TRUNK STABILIZATION, ADAPTATIONS TO ENVIRONMENT, TASK AND PAIN

Jaap van Dieën, Department of Human Movement Sciences, 'Vrije Universiteit Amsterdam',
Amsterdam Movement Sciences, Amsterdam, the Netherlands
j.van.dieen@vu.nl

Trunk stabilization can be defined as maintaining control over trunk posture and movement, in spite of the disturbing effects of gravity and mechanical perturbations. Adequate trunk stabilization is required for precise hand movements, for ballistic arm or leg movements and for control of balance. Moreover, inadequate stabilization of the trunk may be a cause of injury and could play a role in the development and recurrence of low-back pain (LBP). In this presentation, I will provide a review of how the trunk is stabilized in healthy subjects and how stabilization is adapted to changes in environment and the task performed and to the occurrence of pain.
In a stable mechanical environment, healthy subjects stabilize their trunk relative to their pelvis, by means of low levels of co-activation and feedback responses of trunk muscles. Co-activation is increased when perturbations are expected but not fully predictable. In addition, in such threatening conditions, healthy volunteers preferentially recruit lumbar compared to thoracic bundles of the trunk extensor muscle group, which is consistent with a strategy to stiffen the lumbar spine. Feedback responses are generated based on proprioceptive, visual, vestibular and tactile inputs resulting from perturbations, with feedback gains for each of these inputs being dependent on the mechanical environment, task instruction, and on the amplitude, frequency and direction of perturbations. For example, in unstable environments and with increased perturbation frequencies, head-bound visual and vestibular inputs are upweighted relative to other inputs and, related to this, the kinematic strategy changes from trunk on pelvis stabilization towards trunk and head in space stabilization.

In patients with LBP, evidence for increased co-activation and for preferential recruitment of lumbar trunk extensor muscles has been reported. In previous work, we have suggested that these changes in muscle recruitment may reflect a protective strategy, adopted by LBP patients to deal with impaired feedback control. Systematic reviews indicate that proprioception can be impaired and that feedback delays may be increased in LBP. Stiffening of the lumbar spine through feedforward muscle recruitment may be required if this is the case. Inconsistencies in the evidence for the feedforward changes in trunk muscle recruitment suggest that such adaptations are observed in a subgroup of patients only. However, recent evidence from my lab indicates that LBP patients quite consistently show a decreased trunk admittance, i.e., a decrease in trunk displacement for a given perturbation force. This decrease in admittance was driven by increased proprioceptive reflex gains in a group comprising mainly younger patients, and by feedforward mechanisms in another mainly older group of patients. While generally older subjects (patients and healthy controls) were characterized by longer feedback delays, delays were not different between patients and controls. The decrease in admittance in patients was correlated to cognitions about pain as signaling a significant threat. Overall, it appears that changes in trunk stabilization in patients are adaptive in nature, but it is unclear whether such adaptations are needed, or whether they are driven by possibly unjustified cognitions about pain. An open question is whether the enhanced trunk on pelvis stabilization in LBP patients limits their adaptability to changes in task or environment and for example hampers switching to trunk in space stabilization.

MONDAY 24 JULY

OSSEOINTEGRATION FOR AMPUTEES

Adjunct Professor Munjed Al Muderis

munjed@almuderis.com.au

A/Prof Munjed Al Muderis is a world leader in a revolutionary technology known as Osseointegration which offers amputees an alternative to traditional socket mounted prostheses. The Osseointegration Group of Australia has helped more than 300 amputees walk again. A/Prof Al Muderis' ambition to help disabled people started when he was a young child watching “The Terminator” movie. This passion inspired him to develop this technology to help amputees rehabilitate with enhanced mobility, comfort, reduced pain and overall achieving a significantly better quality of life. In the presentation A/Prof Al Muderis will share his experiences in developing this novel surgical procedure and highlight how this technology has evolved and advanced to date. A/Prof Al Muderis will discuss the latest innovative technology and surgical responses to limb injury and share with the audience the latest research results from around the world.

DIFFERENTIAL STRAIN IN SOLEUS AND LATERAL GASTROCNEMIUS SUBTENDONS IN RAT

[1]**Taija Finni**, [2]Michel Bernabei, [2]Guus C. Baan, [2]Wendy Noort and [2]Huub Maas

INTRODUCTION

Achilles tendon (AT) comprises of three subtendons arising from three muscles comprising the triceps surae [1]. The soleus (SOL), and lateral (LG) and medial (MG) heads of the gastrocnemius muscle have different properties and cross a different number of joints, which may lead to uneven loading of the tendon. Recent imaging studies have revealed that there can be uneven displacement within the AT [2], but they have not been able to identify the specific anatomic locations of the shear in respect to the AT subtendons. We tested the hypothesis that there exists heterogeneous strain within AT. More specifically, we predicted that activation of each of the triceps surae muscles would cause differential strains in the tendon fascicles originating from SOL and LG muscles (i.e. SOL and LG subtendons).

METHODS

Experiments were performed on 12 adult male Wistar rats (235.5±16.5 g). Procedures were approved by the institutional Committee on Ethics of Animal Experimentation. Surgery and measurements were done under deep anesthesia and animals were euthanized after the experiment. During preparation, AT was exposed and single knotted suture markers were sutured to the proximal part of GL and SOL subtendons (Fig. 1). Following procedures by Tijs et al. [3], the left hindlimb was attached to a load cell and intra-muscular stimulating electrodes were placed near the neuro-muscular junctions of SOL, LG and medial gastrocnemius (MG) muscles. Stimulations at 100Hz were performed in random order in 5 conditions: SOL, GL, GM, GL+GM, and SOL+GL+GM, with knee joint at 120° and ankle at 90°. Two-dimensional kinematic analysis (filmed using Panasonic HC-V720 at 25Hz) yielded tendon marker positions in relaxed and activated conditions. Using 4 markers in both SOL and LG (Fig. 1), strains based on 3-segment model were calculated. Three-dimensional ankle moments were recorded at 1000Hz and analyzed. After experiments the marker locations were confirmed by dissections to reside in a given subtendon.

Two-factor (subtendon*stimulation) repeated measures ANOVA with Bonferroni as a post hoc was used to test the differences in subtendon strain in a given stimulation condition.

RESULTS

There was a main effect of stimulation ($P<0.001$) and stimulation*subtendon interaction on strain ($P<0.001$). Pairwise comparisons showed that SOL and LG subtendon strains were different in each stimulation condition ($P<0.05$, Fig. 1). SOL strain was greater when SOL or SOL+GL+GM was stimulated than if GL, GL+GM or GM were stimulated ($P<0.01$). When only GL was activated, GL strain was greater than when SOL or GM were activated ($P<0.01$). When all three muscles were activated, GL strain was similar to that when GL or GL+GM were activated. When GL+GM were activated, the strain in GL was greater than when GM was activated ($P<0.001$).

Ankle moments were 3.9±2.4 mN in SOL, 32.9±6.7 mN in SOL+GL+GM, 16.9±5.6 mN in GL, 29.5±5.9 mN in GL+GM and 12.8±2.9 mN in GM stimulation condition. There was a main effect of stimulation condition ($P<0.001$) with all conditions differing from each other except in GL and GM conditions the moments were similar.

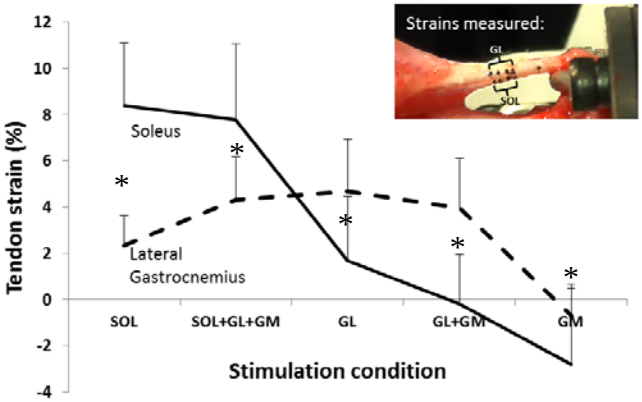

Figure 1: Mean (SD) strains of soleus and lateral gastrocnemius subtendons in response to stimulation of different muscles: SOL: soleus was stimulated, SOL+GL+GM: all triceps surae muscles were stimulated etc. Inset shows the location of the markers and the strains measured. * $P<0.001$ between subtendons.

DISCUSSION

Within AT, the subtendons originating from SOL and GL muscles were shown to experience differential strains. Although SOL is a smaller muscle and produces lower moments when activated, the greatest strains were found in SOL subtendon. When all muscles were stimulated simultaneously, SOL strain was nearly twofold compared to GL strain. This indicates that the SOL subtendon has a lower stiffness than GL. The negative strains observed upon GM activation suggest that the most distal parts of GL and SOL were pulled proximally, or that this result is due to error from inability of the two-dimensional analysis to quantify tendon rotation.

CONCLUSIONS

- We found differential strains in SOL and LG subtendons conforming to humans imaging studies reporting that AT can undergo shear deformation.
- Activation of either SOL or LG muscle resulted in strain within the subtendon of the other, suggesting that these subtendons do not act fully independently.

ACKNOWLEDGEMENTS

DO TRICEPS SURAE MUSCLE DYNAMICS GOVERN NON-UNIFORM ACHILLES TENDON DEFORMATIONS?

William H. Clark and Jason R. Franz

Corresponding author email: jrfranz@email.unc.edu

INTRODUCTION

The Achilles tendon (AT) consists of distinct bundles of tendon fascicles arising from the gastrocnemius (GAS) and soleus (SOL) muscles that may act as mechanically independent structures. Indeed, we have shown that these "sub-tendons" exhibit non-uniform displacement patterns during walking, which may reflect sliding between adjacent tendinous structures [1]. While the mechanisms governing these non-uniform displacement patterns have remained allusive, recent computational model predictions implicate differential GAS versus SOL muscle loading as a biomechanical candidate [2]. Here, we implemented a novel dual-imaging approach to investigate triceps surae muscle loading as a determinant of non-uniform AT tissue displacements during ramped isometric contractions. We hypothesized that superficial versus deep differences in AT tissue displacements would be accompanied by (and correlate with) anatomically consistent differences in GAS versus SOL muscle shortening.

METHODS

We have thus far collected data for 5 subjects (age: 27.6 ± 6.3 years, mass: 73.7 ± 6.3 kg, height: 1.8 ± 0.1 m, 1 female and 4 males). Subjects performed three ramped maximum voluntary isometric contractions at each of five ankle joint angles spanning 10° dorsiflexion to 30° plantarflexion in an isokinetic dynamometer (Biodex System 4 Pro), with the knee flexed to replicate that near the push-off phase of walking. We synchronized two linear array ultrasound transducers to simultaneously record GAS and SOL fascicle kinematics with tissue displacements in their associated tendinous structures (Fig. 1A). A 60 mm Telemed Echo Blaster 128 transducer (LV7.5/60/128Z-2) placed over the medial gastrocnemius and soleus of subjects' right leg recorded cine B-mode images at 86 frames/s. Simultaneously, a 38-mm transducer (L14-5W/38, Ultrasonix Corporation, Richmond, BC) operating at 70 frames/s recorded ultrasound radiofrequency (RF) data from a longitudinal cross-section of the right free AT, distal to the SOL muscle-tendon junction and secured via a custom orthotic. Finally, motion capture tracked right ankle and knee joint kinematics and the positions and orientations of both probes. Available Matlab routines based on an affine extension to an optic flow algorithm quantified time series of GAS and SOL fascicle lengths and pennation (UltraTrack, [3]), which we combined to compute longitudinal muscle lengths. A custom 2D speckle-tracking algorithm estimated localized displacements of AT tendon tissue, which we averaged in two equally sized tendon depths - superficial and deep - corresponding to tendon tissue thought to arise from GAS and SOL, respectively [1].

RESULTS AND DISCUSSION

For all conditions, SOL shortened by an average of 54% more than GAS during force generation (Fig. 1B). This was accompanied by, on average, 45% more lengthening in the deep versus superficial region of the AT (Fig. 1B). The magnitude of GAS and SOL muscle shortening during force-generation positively correlated with lengthening in their associated regions the AT ($p<0.05$) (Fig. 1C). Moreover, and consistent with our hypothesis, superficial versus deep differences in AT lengthening positively correlated with anatomically consistent differences in GAS versus SOL muscle shortening. ($p<0.05$) (Fig. 1D).

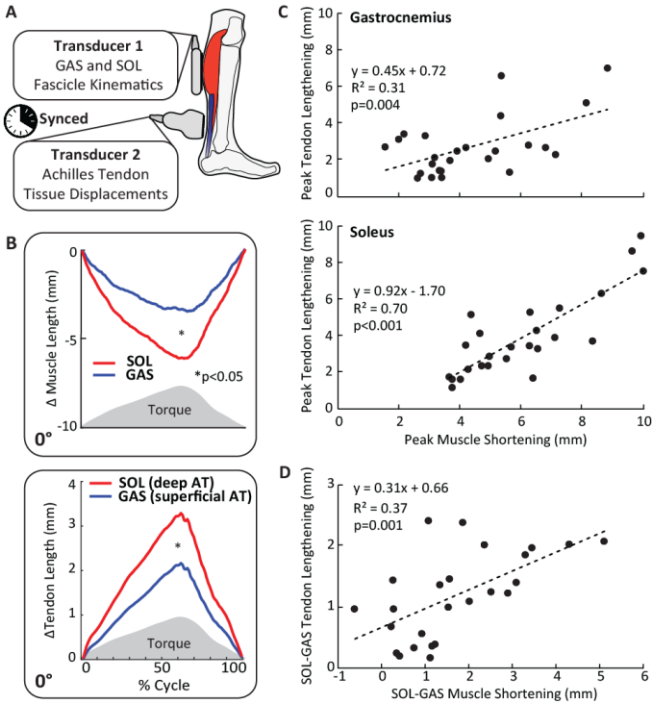

Figure 1. (A) Dual-imaging of the GAS, SOL, and free AT. (B) Group average results for the 0° condition (n=5). (C) Correlations between peak GAS or SOL muscle shortening and lengthening in their associated regions of the AT across all conditions. (D) Correlation between superficial versus deep differences in AT lengthening and GAS versus SOL differences in muscle shortening across all conditions.

CONCLUSIONS

We present *in vivo* evidence that triceps surae muscle dynamics may precipitate non-uniform displacement patterns in the architecturally complex Achilles tendon. Moreover, we present a novel dual-imaging approach to empower simultaneous *in vivo* assessment of muscle and tendon toward an improved mechanistic understanding of triceps surae behavior. Our findings may have important implications for understanding age-associated changes in AT displacement patterns [4], which we suspect alter the muscle contractile behavior of older adults.

MEASURING CHANGES IN MUSCLE AND TENDON STIFFNESS FOLLOWING EXERCISE INDUCED MUSCLE DAMAGE USING SHEAR WAVE ELASTOGRAPHY

[1,2]**Luke J Heales**, [1]Rohitha Badya, [1]Brandon Ziegenfuss, [1,3]Francois Hug, [1]Jeff Coombes, [1]Wolbert van den Hoorn, [1]Kylie Tucker and [1]Brooke Coombes

INTRODUCTION

Understanding the mechanical adaptation of muscle and tendon in response to acute exercise could have important implications for athletic performance, injury prevention and rehabilitation. Unaccustomed strenuous eccentric contractions can result in disruptions to cytoskeletal structures and impairments of neuromuscular function, typically referred to as exercise-induced muscle damage (EIMD) [1]. EIMD is characterised by muscle soreness, which is delayed in onset, typically peaking after 48 hours and resolving within one week [2,3]. Although EIMD is well documented in the literature, an integrated appreciation of the mechanical adaptation of muscle and tendon within the musculotendinous unit is lacking. We aimed to determine whether the mechanical properties of rectus femoris (RF), vastus medialis and lateralis (VM and VL) and the patellar tendon are altered following a single bout of maximal eccentric exercises of the knee extensor muscles.

METHODS

Thirteen participants (7 females, 6 males, aged 22.4 ±3.5 years, height 168.4 ±8.1 cm, weight 65.1 ±13.0 kg), with no history of lower limb injury were recruited. Participants sat in an isokinetic dynamometer with the non-dominant knee positioned at 70° of flexion. An ultrasound shear wave elastography technique (Supersonic Shear Imaging) was used to obtain shear wave velocity (SWV) measures (as an index of tissue stiffness) from VM, VL, RF and the patellar tendon, before, immediately after, and 48-hours after 5 sets of 20 maximal eccentric contractions of the knee extensor muscles. Maximal voluntary isometric contraction (MVIC), self-reported pain and stiffness (by numerical rating scales), and serum creatine kinase (CK) were measured as traditional indices of EIMD. Separate one-way repeated measures analysis of variance (ANOVA) assessed the effects of time (Pre, Post, 48-Hours) on muscle stiffness (VM, VL, RF), patellar tendon stiffness, MVIC, self-reported pain and stiffness, and CK (Pre & 48-Hours only).

RESULTS AND DISCUSSION

Immediately following eccentric exercise, MVIC decreased (–20%, $p<0.001$) and self-reported stiffness increased (384%, $p=0.027$). After 48-hours, CK levels increased (189%, $p=0.017$), self-reported pain increased (3834%, $p=0.002$) and MVIC remained decreased (–15%, $p=0.003$) compared to baseline. SWV was increased immediately following eccentric exercise returning to baseline values after 48-hours for VM ((Mean Difference (95% CI)) 0.23m/s (0.02 to 0.44), $p=0.017$), RF (0.51m/s (0.30 to 0.72), $p<0.001$), and the patellar tendon (1.2 m/s (0.05 to 2.4), $p=0.039$). No significant differences were observed for VL immediately post eccentric exercise or at 48-hours.

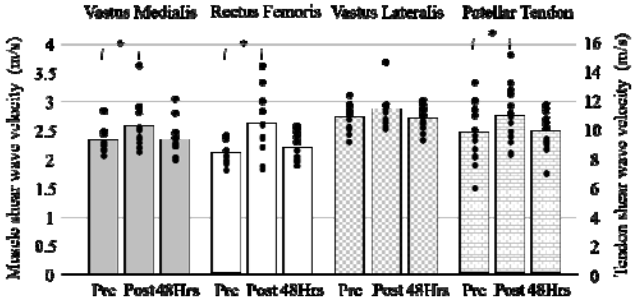

Figure 1: Muscle and tendon shear wave velocity measures obtained before (Pre), immediately post (Post) and 48-hours (48Hrs) following a single bout of maximal eccentric exercise of the knee extensor muscles. Data are presented as mean (bar graph) and individual variation (each dot represents one participant).

