° of flexion) than at flexed (100° of flexion) knee positions ($p<0.05$). These results can be explained by the relatively small contribution of VM to knee extension torque at short muscle length, see figure 1, probably due to joint angle-specific architectural differences between the two muscle groups [6].

These results are in line with some [4] but not all previous studies [1] in which no effect of knee angle was observed on these variables. The observed discrepancies may stem from methodological differences between the studies, inter-study differences in experimental conditions, but also from the intrinsic limitations of surface EMG, which are increasingly acknowledged [5].

These findings allow to speculate that strength training and rehabilitation exercises for maximizing the relative activation of the VM muscle might be better performed in a flexed position rather than in an extended knee positions, however more research toward this topic is necessary.

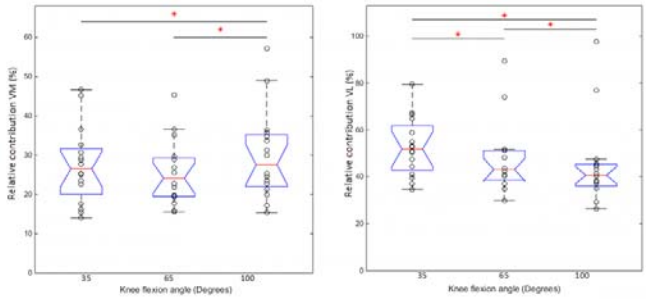

Figure 1: Boxplots of VM and VL relative contribution to evoked knee extension torque by knee flexion angle, showing individual data points, median, quartiles (first and third) and range. *significant difference ($p<0.05$).

CONCLUSIONS

This study showed a relatively small contribution of the VM muscle to knee extension torque at short muscle length. Such disadvantage of the VM muscle at extended knee positions does not seem to be compensated by an increased neural drive.

P175 - NEUROMUSCULAR ADAPTATIONS DURING KNEE EXTENSIONS INDUCED BY HIP FLEXION TRAINING: INSIGHTS INTO TRAINING SPECIFICITY

INTRODUCTION

Neuromuscular improvements induced by resistance training occur within a few weeks. When interpreting the training-induced effect on neuromuscular performance of a muscle group, we need to take into account training specificity. The performance is not necessarily improved in a task in which the joint angle and/or muscle contraction type are different from those in the training task but involving the same muscle group [1]. In contrast, if we focus on the training specificity on a muscle rather than on a muscle group, there is room for consideration from a view point of joint motions. There are some muscles that act as an agonist at several joint motions. For example, the biarticular rectus femoris (RF) acts as hip flexor as well as knee extensor. It remains unclear whether neuromuscular performance of RF during knee extensions is improved by hip flexion training. The magnitude of RF activation during hip flexion was lower than that during knee extension [2], and the magnitude of muscle activation before training has been suggested to be related to the potential for improvement with resistance training [3]. Considering these points, it is hypothesized that great neuromuscular adaptation of RF during knee extension is induced by hip flexion training, and as a result, neuromuscular performance of knee extension is improved. We tested the hypothesis.

METHODS

Fourteen untrained healthy young men (22 ± 2 yr) completed a 4-wk isometric resistance training program (3 days per week, i.e., 12 sessions) for hip flexors. Before and after the intervention, maximal voluntary isometric hip flexion (MVC_{HF}) and knee extension (MVC_{KE}) torques were measured. Voluntary activation during MVC_{KE} was assessed with a twitch interpolation technique using the following formula: voluntary activation = 1 - (superimposed triplet torque/resting triplet torque). Electrically evoked twitch and triplet contractile properties (peak torque, time to peak torque) were measured by femoral nerve stimulation. Surface electromyographic (EMG) signals were obtained from RF, vastus lateralis and biceps femoris. The root mean square values of EMG signals (RMS-EMGs) during contractions were calculated. The values were normalized to the maximal compound muscle action potential amplitude (M wave) amplitude for RF and the vastus lateralis and then normalized to RMS-EMG during maximal voluntary knee flexion for the biceps femoris. The muscle thickness of RF at mid-thigh was determined using ultrasonography.