Our findings of an immediate increase in muscle stiffness following eccentric exercise are consistent with previous evidence using shear wave elastography [2]. Variation in the behavior between the quadriceps muscles might be explained by difference in the architecture (e.g. biarticular vs monoarticular, optimal fibre length and fibre type, physiological cross sectional area) and coordination of individual muscles during the eccentric task. This is the first study to investigate changes in tendon stiffness following eccentric exercise using shear wave elastography. Increased tendon stiffness following eccentric exercise may reflect increased tension of in-series muscle or changes within the local tendon matrix. This warrants further investigation.

CONCLUSIONS

In untrained participants, acute eccentric exercise of the knee extensors, which induced typical features of muscle soreness and damage, produced an immediate increase in muscle and tendon stiffness, resolving by 48-hours.

INCREASED ACHILLES TENDON LOADS AT SLOW WALKING SPEEDS QUESTION PROGRESSIVE LOADING PROTOCOLS IN TENDINOPATHY

INTRODUCTION

Achilles tendon rehabilitation protocols commonly recommend a gradual increase in walking speed to progressively intensify tendon loading. In particular, slow walking is specifically recommended early in the management of Achilles tendon disorders in order to lower tendon force, with progressively faster gait speeds recommended later in the course of treatment to increase tendon loading as pain allows [1]. This study used transmission–mode ultrasound to evaluate the influence of walking speed on loading of the human Achilles tendon in vivo.

METHODS

The Axial transmission speed of ultrasound was measured in the right Achilles tendon of 33 adults (mean ± SD; age, 29±3 years; height, 1.725±0.069 m; weight, 71.4±19.9 kg) during unshod, steady-state treadmill walking at three speeds (slow, 0.85±0.12ms; preferred, 1.06±0.13m/s; fast, 1.35±0.20 m/s). Axial acoustic velocity was measured in the right Achilles tendon using a custom built ultrasonic device and a five element ultrasound probe. The probe consisted of a 1MHz broadband pulse emitter and four regularly spaced receivers (range, 7.5 mm) and was positioned over the midline of the posterior aspect of the Achilles tendon, with the emitter located approximately 1cm above the calcaneus. Ankle kinematics (flexible twin–axis strain–gauge electrogoniometer, Penny and Giles, Biometrics, Gwent, UK), spatiotemporal gait parameters and vertical ground reaction force (instrumented treadmill system (Zebris Medical GmbH, Isny, Germany) were simultaneously recorded. Statistical comparisons were made using repeated measure ANOVA models (α=.05).

RESULTS AND DISCUSSION

Increasing walking speed was associated with higher cadence, longer step length, shorter stance duration, greater ankle plantarflexion, higher vertical ground reaction force peaks and a greater loading rate ($P < .05$). Maximum ($F_{1,38}=7.38$, $P < .05$) and minimum ($F_{1,46}=8.95$, $P < .05$) ultrasound transmission velocities in the Achilles tendon were significantly lower (16–23 m/s) during the stance but not swing phase of gait, with each increase in walking speed (Table 1).

Peak transmission velocity of ultrasound in the Achilles tendon in our study was comparable to that reported previously for human tendon (≈1900–2050 m/s) [2,3] and was of a similar pattern to the biphasic force profile reported for the Achilles tendon during overground walking when measured directly with implanted force transducers [4,5]. However, in contrast to the latter studies in which peak Achilles tendon force was found to be relatively invariant to changes in walking speed between 1.1m/s and 1.8 m/s [4,5] we observed a progressive decrease in axial transmission velocity of ultrasound in the Achilles tendon over walking speeds of 0.85 m/s to 1.35 m/s.

CONCLUSIONS

Despite higher vertical ground reaction forces and greater ankle plantarflexion, increasing walking speed resulted in a reduction in the axial transmission velocity of ultrasound in the Achilles tendon; indicating a speed–dependent reduction in tensile load within the gastrosoleus muscle–tendon unit during walking. These findings question the rationale for current progressive loading protocols involving the Achilles tendon, in which reduced walking speeds are advocated early in the course of treatment to lower Achilles tendon loads.

INTRODUCTION

The torque produced by a muscle results from the interplay between its activation by the nervous system and several biomechanical characteristics. This issue is fundamental to understanding the control of almost every joint in the body. There is some evidence that muscle activation is biased by muscle torque-generating capacity [1]. However, it remains unclear how muscle coordination strategies adapt to differential acute changes in the mechanical properties of individual synergist muscles. The *triceps surae* muscle group, which is pivotal for functional tasks such as walking, is an ideal model to understand how muscle activation adapts to differential changes in mechanical characteristics between synergist muscles. Taking advantage of elastography, our group [2] has shown that passive dorsiflexion induces a much larger increase in stiffness of GM than GL and SOL when the knee is fully extended. The aim of this study was to determine how the relative activation of the three heads of the *triceps surae* during submaximal contractions adapts to differential changes in passive mechanical properties between these muscles.

METHODS

Twenty-four volunteers participated in this study. They were positioned lying prone on a dynamometer at three ankle angle [30° in plantar flexion (PF 30°), 0°, and 25° of dorsiflexion (DF 25°)]. Myoelectrical activity was recorded with surface EMG electrodes placed over the GM, GL, and SOL. An Aixplorer ultrasound scanner (v6.0, Supersonic Imagine, France) coupled with a linear transducer array (2–10 MHz, Vermon, France) was used to measure the GM, GL, and SOL shear modulus (index of stiffness). At each ankle angle, the passive shear modulus was first measured for each muscle. Then, two maximal isometric voluntary (MVC) *plantarflexions* were performed. An experimental task involved matching a submaximal target force set at 20% of the MVC torque achieved at the tested ankle angle. During the force-matched submaximal contraction, either myoelectrical activity (RMS EMG, % RMS EMGmax) or shear modulus (index of individual muscle force [3]) of the GM, GL and SOL was measured. To test the effect of ankle angle on resting muscle shear modulus, we performed a repeated measures ANOVA (muscle [GM, GL and, SOL] and angle [PF 30°, 0°, and DF 25°]). To determine whether the RMS EMG or muscle shear modulus was influenced by changes in ankle angle during submaximal contractions, a repeated measures ANOVA was performed (muscle [GM, GL and, SOL] and angle [PF 30°, 0°, and DF 25°]).

RESULTS AND DISCUSSION

We observed a significant angle × muscle interaction on resting shear modulus (P<0.001). According to a previous study [2], the shear modulus measured at DF 25° was higher for GM than both GL (P<0.001) and SOL (P<0.001). At 20% of MVC, we observed a significant interaction between muscle × angle in RMS EMG (P=0.010). The RMS EMG value was significantly lower for GL at both 0° (P<0.001) and DF 25° (P<0.005) compared to PF 30° (Fig. 1). There was no significant change for GM and SOL (P values>0.08). Similarly, a significant muscle × angle interaction was found on shear modulus (P<0.001). GM muscle exhibited higher shear modulus values than GL and SOL at both 0° (P<0.001) and DF 25° (P values<0.001) (Fig.1). No difference between GL and SOL (all P values>0.06).

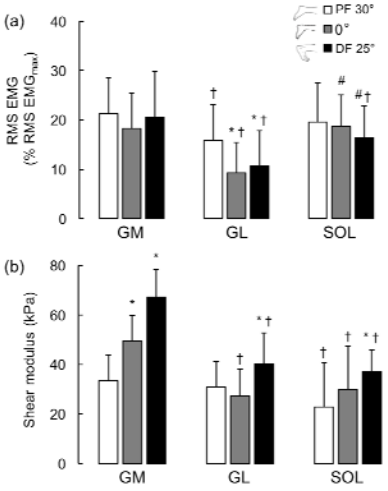

Figure 1. Myoelectrical activity [RMS EMG, (a)] and shear modulus (b) of the gastrocnemius medialis (GM), gastrocnemius lateralis (GL) and soleus (SOL) measured at 30° of plantarflexion (PF 30°), 0°, and 25° of dorsiflexion (DF 25°) during an isometric plantarflexion performed at 20% of MVC. *P<0.05: compared to PF 30°; †P<0.05: compared to GM; $^{\#}$P<0.05: between GL and SOL.

CONCLUSIONS

The present study showed that the neural drive during submaximal *plantarflexion* task did not compensate for an acute change in the balance of the passive mechanical properties between the individual heads of the *triceps surae*, leading to a change in force sharing between synergist muscles. These results may also have clinical relevance as they provide a basis on which to consider the potential for an imbalance of force between synergist muscles as a contributing factor to the development of Achilles tendon problems.

INTRODUCTION

Spastic cerebral palsy (sCP) is the most common childhood development disorder caused by damage to the motor cortex and the pyramidal tracts of the brain [1]. It is associated with stiff muscles which affects movement and posture. sCP is a non-progressive neuromuscular disease that spans throughout lifetime with no proper cure, hence diverse interventions are employed for restoration of motor activities [2]. Most of these interventions emphasize on muscular activity restoration, neglecting neuronal aspect. Our approach with repetitive Transcranial magnetic stimulation (rTMS) combined with physical therapy (PT) was aimed at understanding changes in the neuromuscular behavior which demonstrated significant improvement in motor abilities along with reduction in muscle spasticity [3, 4]. rTMS is a non-invasive brain stimulation technique wherein repetitive magnetic pulses are delivered into the brain's soft tissues through the cranium. These magnetic pulses cause excitation of the underlying motor neurons and their inhibited pathway thereby stimulating the muscles [1]. The muscles when trained using PT start to regain activity, improving the motor activity of the patient. In this study, our aim was to evaluate the effect of changes in rTMS pulse characteristics on gross motor function and muscle spasticity of sCP children.

METHODS

Twenty one (21) children diagnosed with sCP by physicians or pediatric neurologists participated in this study after obtaining written informed consent from their parents or guardians and approval from the institutional ethics committee (IECHSP) for employing human participants. They were equally divided into three groups namely P1500, P2000 and P2500 with mean age 6.86±3.73, 7.17±5.78 and 5.98±3.36 respectively. Universally accepted assessment tools namely Gross Motor Function Measure (GMFM) and Modified Ashworth Scale (MAS), were used to evaluate the motor ability and muscle spasticity of selected patients. MAS was applied to biceps, supinator, wrist extensor of upper limb and hamstring, gastrocnemius, soleus and adductor of lower limbs. Prior to start of therapy, pre assessment of GMFM and MAS scores was performed by trained physical therapists and doctors on the participants. All participants were delivered 10Hz rTMS frequency by varying stimulation pulses for 15 minutes duration daily followed by 30 minutes of PT for 20 days. Participants in the group P1500 were administered with 1500 pulses of stimulation, P2000 with 2000 pulses and P2500 with 2500 pulses. After completion of 20 sessions, post assessment of GMFM and MAS scores was performed again. Statistical analysis of GMFM and MAS scores of different groups was performed using SPSS 20.0 (Armonk, NY, IBM Corp., USA) and the change in mean score was calculated to evaluate the degree of improvement induced by different pulses on the motor activity and muscle spasticity of these children.

RESULTS AND DISCUSSION

The paired sample *t*-test of pre versus post GMFM scores of different groups were found to be statistically significant ($p<0.01$) with t = -4.18, t = -6.19 and t = -4.98 for P1500, P2000 and P2500 respectively. The improvement in gross motor function of sCP patients between different groups were 2.19%, 3.32% and 4.29% for P1500, P2000 and P2500 groups respectively (Fig 1A). Similarly, MAS scores also demonstrated that muscle spasticity reduced significantly both in upper and lower limbs in group P2500 as compared to P2000 and P1500. The results indicate that increasing rTMS pulses can lead to faster achievement of functional activity in limited number of therapy sessions (Fig 1B).

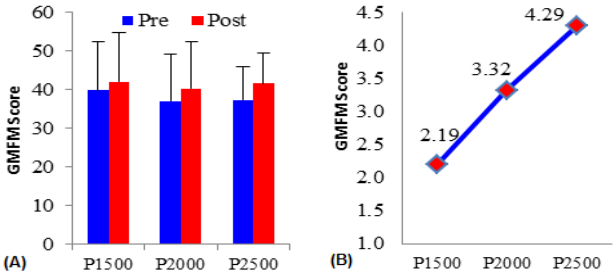

Figure 1. Effect of different rTMS pulses in (A) motor function with SEM and (B) relative functional gain (%) in motor function.

The effect of varying rTMS pulses observed in this study can be attributed to the induced neuroplasticity [5] that leads to better functional gain in motor activity. Furthermore, from safety prospective it was observed that during rTMS therapy none of the patients complained of any side effects or seizures. Moreover, the parents reported that their wards showed improvement in cognitive functions which was validated after analyzing EEG recordings of these patients using EEGLAB.

CONCLUSIONS

This study demonstrated two results – one, rTMS is effective in improving gross motor functions by reducing muscle spasticity in limited number of sessions; and two, increasing the numbers of pulses could lead to faster milestone achievement in motor development in sCP patients provided they are within safety limits as prescribed.

DOES HIP ABDUCTOR FUNCTION INCREASE AFTER A FEMORAL DEROTATION OSTEOTOMY IN INDIVIDUALS WITH CEREBRAL PALSY?

[1]Elizabeth R. Boyer, [1]Tom F. Novacheck, and [1,2]Michael H. Schwartz

INTRODUCTION

One reason to perform a femoral derotation osteotomy (FDO) in children with cerebral palsy (CP) is to correct coronal plane hip abductor moment arms, which should functionally strengthen the abductors. Despite this widespread logic, there is a paucity of hip kinetics reported post-FDO [1,2]. We measured if hip abductor moment, a functional measure of hip abductor utilization, increased approximately one year and five years post-FDO in individuals with bilateral CP.

METHODS

A retrospective analysis of our database was performed to identify individuals with CP who were ≤18 years old at preoperative analysis and could ambulate without an assistive device. Additional gait analyses that were approximately one year (short-term) and at least three years post-FDO (mid-term) were compared. The primary outcome was dimensionless mean hip abductor moment during single-support [3]. Secondary outcomes included anteversion, mean hip rotation, and estimated coronal plane hip abductor moment arm derived from a musculoskeletal model that included both anteversion and hip rotation [4]. Wilcoxon signed rank or paired t-tests were used as appropriate ($p<0.05$). A Bonferroni correction was applied.

RESULTS AND DISCUSSION

There were 135 individuals who met the short-term criteria and 37 for mid-term. Most FDOs were performed proximally. Hip abductor moment remained unchanged at short-term (Table). This was unexpected given that anteversion and internal hip rotation decreased 35° and 13°, respectively, which increased estimated hip abductor moment arm. On average, hip abductor moment at mid-term improved from 43% less than typically developing to 23% less than typically developing. For 49% of individuals, the increase in moment (pre- to mid-term) exceeded our minimal detectable change, while it did not change for 43%, and decreased for 8%. The overall improvement in moment was observed along with 11° of recurrent internal hip rotation (which would increase moment arms) and no change in other measured kinematics, strength, or walking velocity. The unchanged hip abductor moment from pre- to short-term may be attributed to gait compensation that unloads the hip to avoid pain from retained implants, whereas the increase from short- to mid-term may be due to implant removal or greater rehabilitation time.

CONCLUSIONS

Clinicians should be aware that, on average, hip abductor moment does not improve in the short-term post-FDO but does improve after implant removal three or more years later. This mid-term increase in hip abductor function post-FDO underscores the benefits of an FDO into adolescence for independent ambulating individuals with CP.

INTRODUCTION: Idiopathic toe walking (ITW) is a condition seen in children with no underlying motor or neurological disorder and is characterised by an increase in plantarflexion during gait. Intervention for an ankle plantarflexion contracture commonly involves lengthening of the triceps surae muscle-tendon unit. Surgery options can be divided into three broad categories based on the location of the excision: Zone 1 - the gastrocnemius (GAS) muscle belly, Zone 2 - the level of the GAS tendon / soleus (SOL) muscle, and Zone 2 – the Achilles tendon. The greatest length increase is achieved with Zone 3 surgery [1] and therefore this is the most frequently chosen intervention [2-4]. Despite the popularity of Zone 3 surgery, Delp et al. [5] showed using a musculoskeletal model that a lengthening procedures to isolate the GAS might preserves the length tension relationship of the SOL and prusumabley ankle push-off power during walking. Thus, if the contracture is limited to the GAS there is evience to suggest at that Zone 1 or 2 surgery may be benificial. The aim of this study was to investigate post-operative outcomes of chidren who presented to the Queensland Children's Motion Analysis Service (QCMAS) between the years of 2009 and 2015 and were treated with Zone 1 – Zone 3 surgery in isolation.

METHODS: A retrospective search of the QCMAS database was performed to locate data for children who had undergone calf lengthening surgery for ITW. Sixteen patients with a mean age of 9.6± 2.22 years were included in the study. Of these patients 70% received Zone 2 surgery and 30% received Zone 1 surgery. Data collection for all participants was conducted according to the standard clinical protocol in QCMAS. Briefly, reflective markers were attached to the trunk, pelvis and lower limbs in accordance with the Plug in Gait model [6]. Participants were instructed to perform approximately 25 gait trials. Marker trajectory reconstruction and labelling was performed in Vicon Nexus. MSK modelling using a modified gait2392 model was used to output inverse kinematics and inverse dynamics, and muscle analysis was performed in OpenSim (v3.3)[7]. Pre to post surgery comparisons were performed in SPSS (v22) using a repeated measures general linear model. Dependent variables included ankle joint kinematics, ankle power and muscle tendon length estimates for medial gastrocnemius.

RESULTS AND DISCUSSION: On clinical examination there was a mean maximum dorsiflexion range of -17.5±7.0 degrees pre-surgery and 6.3±3.5 degrees post-surgery. Post-operative gait analysis results revealed a significant improvement in ankle dorsiflexion at initial contact (-30.5 degrees compared to -6.7 degrees) and in the peak ankle dorsiflexion achieved in mid-stance (-8.2 degrees compared to 6.9 degrees) (Figure 1). Kinetic results revealed no statistical difference in peak ankle power during push off, although post-surgery power tended to be slightly improved. Musculoskeletal model results revealed that the peak muscle tendon length during gait was increased by approximately 4cm post-surgery (Figure 1). Taken together with the findings of Firth et al. [1] and given that 70% of the participants in this study were treated with Zone 2 lengthening our results indicate that Zone 2 lengthening procedures produce calf length increases comparable to those seen in Zone 3 lengthening's.