RESULTS AND DISCUSSION

After the training period, both MVC_{HF} and MVC_{KE} torques significantly increased. The relative change of MVC_{HF} torque (22 ± 13%) was significantly greater than that of MVC_{KE} torque (6 ± 10%). The increase in MVC_{KE} torque was accompanied by a significant increase in voluntary activation (4 ± 6%) and in the muscle thickness of RF (5 ± 6%). In contrast, twitch and triplet contractile properties did not change in any variables. With respect to the indices of muscle activations, at baseline, the normalized RMS-EMG of RF was significantly lower during MVC_{HF} than during MVC_{KE}. After the intervention, the normalized RMS-EMG of RF significantly increased during both MVC_{HF} (from 0.07 ± 0.03 to 0.11 ± 0.04) and MVC_{KE} (from 0.10 ± 0.04 to 0.13 ± 0.04). However, there was no significant difference in the change of normalized RMS-EMG of RF between MVC_{HF} and MVC_{KE}, with a standardized difference in the changes of 0.35 (i.e., the difference in mean change divided by the standard deviation of all the subjects at baseline), which is interpreted as a "small" effect [4]. The normalized RMS-EMG of the vastus lateralis and biceps femoris during MVC_{KE} did not change. The results suggest that the increase in MVC_{KE} torque following short-term isometric hip flexion training was mainly due to neural adaptation of RF rather than the changes in intrinsic contractile properties of the quadriceps femoris. Consistent with previous knowledge, the current study demonstrated the training specificity in the improvement of voluntary strength. On the other hand, there was no substantial difference in the neural adaptation of RF between knee extensions and hip flexions. The present findings suggest that the training-induced effect on the neuromuscular performance of a muscle depends on the magnitude of muscle's potential for improvement with training rather than the joint motions involved during training.

CONCLUSIONS

Neuromuscular adaptation during knee extensions is induced by short-term isometric hip flexion training. The current findings are expected to result in a better understanding of training specificity, and contribute to the development of effective and evidence-based strength training and rehabilitation programs.

P176 - IDENTIFICATION OF REGIONAL ACTIVATION IN HIGH-DENSITY EMG SIGNALS: A COMPARISON OF TWO FACTORIZATION ALGORITHMS

[1] **Alessio Gallina**, [2]S Jayne Garland and [3]James Wakeling
[1]University of British Columbia
[2]University of Western Ontario

INTRODUCTION

Principal Component Analysis (PCA; 1) and Non-negative Matrix Factorization (NMF; 2, 3) can factorize high-density surface EMG (HDsEMG) signals in clusters of electrodes with similar profiles of activation in time. When HDsEMG signals are collected from a single muscle, these algorithms may be useful to describe how well the original signal can be reconstructed assuming absence of regional activation (a single factor that fluctuates similarly across channels) as opposed to more complex spatio-temporal patterns (a larger number of factors). In this study, we compared PCA and NMF applied on HDsEMG signals as a means to identify regional activation within the human vastus medialis during a low-force isometric contraction.

METHODS

Twelve participants performed a low-force isometric knee extension (less than 10% of the electrical activity produced in a maximal contraction). HDsEMG signals were collected from the vastus medialis (VM) using a grid of 13x5 electrodes. The VM innervation zone was identified in multiple regions across the muscle, and the grid was placed so that the innervation zone was between the second and third columns of electrodes. The envelope of the EMG signal of each channel was calculated by low-pass filtering (8 Hz) the monopolar EMG signal after rectification. The data matrix was factorized using PCA and NMF. NMF was repeated 50 times starting from random values. For each technique, the signal was reconstructed as the matrix product of spatial weights and temporal scores, increasing the number of factors from 1 to 5. The goodness of the reconstruction of the original EMG envelopes was assessed as the explained variance (EV, sum of the variance of each reconstructed channel divided by the sum of the variance of each original channel, expressed as a percentage). As 2 factors explained on average more than 85% of the variance, the first two spatial weights and temporal scores were compared between PCA and NMF. Activation zones were also reconstructed from the PCA weights and scores using a non-negative criterion. Pearson correlation coefficient and paired T-tests were used to test association and differences between the EV with PCA and NMF. Similarly, the Pearson correlation was calculated for the activation zones and temporal coefficients extracted with PCA and NMF.