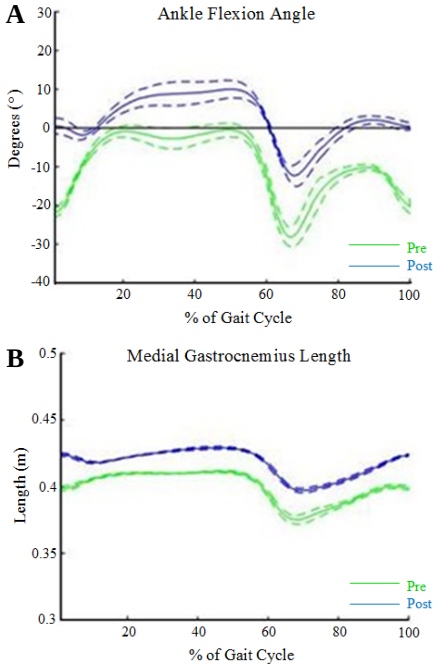

Figure 1: (A) Ankle flexion angle and (B) medial gastrocnemius muscle length pre- and post-surgery for a representative participant.

CONCLUSION: The use of Zone 2 calf lengthening for patients presenting with calf contracture was successful in increasing calf length and improving ankle dorsiflexion, without diminishing ankle power during push off.

SUPPRESSION OF RESTING TREMOR BY SENSORY ELECTRICAL STIMULATION IN PATIENTS WITH PARKINSON'S DISEASE

[1]**Jae-Hoon Heo**, [1]Ji-Won Kim, [1]Hyeong-Min Jeon, [1]YuRi Kwon, [1,#]Gwang-Moon Eom, [2]Do-Young Kwon

INTRODUCTION

Parkinsonian tremor is one of the core features of Parkinson's disease (PD). It is caused by malfunction of the movement control in the brain. The most common tremor in PD is the tremor during rest, called "resting tremor" [1].

Traditional treatment of parkinsonian tremor includes medication and surgery. Medication often induces unwanted side-effects such as tardive dyskinesia and akathisia. Typical surgery implants electrodes in the brain to apply electrical stimulation, but it may provoke disorders of brain [2].

As a new method to reduce tremor, we proposed "sensory electrical stimulation" which was defined as the stimulation with the intensity smaller than the motor threshold. In a previous study [3], we confirmed the effect of sensory stimulation in essential tremor (ET), but parkinsonian tremor was not tested. The tremor suppression was argued to be due to re-functioning of motor-command generation network in the brain, initiated by the sensory feedback signal of the electrical stimulation. This mechanism may work on the parkinsonian tremor, because parkinsonian tremor is also coming from the malfunction of motor command generation pathways.

Therefore, the purpose of this study was to investigate the effect of sensory stimulation on the parkinsonian tremor, specifically on the resting tremor.

METHODS

Ten patients with PD (7 males and 3 females, 60.9 ± 14.0 yrs) participated in this study. Sensory stimulation was applied on flexor carpi radialis, extensor carpi radialis, abductor pollicis brevis, and flexor pollicis longus.

Three-dimension (3D) gyro sensors were attached on index finger and thumb. Resting tremor was measured with the hand on thigh (palms up posture) for three sessions, i.e., pre-stimulation (Pre), during stimulation (On), and 5 minute after stimulation (Post). Three trials were repeated in each session. Three dimensional angular velocities at index finger and thumb were filtered by 4-7 Hz band-pass filter [4]. Root-mean-square (RMS) value was calculated for the angular velocity of each direction. We performed repeated measure 1-way ANOVA and post-hoc pairwise comparisons (Bonferroni). The significance level was set to 0.05.

RESULTS AND DISCUSSION

Fig. 1 shows RMS angular velocities at index finger and thumb. In overall, the sensory stimulation was effective on both fingers, though detailed tremor amplitude pattern of Pre-On-Post sessions was rather different between fingers. Monotonic decrease of tremor during and after the stimulation was shown at thumb, but the once-reduced tremor during stimulation (On) tended to be partly recovered 5 min after stimulation (Post) at index finger.

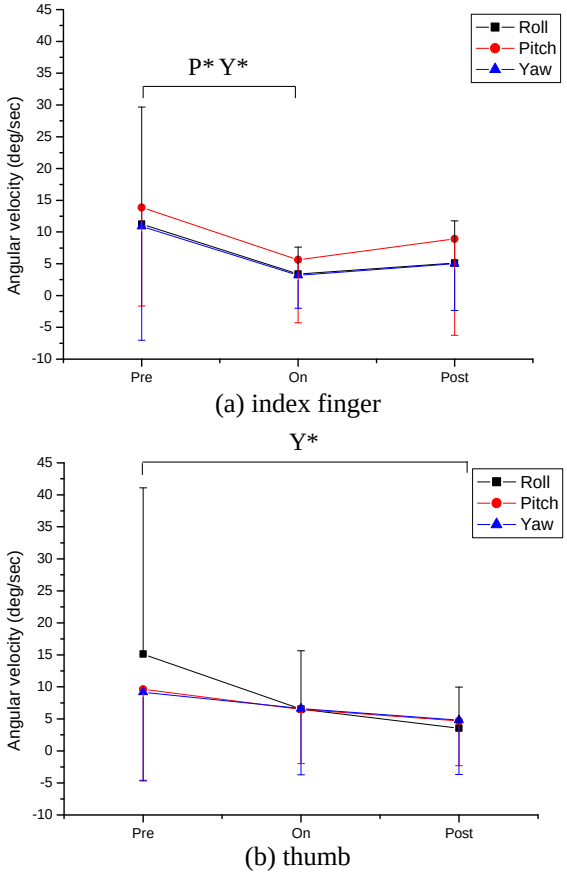

Figure 1: 3D RMS angular velocity for different sessions at index finger (a) and thumb (b)

CONCLUSIONS

Parkinsonian tremor was suppressed by sensory electrical stimulation at index finger and thumb.

COMPUTATION OF JOINT CONTACT PRESSURE IN A PATIENT SPECIFIC ANKLE MODEL

[1, 2] **Ivan Benemerito**, [1, 3] Luca Modenese, [1, 3] Erica Montefiori, [1, 3] Marco Viceconti, [1, 3] Damien Lacroix, and [1, 2] Lingzhong Guo

INTRODUCTION

The onset of degenerative joint diseases such as osteoarthritis has been linked to abnormal or excessively high pressure distribution within the articular cartilage [1]. A precise knowledge of this distribution would be helpful for understanding the mechanism of degeneration and early diagnostic [2]. *In vivo* measurements are however not possible, and *in silico* techniques such as the finite element method (FEM) represent a promising alternative, although their use in the clinical practice is still limited by the intense training and long computational time required [2].

The Discrete Element Method (DEM) is a computational technique which provides a fast evaluation of the joint contact pressure, with results agreeing well with FE predictions [2]. Initially developed for static problems, each time step in a full gait simulation is taken as independent of the others. This results in initial conditions at each time step of the simulation which may differ from the physiological ones, leading to models which don't accurately reproduce the natural behaviour of the joint. Furthermore, potential prestress is neglected, making this method hardly applicable to viscoelastic problems [3].

We propose here a patient specific DEM-based ankle model which tracks the position of tibia and talus during the whole gait cycle, and we use it to compute contact kinematics, contact area and joint contact pressure during one gait cycle.

METHODS

Ankle MRI scans of a female subject (16 years, 160 cm, 68 kg) were acquired and segmented to extract bones' geometries and inertial properties. A patient specific musculoskeletal model, with the ankle defined as a hinge joint, was used to compute the joint contact forces through a standard inverse kinematics and inverse dynamics approach in OpenSim [4].

The surfaces of right tibia and talus were imported into MATLAB (The MathWorks, Natick, MA), discretized in triangles and registered with angles obtained from inverse kinematics. Each bone was covered by a uniformly thick cartilage layer, modelled as a bed of compressive springs, extruded along the normal direction to the subchondral bone surface. The prestress of the cartilage, necessary to compute the contact kinematics, was also included. Four ligaments were added to restrict the movement of the talus.

At each time step, tibia and talus were oriented according to the measured joint angle, the ankle contact force was applied and the equilibrium equation solved for the displacement of the talus. This was then used to compute, iteratively, contact pressure and contact area, and to update the position of the talus.

RESULTS AND DISCUSSION

Solving the problem for 249 time steps took 19 minutes. The contact pressure attains its maximum value, 13.74 MPa, in line with FE [5] and experimental results [6], immediately before the toe off. The maximum is always located in the posterolateral part of the talus where, in this individual, the distance between tibia and talus is minimum. Figure 1 shows the pressure distribution on the talus at the instant when the maximum value is attained.

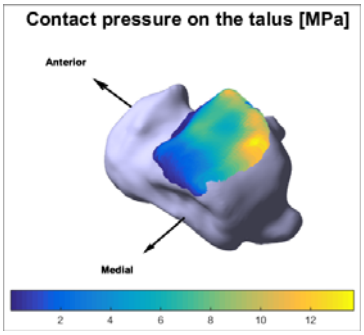

Figure 1 Contact pressure on the talus

Articular cartilage is fully engaged in contact for the majority of the cycle, with average contact area of 7.83 cm^2.

CONCLUSIONS

The model gives fast estimations of the contact pressure occurring at the ankle joint, being at the same time respectful of its natural physiology. These model features are promising for potential future clinical applications requiring fast processing times.

The inclusion of the prestress, preliminary to the modelling of viscoelastic contact, is fundamental for the computation of contact kinematics because it allows the simulation of forward and backward movement of the talus which would otherwise not be possible.

RAPID DEVELOPMENT OF A 3D SIMPLIFIED PARAMETRIC FINITE ELEMENT FOOT MODEL

INTRODUCTION

Computational foot models have significant application in surgical decision making, injury and diseases diagnosis and prevention, sports performance analysis and footwear engineering. Traditional experimental methods to describe foot bones require either measurement of cadaveric specimens [1] or 3D image reconstruction from CT or MRI images [2]. These methods are both a time consuming and expensive part of building a computational foot model. Although the foot bone geometrical parameters are available for measurement and analysis, the relationships between the foot geometrical parameters and injury or performance are unknown.

The purpose of this study is to develop a computational parametric foot model based on CT section image data, standard shape fitting, and finite element auto meshing algorithms. Modeling the bones as rigid is common, but modeling the contact surfaces only saves computational resources. Priority, therefore, in the shape fitting with optimization is given to the contact surfaces between bones. We also use standard shapes such as ellipsoids and planes to fit our selected contact surfaces so that the geometrical parameters maintain physical significance. Finally, based on these parameters, we automatically meshed the least-squares fitted shapes and rapidly developed a 3D simplified finite element parametric foot model.

METHODS

First, we reconstructed foot bones from CT section images, and then we segmented bones with an improved 2D transfer function based on scalar value and gradient magnitude (SG-TF). Here we selected the talus as shown in Figure 1a, 1b, and 1c, respectively.

Next, we used Fast Approximate Nearest Neighbors Algorithm to automatically find and define contact surface between the talus and tibia, fibula, calcaneus, and navicular respectively as shown in Figure 1d.

Based on Sarrafian's description, we assume that all contact surfaces of talus may be described by ellipsoidal or planar shapes with 3D optimization (least squares) fitting. We then extracted the corresponding geometrical parameters.

Finally, we auto-meshed the talus contact surfaces using the parametrizable geometric relations, as shown in Figure 1e, for later finite element analysis.

RESULTS AND DISCUSSION

Results are shown step-by-step in Figure 1.

All methods we used and developed are general, automatic and robust.

The inputs of our system are CT files only. Very few manual operations and running time are needed in the whole process.

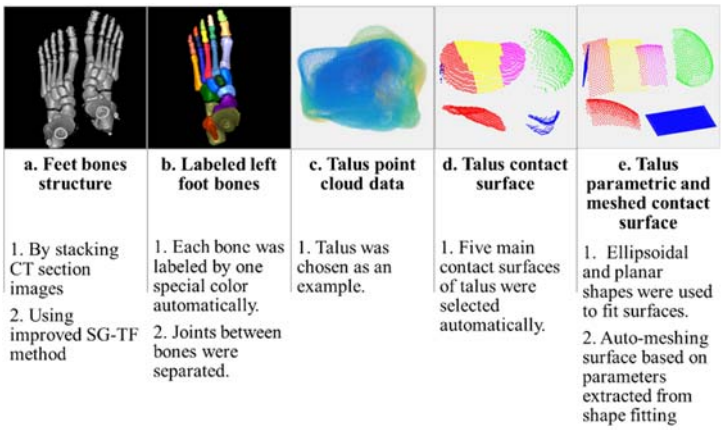

Figure 1: Step-by-step process for obtaining a 3D simplified parametric finite element model from CT section scanning, segmentation, optimized surface fitting with ellipsoids and planes, and finally FEA auto-meshing

CONCLUSIONS

In this manuscript we proposed an innovative method to develop a 3D simplified parametric foot model to reduce the time to build finite element models of the foot to speed the development of subject specific analysis. This work builds a new foundation by maintaining the geometrical relations of the joints to later investigate the relation between foot bone parameters and injury or biomechanical performance. We developed new image analysis algorithms for reconstructing foot bones and bone segmentation using the improved SG-TF method, optimization for geometric shape fitting using ellipsoids and planes to fit the contact surfaces, and finite element auto-meshing algorithms for later finite element analysis.

MODEL OF ENERGY TRANSFER IN THE FOOT DURING RUNNING

[1] **Ryan C Riddick** and [2]Art D Kuo

[2]University of Calgary

Corresponding author email: riddryan@umich.edu

INTRODUCTION

The biomechanical action of the human foot during locomotion is often examined in terms of joint power between rigid bodies. Such inverse dynamics-based analysis shows significant negative work at the metatarsophalangeal (MTP) joint, which may therefore be a major source of energy dissipation [1], and contribute to metabolic cost. However, inverse dynamics analysis depends on the assumed interactions across joints, and could yield significantly different results with other assumptions. The muscles, tendons, and ligaments on the plantar aspect of the foot cross multiple joints, and could potentially transfer energy across these components without being apparent from joint analysis. Indeed, recent evidence suggests that the MTP transfers energy to the plantar fascia [3]. We therefore developed a simple model to examine whether elastically conservative multi-joint energy transfer could explain the apparent single-joint energy dissipation observed during running.

METHODS

We compared a computational model of running with a two-segment foot to human running. The body was modelled as a point mass at the pelvis, with a leg spring sufficient to roughly produce human-like ground reaction forces and body center-of-mass motion (Fig. 1A). The foot is modelled with two segments: a rear-foot and fore-foot. One spring acts between the rear-foot and leg, analogous to the Achilles tendon, while another spring acts bi-articularly between the fore-foot and leg, analogous to the action of the foot arch and plantar fascia. For comparison, a separate point-mass foot model was also simulated.

All models were simulated to run with similar dimensionless speed and stance time as the human running data described in [2], where fore-foot runners ran at a speed of 2.7 m/s. We calculated inverse dynamics on the model to compare to the human data and tested whether inverse dynamics can exhibit apparent dissipation at the MTP joint, even though the model itself is fully energy-conservative.

RESULTS AND DISCUSSION

We compared the model's kinetics to humans [2], and found that the ground reaction forces were fairly similar (Fig. 1B). The model showed net negative work at the MTP and net positive work at the ankle, both roughly like observations of humans (Fig. 1C). However, because the foot model was elastic, it performed zero net work, and the negative work at the MTP joint was exactly offset by the positive work at the ankle joint. The overall effect of the two-joint model is summarized by the summed power of MTP and ankle (Fig. 1C), which approximately resembles the corresponding sum of humans, although humans do perform positive net work across both joints [2]. The instantaneous changes in the model foot is due to the foot having zero mass.

Re-examining the ground reaction forces, humans produce a relatively faster increase in ground reaction force compared to the slower decrease later in stance, an effect not captured by the mass-spring model with point foot. The two-segment model reproduces this time-asymmetry of human data.

Defining push-off as between the peak of the ground reaction force and toe off, a consequence of having a two-segment foot versus a point-foot is to increase the time over which push-off occurs (Fig. 1C). A longer contraction in this scenario is more efficient due to the relationship between muscle efficiency and contraction duration [3].

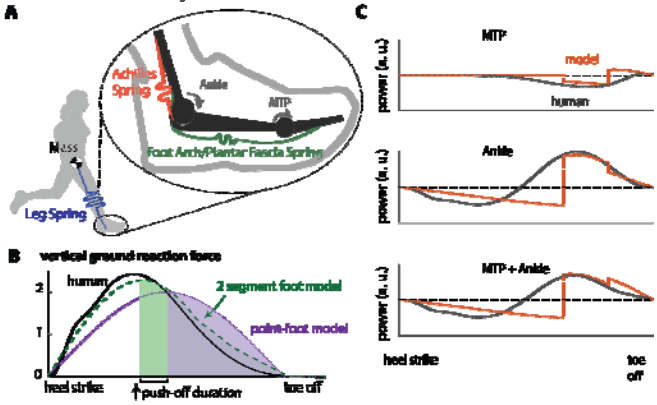

Figure 1. A) Description of 2-segment foot arch model. **B)** Comparison of ground reaction forces between 2-segment foot, point-foot, and human. **C)** MTP, ankle, combined joint power running of humans [2] vs model.

CONCLUSIONS

A simple model shows how energy apparently dissipated at the MTP joint during running might actually be transferred across the foot. This model is surely insufficient to explain the actual mechanics of human running, but it serves to illustrate how assumptions regarding multi-joint tendons can affect interpretation of inverse dynamics measurements. Apparent MTP dissipation could be transferred to other parts of the foot such as the arch or plantar fascia, although not with the perfect elasticity of model. Dissipation and energy transfer could have implications for understanding the function of the foot during running, and design of shoes, prosthetic feet, and robotic feet.

MUSCLE FIBER LENGTHS IN GASTROCEMIUS DURING RUNNING WITH REARFOOT AND FOREFOOT STRIKING

Jennifer R Yong, Christopher L Dembia, Amy Silder, Jennifer L Hicks and Scott L Delp
Stanford University
Corresponding author email: jryong@stanford.edu

INTRODUCTION

Forefoot striking (FFS) has gained popularity, but differences between this running pattern and the more common rearfoot striking (RFS) pattern are still being discovered. While it is known that there is greater Achilles tendon impulse per step during FFS [1], differences in muscle fiber lengths and velocities, which are important for understanding the force generating capacity of muscles, have not been analyzed. FFS involves running with a more plantarflexed ankle [2] and flexed knee [3] at initial contact, both of which could shorten the bi-articular medial gastrocnemius. Additionally, FFS results in greater muscle activity in the medial gastrocnemius during terminal swing phase [4]. Based on these kinematic and activation differences, we hypothesize that the medial gastrocnemius will have shorter fiber lengths at initial contact during running with FFS.

METHODS

Five healthy habitual RFS recreational female runners were recruited. Motion capture data and muscle activity were collected while subjects ran over ground at a self-selected speed using their natural RFS pattern and, after five minutes of gait retraining, using a FFS pattern.

To calculate normalized fiber lengths for the medial gastrocnemius, we ran EMG-driven simulations of the muscle-tendon dynamics. We first obtained subject-specific models in OpenSim [5] by scaling a musculoskeletal model [6] using markers placed on bony landmarks and calculated hip joint centers. We then calculated joint angles using OpenSim's Inverse Kinematics tool [5]. The EMG data were filtered using a 4th order critically damped filter with a cut-off frequency of 50 Hz, and normalized by peak activity over all running trials. We applied a 40ms delay to the EMG data to account for electromechanical delay. The EMG data and kinematics were used as inputs to a simulation of muscle-tendon dynamics of the gastrocnemius during the two running patterns. In our simulations, tendon strain was set to 4.9% at maximum isometric force. We used a paired t-test to compare normalized fiber lengths between RFS and FFS at initial contact.

RESULTS AND DISCUSSION

During late swing and early stance, fiber lengths of the medial gastrocnemius are shorter during FFS, with significantly shorter fibers at initial contact during FFS compared to RFS ($p < 0.001$) (Figure 1). As expected, fiber lengths are similar during the portion of the gait cycle when kinematics and muscle activity do not differ substantially, from mid-stance through early swing, and fiber lengths diverge when kinematics and muscle activity are known to differ between running patterns [2-4].

During terminal swing, our simulations show FFS exhibits higher medial gastrocnemius activity than RFS while fiber lengths are simultaneously positioned to be efficient at generating active force. In contrast, during RFS, the gastrocnemius is generating higher passive forces than FFS as its already longer fibers continue to lengthen before foot contact. During early stance, medial gastrocnemius fibers are primarily lengthening while active during FFS, but are shortening during RFS.

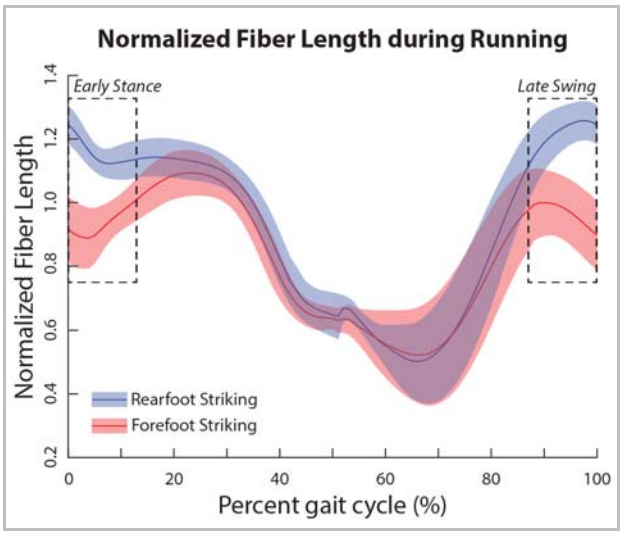

Figure 1: Normalized fiber lengths (mean ± one standard deviation) for RFS and FFS during running. Black dotted boxes indicate early stance and late swing.

CONCLUSIONS

Although the normalized fiber lengths are similar when kinematics are similar, fiber lengths shift towards shorter lengths in FFS during terminal swing and early stance. More work is needed to fully understand the differences in force-generating capacity of the muscles including testing alternate tendon compliances and considering the operating point along the force-velocity curve. However, we found that there are differences in the normalized fiber lengths based on muscle activity and kinematic differences between FFS and RFS. This analysis may be useful in understanding why muscle activation of the medial gastrocnemius differs between these gait patterns, and is a first step toward understanding differences in force generating capacity of this muscle between FFS and RFS.

A METHOD FOR CALCULATING THE VISCO-HYPERELASTIC MECHANICAL PROPERTIES OF THE HEEL PAD AND TO ASSESS THE EFFECTS OF THESE PROPERTIES ON THE PEAK PLANTAR PRESSURE

Sara Behforootan(*), Panagiotis E. Chatzistergos, Nachiappan Chockalingam and Roozbeh Naemi

INTRODUCTION: Pathological conditions such as diabetic foot are associated with changes in the mechanical properties of plantar soft tissue (Hsu et al., 2007). Previous studies involving age-matched groups of people with and without diabetes have indicated that plantar soft tissue tends to be stiffer (Chao et al., 2011) in diabetic patients. However, the causes and implications of these changes are not yet fully understood.

The aim of this study is to develop a clinically viable non-invasive method of assessing the mechanical properties of the heel pad and to investigate the effect of altered mechanical properties of tissue on its ability to evenly distribute plantar loads.

METHODS: A custom-made automated ultrasound indentation device (Chatzistergos et al. 2014) was utilised to perform quasi-static, dynamic and stress-relaxation tests at the apex of the calcaneus of five healthy participants (Fig. 1a). Subject-specific geometry (Fig. 1b) was reconstructed based on two ultrasound images of sagittal and frontal planes (Fig.1a) using a semi-automated method and subject-specific visco-hyperelastic material properties were inverse engineered based on the results from the quasi-static and stress-relaxation tests. The mechanical behaviour of the heel pad was simulated using the Ogden (1st order) hyperelastic material model, with strain energy function as follows:

$$W(\lambda_1,\lambda_2,\lambda_3) = \frac{1}{2}c_p(J-1)^2 + \frac{C}{m^2}(\bar{\lambda}_1^m + \bar{\lambda}_2^m + \bar{\lambda}_3^m - 3)$$

Where λi is the deviatoric principal stretches, J is the determinant of the deformation gradient and c_p, C and m are material parameters. Coefficients C and m are related to initial shear modulus and strain hardening respectively and c_p is directly related to the tissue's Poisson's ratio (v= 0.475). The time dependent mechanical behaviour of heel pad was simulated using the model shown below:

$$\boldsymbol{S}(t) = \int_{-\infty}^{t} G(t-s)\frac{d\boldsymbol{S}^e}{ds}ds,$$

Where $S(t)$ is the Piola Kirchhoff stress tensor, S^e is the stress that relates to the elastic behaviour of the tissue, $G(t)$ is the stress relaxation function, where g and t are the two material coefficients that are related to stain rate stiffening and relaxation time respectively.

Two different tests were performed for validation: 1) The calculated properties and ultrasound-based models of heel pad were used to simulate the cyclic dynamic tests and the numerically calculated maximum forces were compared against the data from in vivo measurement (Fig. 1a&b). 2) The inverse engineered mechanical properties is used in an anatomically accurate 3D model of the entire heel pad; (reconstructed based on MRI images); to simulate heel strike (Fig. 1c). Furthermore the numerically predicted peak plantar pressure (PPP) in heel strike was compared against the in vivo measurements (Fig. 1d).

A parametric study was performed to explore the effect of visco-hyperelastic material coefficients on the ability of the heel pad to evenly distribute loads. For this purpose, the abovementioned MRI-based model was used to calculate peak plantar pressure for the same external load and different values of visco-hyperelastic coefficients. Furthermore, 238 scenarios were investigated for hyperelastic coefficients in total, for 25%C_{ref}<C< 500%C_{ref} (C_{ref} = inverse engineered C value) and m between 25%m_{ref}<m<300%m_{ref} (m_{ref}= inverse engineered m value). In case of viscoelastic properties, 100 scenarios were explored in total for g and t values ranging between 25% and 200% of reference values (g_{ref}, t_{ref}).

RESULTS AND DISCUSSION: The average ± STDEV of calculated C, m, g and t for 5 participants were 41.48±26.61 kPa, 23.68±8.45, 0.65±0.23 and 3.62±1.86 respectively. The average ± STDEV difference between the numerically calculated maximum force for dynamic cyclic testing and the in vivo measured one for 5 participants was 6.6% ± 4% (1st validation). The difference between the numerically calculated PPP and the in vivo measured PPP values was 27% (2nd validation).

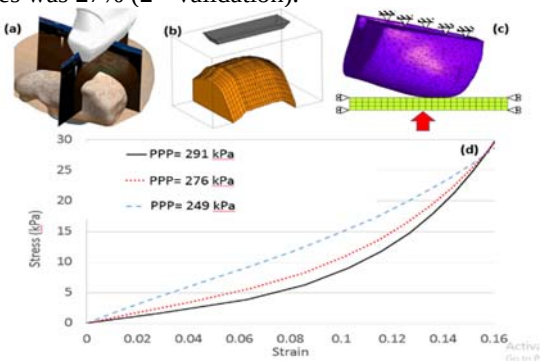

Figure 1: (a) The imaging planes for the reconstruction of geometry. (b) Typical reconstructed surface of the calcaneus based on the ultrasound images. (c) The MRI-based 3D model of the entire heel. (d) The compressive stress-strain graphs for three pairs of values of hyperelastic coefficients where the same amount of externally applied force (F=126N) leads to the same maximum deformation (d=6mm) but different values of PPP (also shown in graph).

Increasing C and m increases the PPP, however g and t affect the PPP negligible. The ability of the heel pad to uniformly distribute plantar loads depends on its overall deformability and the shape of its stress/ strain graph. Comparison between tissues with the same deformability (i.e. same deformation under same load) showed that the tissues that exhibit more linear stress/ strain behaviour are able to distribute forces more evenly (Fig.1d).

CONCLUSIONS: The ultrasound-based numerical method presented here enables reliable calculation of visco-hyperelastic mechanical properties of the heel pad. The study also demonstrates that specific changes in the heel pad's stress-strain behaviour can weaken its ability to uniformly distribute plantar loading, thus increasing the risk for overloading and tissue trauma respectively.

INTRODUCTION

Running is one of the most popular sports globally, but up to 85% of novice runners incur an injury in a given year [1]. High level of impact loading has been reported to associate with many running-related injuries, such as patellofemoral pain, stress fractures, and plantar fasciitis [2]. Previous studies have utilized gait retraining program to successfully lower impact loading in runners [3]. However, softer footfalls may not necessarily lead to injury-free running. To our best knowledge, there are no studies that have examined the effect of a gait retraining program on preventing injury in novice runners.

Hence, this study examined the impact loading before and after the gait retraining. We also evaluated the effectiveness of the program on the annual incidence of running related injury.

METHODS

A total of 120 novice runners (experience < 3 years) were recruited from local running clubs. All the participants underwent a baseline running biomechanics evaluation, which included a test on a self-paced instrumented treadmill with their usual running shoes for 5 minutes. Kinetics data was sampled at 1,000 Hz for the last minute. Average (AVLR) and instantaneous vertical loading rates (IVLR) were computed according to the algorithm reported previously [2].

Participants were then randomly assigned into gait retraining (n=60) and control group (n=60). In the gait retraining group, participants received a two-week real-time visual feedback gait retraining using the protocol described elsewhere [4]. In the control group, participants received treadmill running exercise but without visual feedback on their performance. The training time was identical between two groups.

After the training, participants' running mechanics were reassessed and the protocol was the same as the baseline evaluation. In addition, participants were required to report their injury profile using an online surveillance platform for 12 months. In order to ensure the validity of reported condition, injury was defined when a participant missed two or more days of training and was diagnosed by a medical professional.

RESULTS AND DISCUSSION

There were 12 dropouts; 56 participants completed in the gait retraining group (26 females; age = 28.4±4.5 years; height = 1.72±0.06 m; mass = 55.3±10.2 kg; mileage = 20.4±10.8 km/week) and 52 participants completed in the control group (28 females; age = 29.5±3.2 years; height = 1.74±0.06 m; mass = 58.1±9.7 kg; mileage = 17.8±11.4 km/week). The baseline profiles were comparable between two groups (p>0.443).

There was a significant reduction in both AVLR (p<0.001; Cohen's d=1.64) and IVLR (p<0.001; Cohen's d=1.75) in the gait retraining group. However, the impact loading remained similar in the control group (p>0.230).

At 12-month follow-up, 38% and 58% of runners were injured in the gait retraining and control group respectively. Mantel-Cox test indicated a significant difference in the survival curves between two groups (**Figure 1**). Hazard ratio between gait retraining and control was 0.56 (95% confidence interval=0.32-0.99), indicating a 44% lower injury risk in trained runners, when compared with controls.

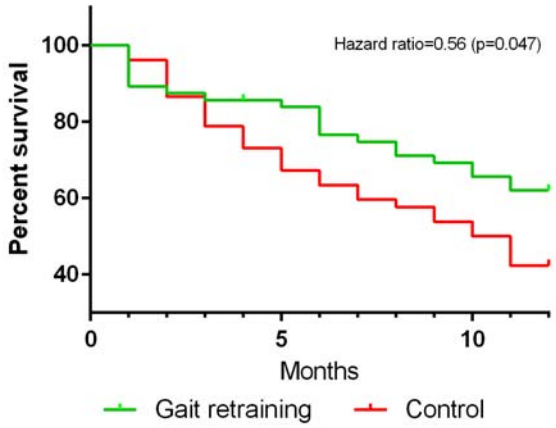

Figure 1: Kaplan-Meier plot of running related injury between participants in the gait retraining and control groups.

CONCLUSIONS

A two-week gait retraining program is effective in lowering impact loading in novice runners. More importantly, the injury risk is 44% lower after gait modification.

THE ASSOCIATION BETWEEN PATELLOFEMORAL JOINT LOADING AND HIGH-RISK POSTURES LINKED TO ACL INJURY RISK DURING LANDING.

[1]Natalie Saunders, [1]Jason Bonacci and [1]Aaron Fox
[1]Deakin University
Corresponding author email: natalie.saunders@deakin.edu.au

INTRODUCTION

Patellofemoral (PF) osteoarthritis has been associated with anterior cruciate ligament (ACL) injury and subsequent surgical intervention [1]. Commonalities in biomechanical risk factors between ACL injury and patellofemoral pain syndrome (PFPS) also exist [2]. Given the biomechanical link between PFPS and ACL injury risk, it is possible that athletes at risk of ACL injury exhibit PF joint loading characteristics that would exacerbate the likelihood of PF osteoarthritis if an injury occurs. Netball is a sport with a reputation for a high rate of ACL injury, often occurring during a leap landing task [3]. The purpose of this study was to determine whether an association exists between PF joint loading and lower limb postures linked with ACL injury risk during a netball-specific leap landing task.

METHODS

Thirty-three female netball players (23.3 ± 3.2 yrs; 171.2 ± 7.8 cm; 67.8 ± 8.2 kg) with no history of ACL injury performed ten trials of a netball-specific leap landing. The leap landing involved a six-metre run-up, followed by a single limb take-off and land on the contralateral limb while catching a pass. Marker trajectory and ground reaction force data were collected using an eight camera motion capture system (Vicon, 250Hz) synchronised with an in-ground force platform (AMTI, 1000Hz). Three-dimensional (3D) hip and knee kinematics and kinetics from the landing were calculated from initial contact (IC) to 150 milliseconds post IC. Peak PF joint reaction force and joint stress during landing were estimated over the same time period using an existing model [4].

A waveform analysis, using one-dimensional statistical parametric mapping (SPM1D) was implemented via open source code [5]. Specifically, SPM1D canonical correlations analysis (CCA) and linear regression were used to examine the relationship between peak PF joint forces and 3D kinematics and kinetics from the leap landing. Correlations between peak PF joint forces were examined for the hip and knee joint rotation (R_{XYZ}) and joint moment (M_{XYZ}) vector-fields from each landing trial. Planned post-hoc analyses of the individual joint rotation (R_X, R_Y, R_Z) and joint moment (M_X, M_Y, M_Z) components using SPM1D linear regression were also conducted. To retain a Type I family-wise error rate of alpha = 0.05, a corrected alpha level based on the number of vector components (i.e. joints = 2 and planes = 3) was calculated and used to determine statistical significance.

RESULTS AND DISCUSSION

SPM1D CCA found peak PF joint reaction forces and joint stress were significantly related to the vector-fields combining sagittal, frontal and transverse plane knee joint rotations (i.e. R_{XYZ}) and moments (i.e. M_{XYZ}). However, post-hoc analyses isolating the individual joint rotation and moment components using SPM1D linear regression revealed significant associations between PF joint reaction forces and joint stress to sagittal (i.e. R_X and M_X), but not frontal and transverse plane, knee joint rotations and moments.

Despite finding an association between PF joint forces and knee biomechanics during landing, these associations predominantly arose from sagittal plane biomechanics. This is likely an incidental finding, as knee flexion angles and moments are used in the model to estimate PF joint forces. However, altered sagittal plane biomechanics at the knee have been linked to increased ACL injury risk and loading [6,7]. Athletes demonstrating poor knee control in the sagittal plane during landing may not only expose themselves to greater ACL injury risk, but also to greater PF joint loading that may accelerate joint degradation. Injury prevention programs that target adequate knee control in the sagittal plane during high-risk landing tasks may therefore serve to protect against both ACL injury risk and PF joint loads.

CONCLUSIONS

It appears that female athletes who exhibit higher PF joint forces during landing do not exhibit high-risk lower limb biomechanics for ACL injury in the frontal and transverse planes. Thus, ACL injuries may induce joint trauma that contributes to the risk of developing PF osteoarthritis. Ongoing intervention strategies that include knee control in the sagittal plane are warranted.

SINGLE LEG LANDING STRATEGY IS ALTERED IN MALE PROFESSIONAL RUGBY UNION PLAYERS WHO DEVELOP ACHILLES TENDINOPATHY COMPARED TO INJURY FREE CONTROLS

Patrick J C Carden, Andrew M Jones and Sharon J Dixon
Sport and Health Sciences, University of Exeter
Corresponding author email: pc370@exeter.ac.uk

INTRODUCTION

Achilles tendinopathy poses a challenge to medical practitioners in professional team sport such as Rugby Union [1].

In both research and applied practice within professional sports such as Rugby Union, assessing how an individual moves when jumping and landing is often used in a battery of injury screening tests [2]. However, there are limited instances of these movements being incorporated into research focusing on Achilles tendinopathy development.

Previous studies have demonstrated excessive rear foot eversion and reduced ankle dorsiflexion during locomotion in individuals who have developed Achilles tendinopathy [3]; however there is a paucity of studies that have examined joint kinetics.

The aim of this study was to determine if differences in lower limb landing biomechanics were present between players who subsequently sustained Achilles tendinopathy and those who do not.