RESULTS AND DISCUSSION

A single factor extracted with either PCA or NMF explained approximately 70% of the variance of the signal (PCA: 69.6±11.4%; NMF: 69.6±11.4%); two and three factors explained just over 85% (PCA: 86.6±5.7%; NMF: 86.2±5.9%) or 90% (PCA: 92.3±4.0%; NMF: 91.1±4.0%) of the variance, respectively (fig.1). When matched for number of factors, the variance explained by PCA and NMF was highly comparable (R>0.99±0.01). Variance explained by PCA was significantly larger than that explained by NMF if 2-5 factors were considered (paired T-tests, all P<0.001), although the difference was minimal (<2%). The variance explained by a single factor did not differ between the two algorithms (paired T-test, P=0.22). Spatial weights and temporal scores extracted with non-negative reconstruction of PCA and NMF were highly associated (all P<0.001, mean R>0.99±0.01%).

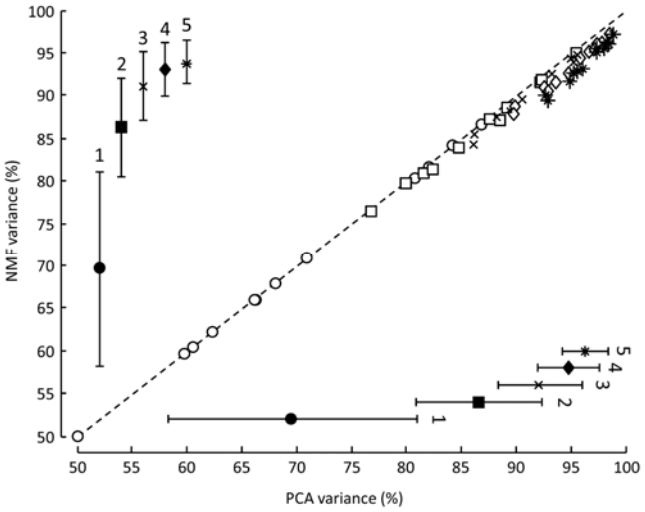

Figure 1: Variance explained by PCA and NMF. Average and standard deviation of EV by 1-5 factors are reported.

As factorization with a single factor explained on average 70% of the variance across channels, a single EMG envelope estimate provides only partial information on the amplitude fluctuations of the vastus medialis EMG during an isometric task. Factorization with (non-negative) PCA and NMF resulted in factors with highly comparable spatial and temporal features, suggesting that the information extracted is a physiological feature of the EMG signals rather than an artifact of the factorization method used.

CONCLUSIONS

Regional VM activation can be identified using high-density surface EMG and factorization algorithms. PCA and NMF perform similarly on monopolar HDsEMG signals.

INTRODUCTION

Glycation, namely the Maillard reaction, is a non-enzymatic reaction between protein or lipid and reducing sugar, resulting in formation of advanced glycation end-products (AGEs). Because glycation of collagen progresses under physiological conditions in living organisms, glycation is one of the most important processes in human aging [1]. Several AGEs bind collagen and act as cross-links between collagen fibrils, thereby changing the mechanical characteristics of collagen-rich tissues. The purpose of this study is to identify AGEs in human dentin using electron microscopy, time-resolved fluorescence microscopy, mechanical testing and chemical analyses. Our findings suggest the potential influence of cross-linking on dentinal physiology with aging.

METHODS

Extracted human teeth with periodontal disease were fixed in 4% paraformaldehyde and cut longitudinally into 1-mm sections using a low-speed diamond saw.
(1) TEM: Non-decalcified teeth were embedded in EPON, sliced into thin sections and observed.
(2) Immunohistochemistry and immuno-EM: Teeth were decalcified for 2 weeks in 10% EDTA, embedded in paraffin or LR-GOLD and sectioned with a microtome. Sections were then stained with anti-AGE and anti-collagen antibodies.
(3) Fluorescence lifetime measurement: Decalcified teeth were observed under a fluorescence microscope. A UV pulsed diode laser was used as the excitation light source, and the resultant blue fluorescence signal was detected with a time-correlated single photon counter.