METHODS

As part of baseline testing for an ongoing study, male professional Rugby Union players competing in the English Aviva Premiership (n = 56 during 2015/16 Season, n = 63 during 2016/17 Season) performed five single-leg drop vertical jumps per leg at the start of their pre-season training. Eight players developed Achilles tendinopathy during the course of the study (7%), injuries were diagnosed by the club doctor. During data collection four CODA cx1 units (Codamotion, 200 Hz) recorded 3-D motion of the lower limbs and pelvis synchronously with ground reaction force (AMTI, 1000 Hz). Players were instructed to drop off a 0.2 m box and contact the center of the force plate with one leg and jump as high as possible, with a short ground contact time. Independent t-tests were conducted to compare between groups ($\alpha = 0.05$).

RESULTS

Players who sustained Achilles tendinopathy demonstrated significantly increased rear-foot inversion-eversion range of motion ($p = 0.03$). In addition a reduction in dorsi-plantarflexion range of motion ($p = 0.01$) and knee flexion-extension range of motion ($p = 0.03$) was also observed.

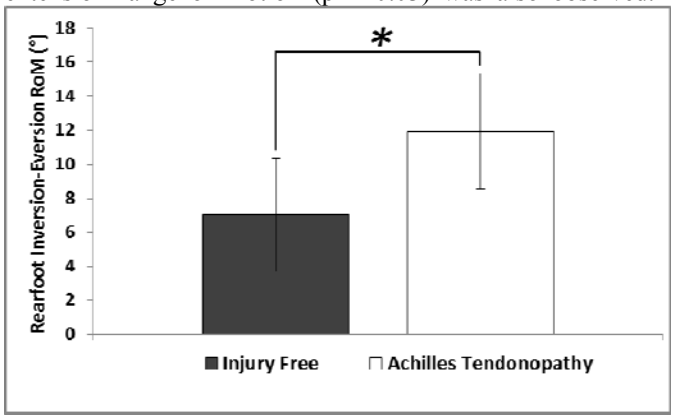

Figure 1: Rear-foot inversion-eversion angle range of motion.

Peak dorsiflexion velocity ($p = 0.02$) and peak knee flexion velocity were also reduced in those with Achilles tendinopathy ($p = 0.03$). No differences in hip joint kinematics were observed. Controls displayed slightly larger peak relative plantarflexion moments; however this difference was not statistically significant ($p = 0.15$, $g = 0.60$).

CONCLUSIONS

The study indicated that professional Rugby Union players who subsequently developed Achilles tendinopathy displayed differences in single leg landing strategy when compared to players who did not sustain injury. The ankle joint and rear-foot were the most affected; with an observed increase in the magnitude of rear-foot motion which is consistent with previous findings examining running gait in individuals with Achilles tendinopathy (Figure 1) [3]. Larger magnitudes of eversion have previously been demonstrated to result in asymmetrical loading with high load on the medial aspect of the Achilles tendon, potentially increasing the risk of tendinopathy [4]. The reductions in magnitude and velocity of plantarflexion-dorsiflexion motion as well as of knee flexion-extension motion were suggestive of altered muscle-tendon unit function in those who sustained Achilles tendinopathy. The relationship between the findings and risk of developing Achilles tendinopathy are currently being analysed using binary logistic regression.

ACKNOWLEDGEMENTS

The authors thank Exeter Chiefs RUFC for co-funding the project and Bertrand Bru of Codamotion for providing additional motion capture equipment during data collection periods.

THE EFFECT OF CHRONIC ANKLE INSTABILITY ON KNEE BIOMECHANICS DURING LANDING

[1] **Yumeng Li**, [2]Jupil Ko, [3]Marika Walker, [3]Julianne D. Schmidt, [4]Cathy N. Brown and [3]Kathy J. Simpson

INTRODUCTION

Although much is known about the mechanisms of knee and ACL injury, one factor that is only recently to receive attention is the influence of previous ankle injury on ACL injury mechanisms. Researchers have observed a significant association between lateral ankle sprain history and ACL injury history [1]. However, whether there is a causal relationship is unclear. We suggest that chronic ankle instability (CAI) is one specific condition that likely could affect the potential for acute or chronic knee injuries. Therefore, the purpose of the study was to determine if individuals with CAI exhibit atypical knee biomechanics during landing onto a tilted surface.

METHODS

21 female participants with CAI were recruited based on previously published guidelines and questionnaires; and 21 healthy control (CON) participants were recruited to pair-match with the CAI participants on gender, height, body mass and physical activity level. The participants were instructed to stand on a box 30 cm high from the force plates, step forward with the test limb (CAI limb) followed by the other limb and landed with test foot on the tilted force plate (25°) and the other foot on the flat force plate (Fig. 1).

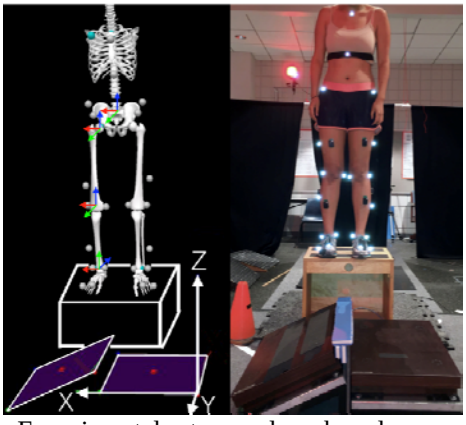

Figure 1: Experimental set up and marker placement.

Locations of 29 reflective markers place on the trunk, pelvis and lower extremity were captured by a 7-camera motion capture system at 120 Hz. Two force plates were collecting the ground reaction force (GRF) at 2040 Hz. Ten acceptable landing trials were collected.

The phases of interest for analysis included the pre-landing phase, from -50 ms to the instant of initial contact (IC), and landing phase (from IC to the instant of lowest COM height). Knee joint angles of the test limb were calculated using Cardan (XYZ) sequence. Knee joint moments were calculated using an inverse dynamic method. Negative work of the joints was calculated based on integrating the negative part of the joint power curve. All kinetic data were normalized to body mass. Comparisons of kinematics and kinetics between CAI and the control group were using paired *t*-tests ($p < 0.05$).

RESULTS AND DISCUSSION

Compared to CON group, CAI group displayed 5° more knee flexion angle at IC and a 10° more knee flexion displacement in the landing phase. The greater knee flexion angle and displacement may be a protective strategy of CAI group to stabilize the ankle joint by rotating the lower leg forward and thus increase the ankle dorsiflexion angle [2].

CAI group exhibited greater peak knee extension (CAI vs. CON: 2.06 ± 0.30 vs. 1.79 ± 0.35 Nm/kg, $p = 0.01$) and internal rotation moments (0.45 ± 0.18 vs. 0.33 ± 0.17, $p = 0.01$), respectively. In the sagittal plane, the greater knee extension moment and flexion displacement resulted in a greater eccentric (negative) work at the knee joint for CAI group (1.07 ± 0.26 vs. 0.83 ± 0.42, $p = 0.04$). The greater knee eccentric work of CAI could be a compensatory strategy for reduced ability of doing ankle eccentric work to absorb the impact. In addition, the greater knee extension moment is possibly due to greater quadriceps activation that imply a greater anterior shear force acting on the proximal tibia thus a greater ACL stress. The greater knee internal rotation moment of CAI could further increase the ACL loading [3].

CONCLUSIONS

In conclusion, individuals with CAI displayed some kinematic and kinetic differences in the knee joint during landings compared to CON group. Some alterations (i.e. greater peak extension and internal rotation moment) could be related to greater ACL loading. Future studies may need to measure or estimate the ACL loading to confirm whether CAI could relate to the mechanism of ACL injury.

INTRODUCTION

Non-contact anterior cruciate ligament (ACL) injuries are common in females and can contribute to debilitating consequences. The purpose of this study was to investigate the effects of a high intensity fatigue simulation (HIFS[5]) on the Landing Error Scoring System (LESS) injury risk assessment.

METHODS

Fifteen (n=15) healthy recreationally trained females (height: 160 ± 4.3 cm; weight: 53 ± 3.2 kg; age: 25 ± 3.2 years; BMI: 21 ± 1.4) were recruited in this repeated measures design study. During testing, prior to HIFS[5] (time 0 min), immediately post 5-min HIFS[5] (time 5 min) and after 15 min of passive recovery (time 20 min), participants were required to perform the LESS jump-landing task which has been devised by Padua *et al.* [4]. The HIFS[5] simulation was adopted from Bossuyt *et al*. [1] which consist of high acceleration, deceleration multidirectional movements with sports utility movements. Two-dimensional sagittal and frontal plane kinematic data were recorded and analyzed using the LESS score. Heart rate (HR) and rate of perceived exertion (RPE) were observed every minutes throughout the simulation. A one-way ANOVA repeated measures design was used to identify significant differences over time, with alpha equal to 0.05.

RESULTS AND DISCUSSION

The mean heart rate during HIFS[5] was 183 ± 3.4 beat.min^{-1} and RPE was 17 ± 0.7. There was a significant difference on LESS results over time ($F_{2,24}$ = 43.75, p = .001). Pairwise comparison revealed that LESS score at time 5 min (p = .001) and time 20 min (p = .001) was significantly greater (poor jump-landing technique) compared to time 0 min. Significant difference was observed between body segment ($F_{2,28}$ = 11.73, p = .001). Pairwise comparison revealed that the LESS score of the knee and hip was significantly higher compared to the ankle at post fatigue (time 5 min) and post recovery (time 20 min).

Our investigation revealed after the HIFS[5], the LESS score increased 60% from 4.0 (excellent score) to 6.4 (poor score). The LESS score remained high at 43%, 5.7 score (moderate score) even after 15 minutes' post interval, which suggests that the participants are highly susceptible of an ACL injuries risk. This result is consistent with a study by Liang-Ching *et al.* [3] which shows that there is a significance different for the pre, post-test, and even after 20 minutes' recovery period in knee abduction which is one of the main characteristic in having a high risk of ACL injury. Furthermore, the current result on before and after fatigue protocol are consistent with other study by Gokeler *et al*. [2] which shows that the score for LESS is excellent (2.5) before and moderate (6.0) after a fatigue protocol.

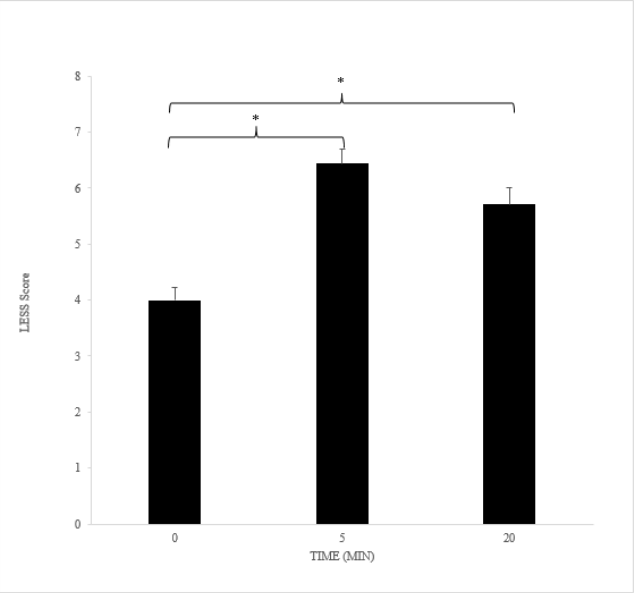

Figure 1: LESS score changes over time. * Indicates significant different compared to time 0 min.

CONCLUSIONS

The LESS is a non-expensive and reliable ACL injury risk assessment. The inclusion of a fatigue protocol during LESS may revealed greater ACL biomechanical marker impairments and should be considered as an important component for a pre-season and return to play injury assessment.

THE HISTORY OF HAND AND WRIST BIOMECHANICS

Kai-Nan An
Mayo Clinic, Rochester, MN 55901 USA
an@mayo.edu

In the past half-century, biomechanics of hand and wrist has gradually attracted more attention. Numerous experimental and analytical investigations have been performed to better understand basic functional anatomy and ultimately target specific disorders and injuries for prevention, diagnosis and treatment. The review of hand and wrist investigation can be grossly divided into the two areas of joint mechanics and soft tissue mechanics.

The kinematic and kinetic study of joint mechanics has benefited from the advances of measurement technologies such as stereo-radiography, magnetic-tracking device, 4-dimensional computer tomography and 2D-3D registration. Many studies have focused on control strategy of digit and wrist movements. Treatments for neuromuscular-associated hand dysfunction and ergonomic design of assistive devices have been considered. In addition, the roles of capsuloligamentous structures in providing constraints of the joint under loading or prescribed movement have been realized. Laceration or degeneration of such structures could potentially lead to joint instability and arthritis, especially for the basal thumb joint, the wrist carpal joints, and the distal radial-ulnar joint. Numerous treatments modalities including soft tissue reconstruction and joint arthroplasty have been developed and evaluated.

Soft tissue mechanics involve the characterization of material properties of the tendon and the evaluation of interaction of tendon with the surrounding tissues during gliding. Likewise, with the advancement of imaging technologies such as ultrasound tracking and shear wave elastography, in vivo assessment is easily attainable. Recent investigations focus on the mechanobiology and metaplasia of tissue due to mechanical loading and have provided a better understanding of the etiology and treatment of carpal tunnel syndrome, trigger finger and other tendinosis disorders. Surgical repair and postsurgical rehabilitation of the flexor tendon have also been a popular topic of research.

The close collaboration between clinicians and basic scientists in studying the hand and wrist biomechanics is a unique alliance. Hopefully, such a collaborative spirit will continue.

INTEGRATED UPPER EXTREMITY 3D KINEMATICS IN THE DART-THROWING MOTION OF THE WRIST

[1234] **Mark Ross**, [123] Greg Couzens

[3] Brisbane Hand and Upperlimb Research Institute
[4] University of Queensland, Brisbane, Queensland, Australia

Corresponding author email: markross@upperlimb.com

Traditionally our understanding of carpal kinematics relates to the orthogonal sagital (flexion/extension) and coronal (radial/ulnar deviation) planes of wrist motion. Nevertheless, most activities involving tool use and throwing are performed in an oblique plane from radial deviation-extension to ulnar deviation-flexion. This movement has been called the dart-throwing motion (DTM).

The DTM also involves rotation of the forearm. In wrist radial deviation/extension, there is pronation of the forearm. In wrist ulnar deviation/flexion, there is supination of the forearm. This is a facilitatory motion of the forearm that maintains the grasped object in the vertical plane. Previous discussion of this aspect of foremarm motion has been sparse, with Stirling Bunnell suggesting a maximum of 5 degrees forearm rotation in his 1944 discussion on oblique plane wrist motion 1

We propose that the net effect of this forearm rotational motion is to keep the oblique DTM axis aligned with the visual axis during wrist motion in order to improve accuracy through visual control. Our hypothesis is that the default functional position of the forearm with regard to rotation is between 20° and 35° of pronation, in order to maintain alignment between the function axis and the visual axis during utilisation of the DTM.
We further hypothesised that the magnitude of forearm rotation coupled with DTM is greater than previously understood.

In previous studies of DTM, the rotation of the forearm as well as motion at the elbow and the shoulder have not been taken into consideration. We have investigated DTM globally as a multiple-joint 3D motion in relation to the visual axis. We utilised an optical motion capture system (Optotrak® Certus™) with infrared emitting surface markers placed on defined landmarks.

Results

Intergated 3D analysis has confirmed our hypotheses.

Subjects adopt a resting forearm posture of approximately 20-35 degrees of pronation when asked to rotate into a comfortable resting position.

There is a 30 degree arc of forearm rotation during oblique plane activities such as hammering.

Of interest were additional findings which whilst not expected, are consistent with our overall hypothesis of integrated upper extremity kinematics.

The majority of these oblique plane activities took place in the radial deviation / extension quadrant, in pronation. There was sparse utilisation of the ulnar deviation / flexion quadrant or supination.
Although the DTM is brought about through the synchronous coupling of flexion/extension plane motion and radial/ulnar deviation plane motion, this coupling is not consistent throughout the cycle of DTM activity. The analysis of real time kinematics has allowed us to define phases of oblique plane activity, which have variable degree of true DTM plane motion:-

1. Cocking – the object, or tool is being drawn backward. During this phase the 2 planes of motion are uncoupled with approximately 2/3 being in the extension plane and 1/3 in the radial deviation plane.

2. Acceleration – this is where power or speed is generated. This phase is almost completely in the flexion plane with only a tiny component of ulnar deviation.

3. Targeting – this is the point at which the object enters the central portion of the visual field on approach to it's target or release. This is the only phase during which there is true synchronous coupling of flexion and ulnar deviation. It is consistent with our hypothesis that this is the phase when there is alignment between the oblique plane and the visual axis to facilitate accuracy.

4. Impact/ Release – The object by now has been accelerated and targeted.The two planes of motion are again uncoupled with a similar 2/3 predominance of flexion

Summary

- The comfortable resting position of the forearm is in slight pronation which corresponds to the position required to align the oblique plane axis with the visual axis

- The majority of these oblique plane activities took place in the radial deviation / extension quadrant, in pronation. There was minor utilisation of the ulnar deviation / flexion quadrant or supination.

- True oblique plane motion (DTM) with synchronous coupling of motion in both the flexion/extension AND radial / ulnar deviation axes occurs for only a small proportion of the overall motion cycle , which we have termed "Targeting" and which we propose facilitates accuracy through alignment between the visual axis and the DTM axis.

PROXIMAL CARPAL ROW CONTROLS MIDCARPAL ALIGNMENT AND MOTION

INTRODUCTION

As each individual's wrist appears to have its own distinct biomechanics, the carpus has eluded simple explanation. The carpus moves with only 2 degrees of freedom – pitch (flexion / extension) and yaw (radial deviation / ulnar deviation), while largely preventing roll (pronation / supination). This mechanical quandary can be addressed by applying the rules based motion (RBM) concept. This states that the motion of a mechanical system, such as the wrist, is the net interplay of 4 rules – morphology, constraint, interaction and load [1].

Wrist motion is thus the composite outcome of these distinct rules. As the value or characteristics of each rule may varies, there is a matching complimentary variation in the other rules to achieve the final wrist motion and function.

The recently published Stable Central Column Theory (SCCT) of wrist mechanics [2] applies the concept of RBM to the carpus, and by using a reverse engineering computational analysis model, identified a consistent pattern of isometric constraints. There appears to be a clear pattern of constraint between the proximal row (Scaphoid-lunate-triquetrum) and the radius, and between the distal row (Trapezium-trapezoid-Capitate-Hamate) and the proximal row. This finding was expanded to suggest that the wrist functions a "Two-Gear Four-Bar" linkage.

This previous study assessed the isometric constraints in extremes of radial and ulnar deviation. The purpose of the current study was to further assess the motion of the various bones of the carpus using a 3D dynamic visualization model, in other directions and identify patterns of linkages.

Given the identified isometric constraints, the hypothesis was that the pattern and direction of motion of the proximal row, and the distal row with respect the immediately cephalad carpal bones or radius would be very similar in all directions of wrist motion. A further hypothesis was that the distal row motion direction was determined by the position of the proximal row, and this could vary dynamically as the wrist moved in particular directions.

METHODS

3D models were created from 5 normal wrists that underwent CT scanning in multiple positions of radial and ulnar deviation as well as flexion and extension. Each carpal row (proximal and distal) was animated with the cephalad carpal bones or radius held immobile.

The rotational axis and position of each bone and each row was then compared in sagittal (Flexion-extension) and coronal (radial and ulnar deviation) motion. The DTM was not assessed.

RESULTS

The proximal row moved in the same direction, but with a varying extent of the unitary arc during sagittal and coronal motion. The isometric constraints were consistent in both directions.

The distal row moved on an axis formed by a pivot joint laterally (between the trapezium and scaphoid), and a saddle joint medially (between hamate and triquetrum). This axis changed as the proximal row moved.

This created a distinct pattern of row motion to achieve the various required positions of wrist motion. On wrist radial deviation, the scaphoid (with the proximal row) flexed, and the distal row extended, whereas in wrist flexion, the scaphoid flexed (with the proximal row) and so did the distal row. The pattern was reversed in the opposite wrist movements.

While the general direction of motion of each row was consistent, the extent was quite variable.

CONCLUSIONS

The overarching concept in this work has been that by assessing general motion patterns, rather than focusing on specific axes and displacement measurements of each of the carpal components, a more useful theory to understand and treat wrist injuries can be developed.

As a more than 10-fold variations in the motion axes and excursion of various bone pairs between different individual has been reported [3], specific carpal bone kinematic analysis may not provide an effective pathway to explain both the mechanics of the normal wrist nor provide the ability to define disruption and consequent reconstructive solutions of an injured wrist.

This study supports the Stable Central Column Theory of carpal mechanics and the carpus acting as a Two-Gear Four-Bar linkage, as well as the concept of RBM as a means to achieve a quantitative analysis of the normal and injured wrist.

A SIMPLE MODEL OF RUNNING: FORCE-LENGTH RELATIONSHIPS AND FOOT STRIKE PATTERNS

[1] **Niamh Gill**, [1] Stephen J Preece and [1] Richard Baker
[1] University of Salford
Corresponding author email: N.Gill1@edu.salford.ac.uk

INTRODUCTION

The spring mass model is the simplest mathematical model that can be applied to bouncing gaits, i.e. running [1]. Although the model is very simple, it has had success in modelling certain characteristics of running [2]. The most fundamental assumption of this model is that it assumes a human runner behaves similarly to a single mass bouncing on a linear massless spring. The oscillation of the mass on the spring is said to reflect the movement of a body's CoM as it runs. The degree to which the mass oscillates is determined by the characteristics of the spring; one of the most fundamental of which is stiffness.

The concept of leg stiffness relies on the key assumption of the model, that the limb can be approximated by a passive linear system. This assumption is inevitably violated due to the complexity of the musculoskeletal system. For example, multiple levers (bones) articulated by joints introduce non-linearities due to their geometric configuration, and limb movement is controlled by muscles (active elements) capable of generating of energy through tendons extending in response to an applied force. Thus, the assumption of a linear spring is merely a hypothesis, the aim of this study was to test this hypothesis, by investigating the linearity of the force-length relationship, and the amount of energy lost to hysteresis over the stance phase of running.

METHODS

Kinematic and kinetic data were collected for 28 participants (12 female; mean (SD): age: 28 (4) yrs., height: 1.75 (0.93) m, weight: 62.9 (9.1) kg), running at four different speeds (3.3, 3.9, 4.8 and 5.6 m/s). Signed informed consent and ethical approval were obtained prior to testing. Participants were grouped based on foot-strike index [3]. A clear bimodal distribution in foot strike index was identified, with a strike index up to and including 0.33 (33 %) being classified as a rear-foot strike pattern, and a foot strike index equal to or greater than 0.5 (50 %) being classified as a fore-foot strike pattern.

The leg force was calculated as the component of the GRF acting along the line of the leg (from the average CoP to instantaneous hip joint centre). To assess how much the experimental force-length curves deviated from the assumed linear behaviour, a root mean square residual (RMSr) was calculated between the data for each half of stance (the loading and unloading phases) and the straight line between the force-length values at initial contact and mid-stance. Hysteresis was defined as the change in elastic potential energy, ΔE, associated with each force-length curve, normalised to body mass. It was then estimated as the difference between the area under the loading and unloading curves. It should be noted, a number of participants transitioned from rear- to fore-foot strike patterns, as the speed increased. Therefore, statistical comparisons were made using independent samples t-tests, with an adjusted p-value.

RESULTS AND DISCUSSION

Results showed a significant difference ($p \leq 0.013$) between the groups for the loading portion of the force-length curve at speeds 1-3, near significance at speed 4 ($p \leq 0.021$), and no significant differences for the unloading portion at any speed. The mean loading RMSr and hysteresis values for rear-foot strikers were consistently higher (65-95% and 25-87%, respectively) than those of the fore-foot strikers.

Due to the similarity of the unloading portion of the F-L curve, lack of relationship in this case is expected. Furthermore, although statistical significance for hysteresis was only found at speed 3, this is likely because of the variability in the data (SD ≈ 50% mean). Despite this, differences in linearity and hysteresis indicate the assumption of linear elasticity is not necessarily appropriate for all foot strike patterns.

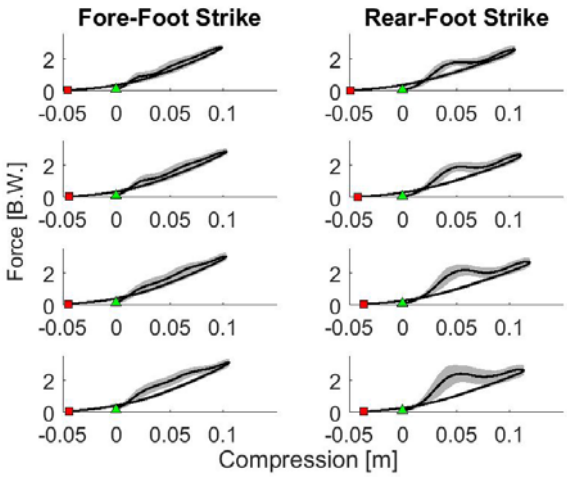

Figure 1: Force-Length relationships of the different foot-strike patterns. Rows 1 – 4 correspond to speeds 1 – 4.

CONCLUSIONS

The results of this study show clear differences in the force-length relationships of fore- and rear-foot strikers. The main differences occur during early stance, with rear-foot strikers exhibiting a period of rapid loading not seen in fore-foot strikers. Furthermore, hysteresis measurements suggest rear-foot strikers dissipate more energy, and therefore modelling these runners using a purely passive system is not appropriate.

A BIOMECHANICALLY RATIONAL APPROACH TO CALCULATING LIMB STIFFNESS

[1] **Niamh Gill**, [1] Stephen J Preece and [1] Richard Baker
[1] University of Salford
Corresponding author email: N.Gill1@edu.salford.ac.uk

INTRODUCTION

A range of simple models of running have been developed which incorporate a linear spring of constant stiffness [1,2,3]. Although the Physics-based (PB) definition of stiffness is the ratio of the force applied along the spring to its deformation, previous researchers have used a range of alternative definitions of stiffness. These can be generally categorised into limb stiffness (force and deformation along the orientation of the limb) and vertical stiffness (force and deformation in the vertical direction only). Given this potential inconsistency, the first aim of this study was to determine how limb and vertical stiffness change with speed and hence determine if they can be used interchangeably. The second aim was to compare the current range of limb stiffness definitions, used in the literature, to the physics-based definition.

METHODS

Kinematic and kinetic data were collected for 19 fore-foot strikers, running at four different speeds (3.3, 3.9, 4.8 and 5.6 m/s). All runners ran with a fore-foot pattern at the fastest speed and, to ensure consistency, this analysis focussed on those who maintained this pattern at all speeds (n=11, 12, 13 and 19 at speeds 1–4, respectively). Individual force-length relationships were determined for each participant. Vertical stiffness was defined as the quotient of the peak vertical GRF to the maximum vertical change in the CoM displacement during the contact phase. Limb stiffness was defined using the PB definition, i.e. the slope of the line of linear best fit of the limb's force-length curve from initial contact to the point where the leg length returned to its resting length (≈90% of stance). Limb and vertical stiffness were compared using a bivariate correlation.

Limb stiffness was also calculated using four previously published methods [4,5,6,7]. One method estimated the vertical GRF using a sine-wave [7], while others used the peak vertical GRF [4,6]. Some estimated the changes in leg length from the vertical CoM displacement [6,7] while another double integrated the GRFs [5]. Correlational analyses were completed to determine if a relationship existed between the PB method and the four methods. However, since a high correlation does not necessarily mean good agreement, a Bland-Altman analysis was conducted to determine the level of agreement between the methods.

RESULTS AND DISCUSSION

Vertical stiffness was found to be consistently larger than limb stiffness (115-234%). Interestingly, although vertical stiffness increased with speed, limb stiffness remained constant. The different speed dependencies of vertical and limb stiffness can be attributed to differing displacement changes with speed. While the vertical oscillation of the CoM decreases, the change in leg length increases as speed increases. Thus, in the case of limb stiffness, the increases in force and displacement are offset to give constant stiffness.
Strong to moderate relationships (r=0.77-0.99) were identified between the PB method and the other four methods of calculating limb stiffness, at all speeds. Furthermore, the magnitudes varied substantially (7-20kN/m), with the Bland-Altman analysis revealing no consistent bias between methods and 95% limits of agreement ranging from -6.8 to 13.4kN/m (-33–233% of the mean difference value).

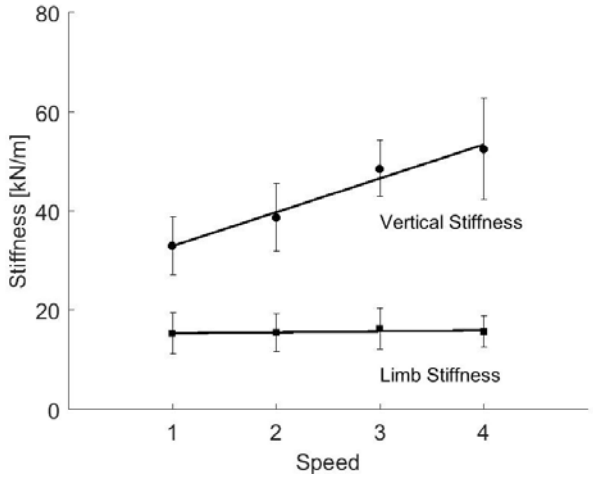

Figure 1: Mean and standard deviation of limb stiffness (PB definition) and vertical stiffness as a function of speed.

CONCLUSIONS

Vertical stiffness does not correspond to any physical "spring", therefore its appropriateness as a parameter to describe running is questionable. Conversely, limb stiffness is essentially a mechanical representation of the physiology. Our results show no consistent relationship between limb and vertical stiffness; therefore, one cannot be used as a proxy for the other, and they are not interchangeable. Furthermore, although significant correlations were found, between the PB method and the other methods (of calculating limb stiffness) presented in the literature, Bland-Altman analysis revealed poor agreement between the magnitudes of the values. This finding highlights the need for consistency when calculating limb stiffness in order for comparisons to be made across the literature.

RELATIONSHIP BETWEEN ACHILLES TENDON STIFFNESS AND GROUND CONTACT TIME DURING DEPTH JUMPS

[1] **Markus Tilp**, [2]Mohamad Abdelsattar and [1]Andreas Konrad
[1]University of Graz
[2]Mansoura University
Corresponding author email: markus.tilp@uni-graz.at

INTRODUCTION

During locomotion forces generated in the muscles are transmitted via tendons to the bones. Additional to the activation pattern of the nervous system and the muscle properties (force-velocity and force-length relationship) also the properties of the tendon are relevant for the movement outcome. Energy that is stored during eccentric phases can be restored during the concentric phase of a movement (Alexander & Bennet-Clark, 1977). Lichwark & Wilson (2007) could even show that Achilles tendon compliance is optimized for muscle efficiency during prolonged running. While efficiency is important for prolonged running, a short ground contact time is important in sprint running. It could be assumed that this is realized by direct transfer of force via a stiff tendon. Therefore, the aim of the study was to relate Achilles tendon stiffness (ATS) with ground contact time (GCT) during depth jumps. We hypothesized that higher ATS is related to shorter GCT in young healthy males.

METHODS

Nineteen physical active healthy males (mean +/- SD: 26.7 +/- 3.9 years, 176.5 +/- 7.3 cm, 76.5 +/- 6.7 kg) participated in this study. The subjects were informed about the testing procedure and they each gave written consent to participate in the study which was approved by the Ethical Committee of the University of Graz.

After a standardized warm-up program, subjects were asked to perform depth jumps with minimal ground contact from a height of 40 cm on a Kistler® force platform (1000 Hz).The ground contact time was then determined from the vertical ground reaction force from force plate data.

Furthermore, subjects were asked to perform isometric ankle torque measurements with maximum voluntary effort (IMVC) on a dynamometer (con-trex MJ, CMV AG, Dübendorf, CH). A real-time ultrasound apparatus (mylab 60, Esaote S.p.A., Genova, Italy) with a 10-cm B-mode linear-array probe was used to obtain longitudinal images from the muscle-tendon junction of the gastrocnemius medialis during IMVC. Achilles tendon stiffness was then determined by dividing the change of force (torque/moment arm) by the length change of the tendon (50-100% of IMVC).

SPSS (version 16.0, SPSS) was used for the statistical analyses. Means and standard deviations are presented. Shapiro-Wilk test was used to test data for normal distribution. Since data was not normally distributed Spearman correlations were calculated to assess the relationship between Achilles tendon stiffness and ground contact time. An alpha level of p=0.05 was defined for statistical significance.

RESULTS AND DISCUSSION

Mean ATS was 28.2 +/- 11,4 N/mm and mean GCT was 253.0 +/- 56,8 ms. We found a significant negative correlation between ATS and GCT following depth jumps (r=0.50, p=0.03). For graphical illustration see Fig. 1.

The present result confirms our hypothesis that a stiffer Achilles tendon is related to shorter ground contact time during depth jumps. This result is similar to the findings of Arampatzis et al. (2001) or Morin et al. (2007) who reported a negative correlation between leg and ankle stiffness and GCT.

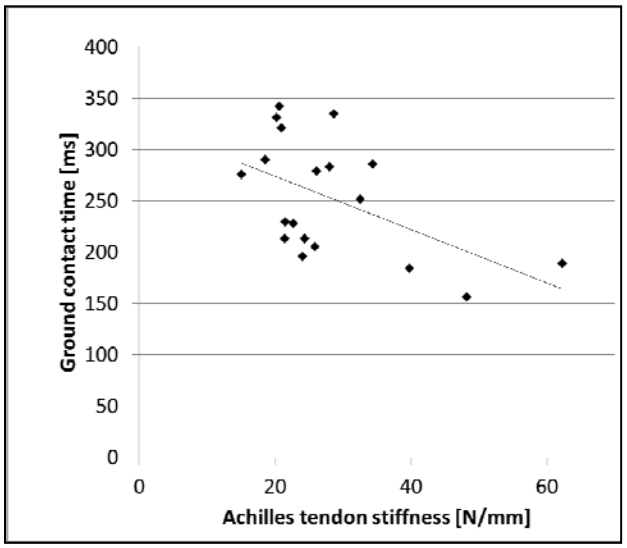

Figure 1: Relationship between Achilles tendon stiffness and ground contact time following depth jumps from 40 cm.

As a consequence, the present result suggests increasing ATS in order to decrease GCT for enhanced performance, e.g. in sprint running. However, a randomized controlled training study would be necessary to confirm this assumption. According to Arampatzis et al. (2010) training with high strain magnitude protocols at low frequency would lead to increased tendon stiffness.

CONCLUSION

We could show that subjects with stiffer Achilles tendons have shorter ground contact times following depth jumps.

CAN PARTICIPANT-SPECIFIC SEGMENTAL INERTIAL PARAMETERS IMPROVE THE VALIDITY OF MUSCULOSKELETAL MODELS FOR FORWARD DYNAMICS SIMULATIONS DURING SIDESTEPPING?

[1]**Marcel M Rossi**, [1]Cyril Donnelly, [1]Amar El-Sallam, [1,2]Andrew Lyttle, [3]Jim Dowling, [4]Jeff Reinbolt and [1]Jacqueline Alderson

INTRODUCTION

Forward dynamic simulations run with musculoskeletal models in OpenSim can shed some light on the multiple, and often non-intuitive, muscle activation strategies employed to support ACL loading during non-contact sidestepping in sport. However, the validity of the musculoskeletal model for forward dynamic simulations may be compromised if the adopted segmental inertial parameters (IP) are not participant-specific. More specifically, inaccurate segmental IP may lead to inconsistencies between the measured ground reaction forces (GRF) and the model kinematics used to find a pattern of muscle excitations via the optimization solution. By default, OpenSim re-scales a generic musculoskeletal model to predict the IP of the participant. Although segmental IP of elite athletes are shown to be not accurately predicted using generic scaling equations [1], the effect of inaccurate segmental IP on the validity of the musculoskeletal model remains unknown.

The inconsistency between the experimental GRF data and the dynamics of the musculoskeletal model is assessed by computing the residual forces held at the pelvis segment using inverse dynamics. Therefore, the aim of this study was to determine whether musculoskeletal models that account for participant-specific segmental IP instead of re-scaled IP from a generic model yield reduced pelvic residual forces during non-contact sidestepping of elite athletes.

METHODS

Fourteen members (24.7 ± 3.4 years) of the Australian National Women's Hockey team, clear of any lower limb injury at the time of data collection participated in this study. Each participant underwent a full body DXA scan with the GE Lunar Prodigy DXA densitometer (GE Healthcare, Bucks, UK) as a means to estimate participant-specific segmental IP using a previously published method (DXA/Vol) [2]. Two musculoskeletal models were created per participant; one model adopted segmental IP re-scaled from a generic OpenSim model (OSIP) and the other model adopted the IPs estimated with DXA/Vol [2,3].

A full-body custom markerset comprising 56 markers was affixed to the participants who then completed a published planned sidestepping protocol [3]. Marker trajectory and GRF data for sidestepping were recorded using a 22-camera (250 Hz) motion capture system (Oxford Metrics, Oxon, UK) and a force platform (2,000 Hz, Advanced Mechanical Technology Inc., Watertown, MA) respectively. These data were then low-pass filtered (14 Hz) using a zero-lag 4th order Butterworth filter and exported to OpenSim to compute the residual force components held at the pelvis segment for each of the two musculoskeletal models [3].

To compare the waveforms of the mean residual force components for each model, the test statistic SPM {t} was computed with the one-dimensional statistical parametric mapping package (SPM1D) in Matlab [4]. A critical threshold t* was computed using the random field theory [4] and the Šidák threshold p=0.0170 to maintain a constant family-wise error rate of α=0.05 for all residual force components.

RESULTS AND DISCUSSION

Significant differences were observed only in the transverse (13%–24% and 85%–100% stance, p<0.001) and sagittal (9%–25% stance, p<0.001) directions (fig 1). In these zones of significance however, DXA/Vol models did not always yield smaller residual force magnitude (i.e., values closer to 0). Indeed, the residual forces, mainly in the longitudinal direction, appear to be more meaningfully affected by other modeling (e.g., segment rigidity and joint constraints) and processing (e.g., kinematic signal) sources of errors (fig 1).

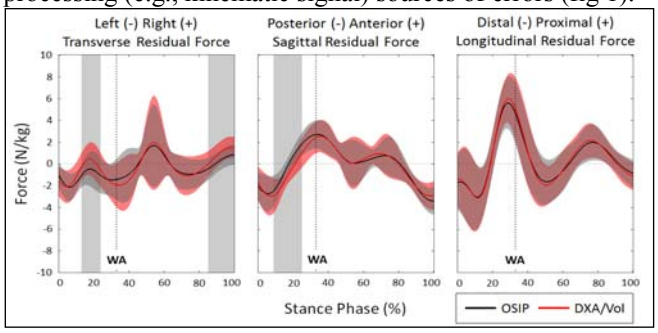

Figure 1: Mean residual force components and the zones of significance (shaded gray area). WA= weight acceptance.

CONCLUSIONS

Participant-specific segmental IP did not have a meaningful impact on the validity of the musculoskeletal model during planned sidestepping of elite female hockey players. Other modeling and processing sources of errors require attention before forward dynamic analysis of sidestepping be adopted.

DETERMINATION OF THE OPTIMAL RIGID-BODY REPRESENTATION OF THE TRUNK DURING DYNAMIC MOVEMENTS

Shoma Kudo, Masahiro Fujimoto and Akinori Nagano
Ritsumeikan University
Corresponding author email: my.way.0205@gmail.com

INTRODUCTION

The trunk has a multi-segmental structure, composed of the cervical, thoracic and lumber spines, and surrounding soft tissue elements, which allows the trunk to flexibly deform during dynamic movements [1]. In three-dimensional movement analyses, the trunk is often modeled as a single or a link of small number of rigid segments to simplify the complexity of its structure [2]. However, it remains unclear how well such the rigid-body segment model represents the complex trunk deformation, and thus an optimal rigid-body representation of the trunk to describe its complex movement has not yet been formed [3]. Therefore, the purpose of this study was to determine the optimal rigid-body representation of the trunk for the analysis of the dynamic movements.

METHODS

Ten male subjects (21.5 ± 1.0 years old, 172.0 ± 5.5 cm, 66.8 ± 8.5 kg) performed running on a treadmill at 4 different speeds: 8km/h, 10km/h, 12km/h, and 14km/h. The three-dimensional kinematic data were obtained with a sixteen-camera motion capture system at 250Hz (MAC3D, Motion Analysis Corporation, California, USA). Forty reflective markers were placed between the acromioclavicular joint and posterior superior iliac spine (PSIS) levels on the back of the subject. The instant of heel strike was detected based on the vertical velocity of the mid-foot to define a running gait cycle [4]. The data for five gait cycles were obtained and averaged for each subject.

The trunk was modeled as a single, two, or three rigid-body segments to examine how well these models describe actual trunk movement. The local coordinate system was defined for each rigid-body segment and simultaneous transformation matrix (STM) from the local to global coordinate system was determined. A set of parameters for STM to minimize the differences between the modeled and actual position data was then found using a non-linear optimization analysis. For the optimization analysis, optimized variables were the parameters of STM, and the objective function was the differences between the modeled and actual position data. The average of differences between the modeled and actual position data was calculated and used as a position error for each model during the gait cycle.

A two-way repeated measures ANOVA was used to examine main effects and interactions of the 3 model types and 4 running speed conditions on the position error for each model. Bonferroni post-hoc analysis was used for multiple comparisons between the model types and running speed conditions when the analysis revealed significant main effects.

RESULTS AND DISCUSSION

Significant main effects were found for the model type and the running speed, indicating that the position errors decreased as the number of rigid body segments increased (Fig.1). However, not much improvement was observed when the trunk was modeled as three rigid-body segments as compared to two rigid-body segments (Single: 7.5 -27.7mm, Two: 5.9 -24.3mm, Three: 5.5 -23.5mm). These results imply that two rigid-body segment model would be good enough to describe complex trunk movements during running.

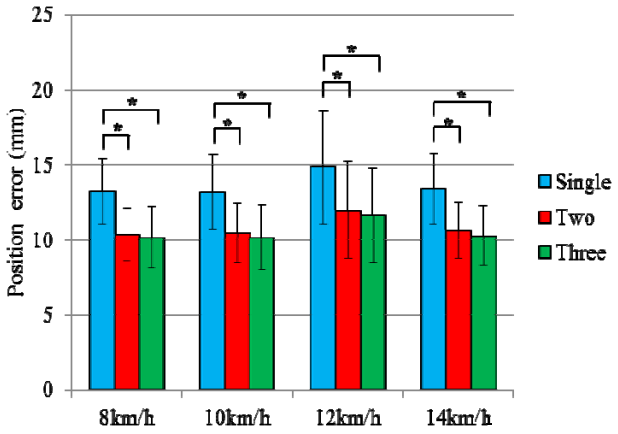

Figure 1: The difference between modeled and actual position data during running. *p<.05

CONCLUSIONS

When modeling the trunk as rigid-body segments during running, the position errors decreased as the number of rigid-body segments increased. However, such improvement in the error appeared in a non-linear fashion, reaching a plateau, where the improvement from the two to three segment model was much smaller than that from one to two segment model. Two rigid-body representation would be good enough to describe the complex trunk movements when modeling the trunk during dynamic movements.

INTRODUCTION AND OBJECTIVES

Effect of load induces various changes in the spatiotemporal gait parameters and postural angles of the user [1, 2]. Backpacks are used daily by school children and University students to carry educational materials and personal belongings with them from one place to other. If used incorrectly, they may cause back pain and injury to the user [3]. The purpose of this study was to find out the variations in gait parameters and the postural angles between school going children carrying the significantly different amount of load over an extended period. An equal number of children from day and boarding school were studied, for the investigation of long-term effects of the backpack load. The average load carried by children from day school was significantly more than those from boarding school. The reason being, day school students carried books, different notebooks for classwork & homework, lunch box and other sports equipment from home to school every day. Whereas in a boarding school, the conveyance was from in-campus accommodation with comparatively less load which comprised of books and notebooks. The hypothesis for this study is that, at identical loading conditions, there is a significant difference of kinematic body postural angles and gait parameters between day school and boarding school children. A significant difference in response parameters may further prove that prolonged carriage of heavy backpack causes permanent changes in the gait parameters and postural angles.

METHODS

The experiment was a between subject design. Twenty-four male subjects (12 from each school) from Chandigarh, India aged between 12 to 14 years who had studied for at least 4 years in the same type of school were selected. 12 students each from boarding and day school with similar height, weight, and social strata conditions were the inclusion criteria whereas students with the history of orthopedic, neuromuscular and cognitive disorder were the exclusion criteria for selection. Prior to the study, written voluntary consent was1gfh taken from the principal of each school, the student and the parent/local guardian in the case of students of the boarding school. The experiment protocol was approved by the ethical committee at PEC University of Technology.

On the day before data collection participants completed a written questionnaire regarding average time spent carrying a backpack every day, backpack weight, hours per week playing sport and history of any injuries or disorders.

The study was divided into two parts. In the first part setup was established in the laboratory and children walked for 8 mins (time selected on the basis of questionnaire) at their natural speed with their own backpack load as per their preferences which were further defined in terms of relative backpack weight (RBW) i.e. {(backpack weight/bodyweight)*100}. Several spatiotemporal parameters and postural angles were recorded for two sessions (with a backpack and without backpack) by using IDEEA accelerometry system and video camera respectively. Each session consisted of three trials, from these trials, the most consistent set of data for each session was selected for the study. The first part of a study aimed to evaluate the effect of RBW on the variation in response variables (gait parameters and postural angles). Whereas variation in response variables is defined in percentage explained as modulus of |{(original (with backpack carriage) – baseline)/baseline}*100|. Baselines assessment of school children was recorded when they carried no backpack at all and original assessment of response parameters when participants carried their own backpacks. Out of all the response variables, only those were selected which had a significant variation in the relative backpack weight. Summary of physical parameters of the subjects (age, body mass, height, body mass index), backpack weight and RBW for the first part is given in Table I.

Table I: Summary of physical parameters of the subject

Parameter	Mean	Std. Deviation	Minimum	Maximum
Age (year)	13.17	1.8	10.4	12.3
Body Mass (kg)	44.41	6.32	38.64	48.50
Height (m)	1.57	0.09	1.49	1.61
BMI (kg/m^2)	17.42	1.8	15.71	18.37
Backpack Weight (Kg)	7.9	3.8	3.1	11.3
RBW (%)	16.43	8.6	8.36	27.82

The second part was to compare the variation in gait parameters and postural angles at different loading conditions for both groups on a long-term basis. To compare the variation in response parameters of respective groups, seven loading conditions of 0%, 5%, 10%, 15%, 20%, 25% and 30% of body weight were used for the experimentation. The criteria for selection of these loading conditions were obtained from the survey questionnaire.

A one-month long program was implemented. Response parameter of each participant from the two groups was evaluated for seven sessions for each loading condition. Each sequence of the session consisted of ten trials of data collection. From these trials, the mean value of all the trials for each response parameters for the given loading condition was calculated for the study. This was done to accustom the boarding school students with the similar amount of load as the day school students. The independent parameter in the study was RBW. The measured response parameters and their description are detailed in Table II.

Table II Response parameters measured in the study

Abbreviation used for variation in	Description of Response parameter

response parameter	
Variation in Stride Length (VSL)	Distance between intra-limb toe-off positions
Variation in Stride Width (VSW)	Distance between heel to heel during the gait cycle of inter-limb
Variation in Cadence (VC)	Number of steps taken in one minute
Variation in Speed (VS)	The traveled distance divided by the elapsed time
Variation in Double Support time (VDST)	Time elapsed when both feet are in contact with the ground.
Variation in the height of Earlobe (VHoE)	The distance between earlobe and the ground at the time of toe off.
Variation in Trunk Angle (VTA)	Formed between the line drawn through the markers at C7 and the greater trochanter, and a vertical line through the greater trochanter.
Variation in Head on Neck Angle (VHoN)	Formed by the line drawn through the anatomical markers at C7 and the tragus of the ear, and the line through the canthus of the eye and the tragus of the ear.
Variation in Craniovertebral Angle (CVA)	Formed at the intersection of the horizontal line through the spinous process of C7 and a line through the tragus of the ear.

RESULTS

Results obtained from the first part of the study showed that there was a significant positive correlation between the relative backpack weight (RBW) with variation in gait parameters & postural angles at $p<0.05$. The mean backpack load carried by the students studied in the day school was higher than the weight carried by the students studied in the boarding school by 47 %. Due to this continued carriage of extra load in the backpack by the day school students, the overall variation in the response variables was significantly more in this group. Mean variation in the gait parameters and postural angles as shown in figure 1 (a) and (b)

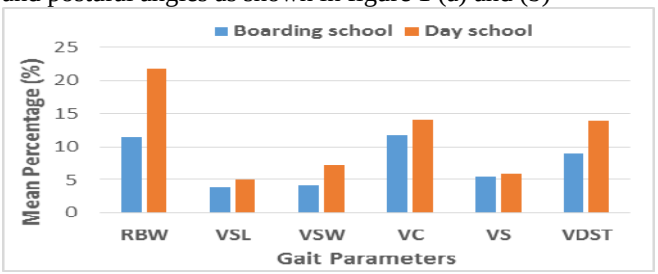

Figure 1(a): Effect of relative backpack weight on mean variation in gait parameters

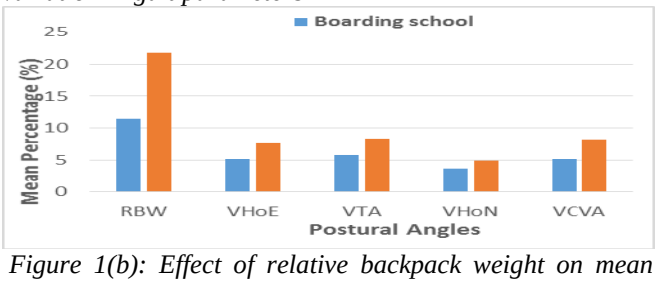

Figure 1(b): Effect of relative backpack weight on mean variation in posture angles

The second part of the study showed the effect of a backpack on the gait parameters and posture angles in both boarding school and day school 0% backpack load weight to 30% backpack load weight. The results revealed that there was significant. Figure 2 (a) & (b) shows that the variation in gait parameters and postural angles is significantly higher in the case of day school students in comparison to boarding school students at $p<0.05$.

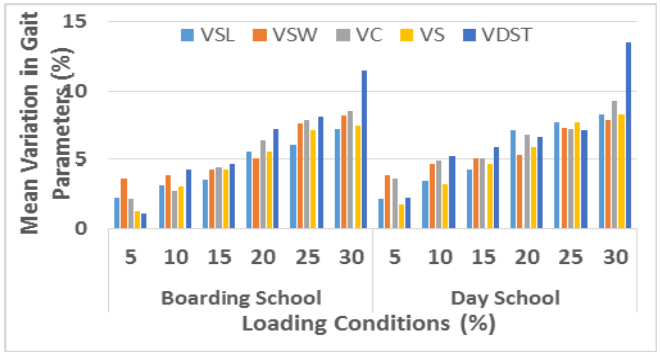

Figure 2 (a): Comparison between gait parameters of participants studied in boarding and day school at different loading conditions

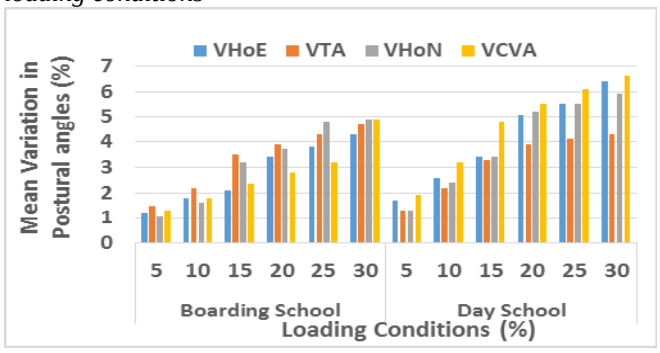

Figure 2 (b): Comparison between postural angles of participants examined in boarding and day school at various loading conditions

CONCLUSIONS

Variation in stride length, stride width, speed, height of earlobe, craniovertebral angle and trunk angle when tested by turkey posthoc analysis at $p<0.05$ showed significantly higher variation from the baseline in case of participants from day school in comparison to participants from boarding school for the same load carriage conditions. This may prove our hypothesis that there are certain permanent changes developed in the adolescents which hamper their growth due to the prolonged transport of heavy backpacks

ACKNOWLEDGEMENTS

We would like to express our gratitude to the management of the various schools and the students who whole heatedly cooperated with our survey. Last but not the least International Society of Biomechanics who give us the opportunity to present our study.

INTRODUCTION

Several research studies have investigated the effects of different backpack loads on the back and lower extremity joint movements, but trunk and pelvic moment analyses are difficult because the backpack blocks the markers used in analysis. We devised a backpack that allowed for detection of markers attached to the trunk. The purpose of this study was to investigate the effect of the location of weights in the backpack, on the trunk, pelvis, and lower extremities during walking on level and sloped surfaces.

METHODS

Ten healthy male volunteers aged 18 to 23 years participated in the study. The subjects had no walking problems due to orthopedic diseases or spine and leg impairments. Before the study was initiated, the aims and methods of the study were explained to the subjects and their consent was obtained. The subjects were asked to walk on a flat surface and ascend and descend a 6-degree slope with non-weighted and weighted backpacks. The weights applied were 15% of the subjects' individual body weight and located randomly in different areas of the upper thorax and lower back. During walking, three-dimensional angular displacements and moments of the trunk, pelvis, hip, knee, and ankle were obtained using the Vicon Nexus system and four force plates. The electromyographic activities of the elector spinae, rectus abdominis, biceps femoris, rectus femoris, lateral gastrocnemius, and tibialis anterior were recorded using surface electrodes at a sampling rate of 1,000 Hz. These data were sequentially processed as the rate of integrated electromyograms (%iEMGs) according to the volume ratio of the maximum voluntary contractions of each muscle. Data were standardized and analyzed in one gait cycle, and compared between different walking methods and loadings. These data were tested by two-factor factorial ANOVA with α level set at 0.05.

RESULTS AND DISCUSSION

The ranges of trunk lateral flexion and rotation, and pelvic rotation in the upper loading were significantly lower than those of the lower loading, and the size of the difference in ranges increased in order from ascending slope (smallest) through level walking, to the largest difference in descending slope ($p < .05$, respectively) (Figure 1). However, the hip rotation range was significantly higher in the upper loading than in the lower loading ($p < .05$). Although the flexion-extension range of the trunk differed according to the difference in walking methods, this did not differ between the upper and lower loadings on the back. The %iEMG during ascending was lower in the rectus abdominis than in the other muscles. No significant findings regarding ranges of moments in the trunk and lower extremities during stance phase were obtained from the different loading positions, except a difference in the moments produced by walking methods. Compared with no loading on the back, application of a load weighing 15% of the body weight on the upper thorax may reduce the angular displacement of the trunk lateral flexion and rotation for inhibition of the trunk motion caused by the relatively higher center of body mass. However, this may be compensated for by increasing the rotation range of the hip. An increase in the forward leaning of the upper trunk has been reported in previous studies when subjects carry a backpack with lower loading [1,2]. It could be suggested that carrying upper loads induces a bent trunk posture and pushes the body forward when walking on an ascending slope. Heavy loading in the form of a backpack is common in everyday life and can be expected to have physiological and perceptual effects. Our findings suggest that there is a biomechanical benefit of higher placement loading.

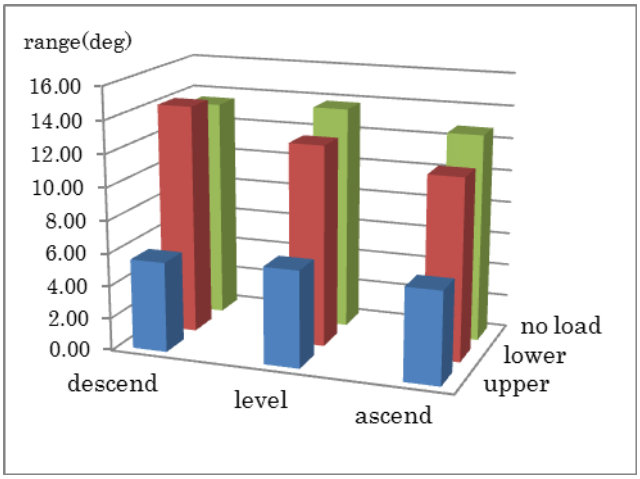

Figure 1: Trunk lateral flexion ranges with upper and lower loading during different walking methods.

CONCLUSIONS

Carrying patterns of a heavy load in a backpack at 15% of body weight in different positions on the back (upper and lower) varies individually according to body mass, body portion and muscle power. A wider range of trunk motion occurs with lower loading compared to upper loading. Further studies should be carried out to investigate the relationship and strategy between the placement of the load and individual physical features and characteristics.

INTRODUCTION

Firefighters and military personnel commonly employ multiple backpack designs for carrying heavy load for occupational purposes. Firefighters carry air tanks along with other heavy gear connected to the pack further adding to the weight of it. As the load increases, the biomechanical and physiological demands on the carrier change as well. [1] The xPk® harness, a new design, claims to improve the load carriage ability for firefighters by allowing the load to be carried closer to the individual's center of mass (COM) thus reducing the energy cost of load-carriage [2]. The design also claims to assist by "reducing the pull on the wearer's shoulders" thus increasing the comfort level compared to the traditional pack design commonly used by firefighters. The purpose of the study was to compare biomechanical differences as demonstrated by individuals while carrying the empty firefighter air tank in traditional harness to xPk® double strap harness designs.

METHODS

Twelve healthy individuals (age: 26.5±5.8 yrs, ht: 1.74±9.9 m, wt: 79.4±15.9Kg) walked at 1.79 m/s (4 mph) on a treadmill at 3 different grades: 5% for 2 minutes (G1), 7.5% for 4 minutes (G2), and 10% for 4 minutes (G3). Participants completed one trial each with the 2 harnesses and empty air tank (7.5 kg) in a counterbalanced order.

Trunk and lower extremity kinematics and stride data were recorded through a Vicon 3D motion capture system (240 Hz; MX3+, Nexus 2.8®) using 53 reflective markers. The Borg rate of perceived exertion (RPE) scale [3] was recorded every minute throughout the testing. 3D data were analyzed in Visual3D (c-motion). Marker positional data were low pass filtered (4th order Butterworth; cutoff: 6Hz) and used to create a 7 segment plus tank model. Heel strike and Toe-off were determined using automatic gait events (Visual 3D). Stride length, width, and stride rate along with ankle, knee and hip sagittal plane ROM, pelvic tilt, pelvic obliquity ROM, anterior trunk tilt, and trunk lateral tilt ROM were calculated for and averaged across stride and leg over 10 s. The position and movement of the center of mass (COM) of the tank + harness was calculated relative to the mid iliac crests along the anterior and longitudinal axes. For each variable, 2 way repeated measures ANOVAs for grade (G1-3) and harnesses (traditional and xPk®) were calculated to determine statistically significant difference along with Greenhouse-Geisser corrections in case of sphericity violation (α=0.05). Post-hoc analysis included paired t-tests with Bonferroni corrections. Cohen's d effects sizes were also calculated.

RESULTS AND DISCUSSION

Five angular kinematic variables and the three tank COM position variables had statistically significant differences. Ankle dorsiflexion/plantar flexion ROM had a significant interaction ($F_{2,22}$ = 11.624, p <.001). Post hoc analysis revealed 1.2° greater ankle ROM with the xPk® harness as compared to the traditional harness at the 5% grade with a moderate effect size (ES =.34). Hip flexion ROM increased 3.5° from the 5% grade to 7.5% grade and 2.5° from 7.5% to 10% grade (p=.009) with large (ES = 1.29) and moderate (ES = 0.42) effect sizes, respectively. Anterior trunk tilt increased 3.3° from the 5% grade to 7.5% grade and 2.9° from 7.5% to 10% grade (p<.001; ES = .84 and .85, respectively) and was 1° more anterior with the xPk® harness (p=.026; ES =.17). Trunk lateral tilt had 0.5 degrees less ROM with the xPk® harness (p=.002; ES = .48). Pelvic anterior tilt increased 2° both from the 5% grade to 7.5% grade and from 7.5% to 10% grade (p=.003; ES = .49 and .48, respectively). The low magnitude of differences in kinematics between harnesses and across grades observed is unlikely to be clinically significant.

The xPk® + tank COM were positioned lower/ closer to the iliac crests of the user (4 cm; p<.001; ES: 1.25), slightly more posterior (2 cm; p=.042; ES: 0.72), and moved 5 cm less (p=.016; ES: 0.91) along the long axis as measured relative to the iliac crests. Tank COM anterior position was 2 cm farther back, relative to the iliac crests, on the 5% grade as compared to the 7.5 % grade (p = .004; ES = .54) and 1 cm farther back on the 7.5% grade as compared to the 10% grade (p =<.001; ES = .28). The lower load position with the xPk® harness accompanied by less superior inferior displacement of the xPk® and tank system relative to the iliac crests may have attributed to more participants preferring to carry the air tank in the xPk® harness system. An increased perception in effort recorded at 10% gradient with xPk® could have been related to the slightly more posterior positioning of the xPk® and tank COM relative the iliac crests, which could create a larger extension torque on the back due to an increased moment arm to the load. 60% of the participants preferred xPk® for being more comfortable than traditional harness.

CONCLUSIONS

While there were significant and meaningful differences in grade kinematics, changes in kinematic data between old and new harnesses were minor and unlikely to provide meaningful differences within a clinical setting. The minimal differences in kinematics and subjective preference for comfort for xPk® suggests that this harness could potentially be helpful in improving load carrying capacity without having to retrain carrying mechanics. Future research is warranted with occupation specific high intensity tasks such as duck-walking and ladder climbing on a larger sample population to better compare the harness systems.

THE EFFECT OF LOAD CARRIAGE, WALKING SPEED AND DOWNHILL GRADE COMBINATIONS ON THE ELECTROMYOGRAPHIC AND SUBJECTIVE RESPONSES OF INDIAN SOLDIERS

[1] Sohini Paul and [2] Dhurjati Majumdar

[1] AmityUniversity
[2]Defense Research and Development Organisation

INTRODUCTION

Load carriage is an inevitable part of military life both during deployment and training sessions. Indian soldiers carry loads and crosses stiff mountain gradients in the eastern and the western Himalayas thus involving uphill and downhill walking. It is hypothesized that downhill walking affects the lower limbs and back muscles differently. This study examined the effect of increasing load, speed and decreasing gradient during downhill treadmill walking on different muscle activities and subjective responses.

METHODS

Twelve healthy infantry soldiers (age 24.8±2.9 yrs, height 173.76±7.4 cm and weight 66.2±6.4 kg) participated in this study. All the experiments were conducted in controlled laboratory conditions with temperature ranging from 25-28^{0}C and 35-40% relative humidity and at random to avoid any biasness. The subjects walked at two different speeds (2.5 km.h^{-1} and 4 km.h^{-1}) on a treadmill unloaded and carrying 10.7 kg, 17kg and 21.4kg loads at a decreasing gradient (%) - 25, 20, 15, 10, 5, and 0. For each gradient the subject walked for 6 minutes amounting to a total of 36 mins walk. All the experiments were conducted at random to avoid any biasness. During the experiment the electromyographic responses of Erector spinae (ES), Vastus medialis (VM), Gastrocnemius medialis (GM) and Soleus (SOL) of both sides were monitored along with the rating of perceived exertion (RPE).

RESULTS

Significant effects of load, speed and gradient on all the leg muscles and RPE scores for all the above mentioned conditions were observed. In case of ES muscles activity, only gradient had a significant effect. It was observed that while walking with 21.4kg loads at 4km.h^{-1} speed the activity of the muscles increased maximally compared to other load and speed combinations. The activity of the ES, VM, SOL and GM muscles increased upto 153%, 338%, 141%, 200% and 165%, 348%, 136%, 197% for the right and left side respectively compared to 0% gradient.

DISCUSSION

The responses in both the sides are almost equal. The intensity and duration of the downhill walk affected the VM muscle activity most (Franz and Kram, 2011). A maximum RPE score of '12' signifying moderate intensity exercise was obtained when the subjects walked at this condition.

CONCLUSION

This form of strenuous activity especially on the knee extensors predisposes the risk of muscular injury and early onset of fatigue. Hence, the combat fitness of the military personnel is reduced. Military training schedule and operational requirement along with other mountain climbing and descending exercises for the general population must take adequate preventive measures while putting any personnel in this form of downhill exercises with load.

LOWER-LIMB JOINT WORK AND POWER ARE MODULATED DIFFERENTLY DURING LOAD CARRIAGE BASED ON SPEED AND LOAD CONFIGURATION

[1]**Gavin K Lenton**, [2]Tim L A Doyle, [1]David J Saxby, [1]Jeremy Higgs, [3]Dan Billing and [1]David G Lloyd
[1]Griffith University; [2]Macquarie University; [3]Defence Science and Technology Group

INTRODUCTION

Training and operational objectives require soldiers to transport loads weighing >20 kg at high speeds for short bouts and at slow speeds over long durations. These tasks elicit high energetic costs, result in muscle fatigue, and decrease combat readiness. There is a proportional increase in both net metabolic energy rate and centre of mass positive work in response to either increased carried load or gait speed [1, 2]. Most of the increase in positive work occurs at the ankle and knee [2, 3]. Increased reliance on knee muscles could precipitate quadriceps fatigue. Instead, re-distributing load could increase hip and ankle joint contributions to forward progression, and preserve normal knee work and power.

This study aimed to examine how lower-limb joint work and power are modulated in different walking speeds and load configurations during gait.

METHODS

Twenty Australian Army Reserve soldiers (29.5±7.1 yrs) participated. A total of 12 body armour variations were tested: six armour types (one standard-issue body armour and five prototype designs) × two load magnitudes (15 or 30 kg). Participants completed testing with the 12 armour variations over four testing sessions with each session separated by at least two days.

Wearing body armour, participants walked on a force-plate instrumented treadmill (AMTI, Watertown, US) at both moderate (1.53 $m \cdot s^{-1}$) and fast (1.81 $m \cdot s^{-1}$) speeds for 10 minutes at each speed, while an 11-camera motion capture system (Vicon, Oxford, UK) collected whole-body three-dimensional marker kinematics.

A modified full-body OpenSim [4] anatomic model was scaled using standing static trial markers. Inverse kinematics and inverse dynamics analyses were used to determine joint angles and net moments. Hip, knee, and ankle powers were determined as the product of respective joint moments and angular velocities. Total positive (W_{tot}^{+}) and negative (W_{tot}^{-}) work was computed by integrating and summing positive (W_j^{+}) and negative (W_j^{-}) regions of joint power curves, respectively. Total average joint power generated ($\bar{P}_j^{+}$) and absorbed ($\bar{P}_j^{-}$) was calculated by doubling W_j^{+} and W_j^{-} and dividing by stride time. Each joint $\bar{P}_j^{+}$ and $\bar{P}_j^{+}$ was expressed as percentage of $\bar{P}_{tot}^{+}$ and $\bar{P}_{tot}^{-}$, respectively.

Repeated measures ANOVAs were used to compare joint work, and percentage joint contribution to total average positive power between different speeds and armour × load variations. Significance was set at $p<0.05$.

RESULTS AND DISCUSSION

Consistent with previous studies, W_{tot}^{+} significantly increased with both speed ($p<0.001$) and carried load ($p<0.001$). When increasing speed, hip power increased and ankle power decreased ($p<0.001$). When carrying 30 kg compared to 15 kg, the ankle generated less and knee generated more power ($p<0.001$). Unique to this study, percent contribution from ankle and hip joints to $\bar{P}_{tot}^{+}$ changed between armour designs ($p=0.018$, $p<0.001$) (Fig 1). The pARM3 armour condition required more power from the hip, whereas pARM1 and cARM2 required more power from the ankle, to be generated. From an efficiency perspective, ankle power is preferred, because power can be generated passively through energy storage and released by the Achilles tendon, while in contrast, muscles actively generate most of hip and knee powers [5].

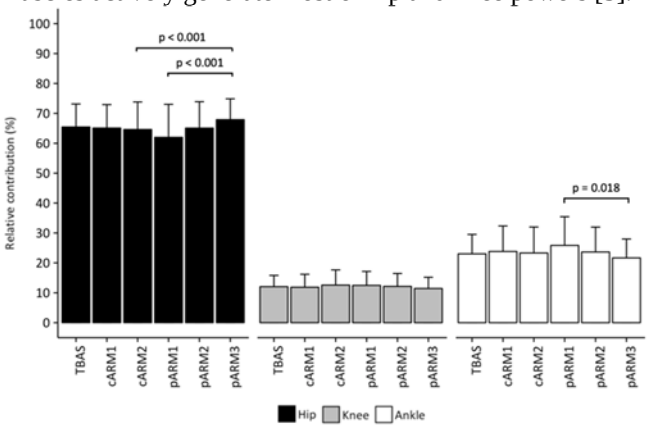

Figure 1: Relative contributions of hip, knee and ankle powers to total average power generated by the lower-limbs during a gait cycle.

CONCLUSIONS

This study is the first to report that different body armour × load configurations and gait speeds elicit different joint power strategies. While total average power generated was largely dictated by task demands, armour systems elicited different joint power profiles. These results may be used to inform an optimal armour configuration and/or physical training program to improve soldier performance and longevity in both training and field operations.

INTRODUCTION

Tests evaluating movement control of the lumbo-pelvic-hip complex are commonly described to assess motor function of the trunk and lower extremity [1]. Quantification of test performance using kinematic analysis may be either 3-dimensional (3D) or 2-dimensional (2D). Although 3D methods have the advantage of more accurately depicting motion in three planes, 2D photographic image capture methods are more readily available in clinical settings [2]. 2D assessment of vertical axis rotation of the pelvis is difficult as the use of an overhead camera is problematic because of obscurement by the trunk.

The overall aim of this study was to test the validity of two, 2D methods to measure pelvic rotation without the use of an overhead camera. First, we evaluated the accuracy of the 2D methods (using 2 SLR cameras in the sagittal and frontal planes) to record known increments of pelvic rotation of a mechanical jig. Second, we calculated pelvic rotation measurement error when combined with pelvic motion around other axes. Third, we compared the agreement between 2D measures and those made concurrently with a 3D system. Finally, we provide recommendations regarding the use of 2D photographic media that includes methods to reduce measurement error.

METHODS

A plastic pelvis was mounted on a mechanical jig that enabled precise incremental movements through five degrees of freedom. The pelvis was orientated through known angular and linear displacements while photographic images (frontal and sagittal planes) and 3D motion capture were simultaneously recorded. Pelvic rotation was estimated from changes in projected linear distances between pelvic landmarks in the frontal and the sagittal planes as the pelvis was rotated. Measurement error caused by concomitant pelvic motion along and around other axes was determined with linear regression modelling and a correction factor was derived. The corrected 2D measures of pelvic rotation were compared against the known increments of the jig and those calculated from the 3D recordings.

RESULTS AND DISCUSSION

As the pelvis was rotated around the vertical axis in isolation, estimation of pelvic rotation from both frontal and sagittal methods closely matched the jig angle data (average Root Mean Square Error (RMSE): frontal 1.39°, sagittal 1.50°). Initial axial rotation of the pelvis from a start position parallel to the front camera led to smaller changes in projected linear distances between markers on the anterior superior iliac spines in the frontal plane than the sagittal plane. This caused greater measurement error for the frontal method for the initial 0-8° of rotation (Fig. 1).

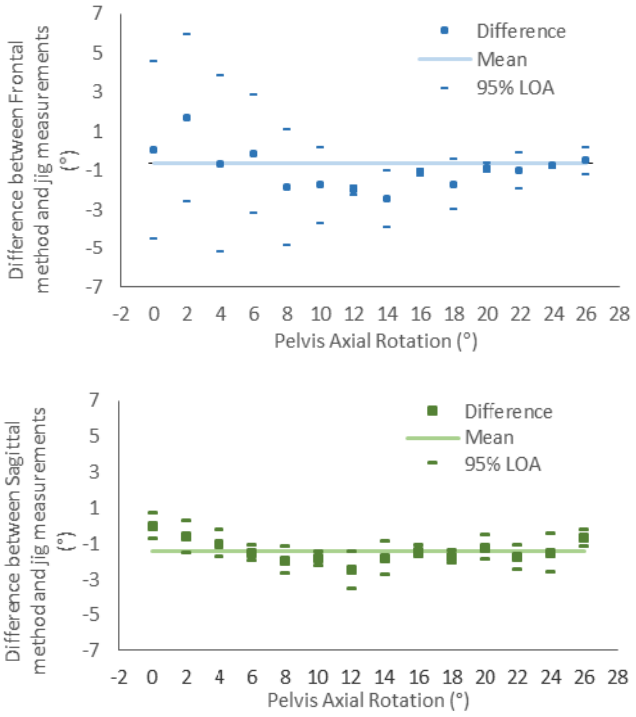

Figure 1: Bland-Altman plots of difference between 2D methods and jig measurements of pelvic rotation. LOA=Limits of Agreement.

Both frontal and sagittal methods to measure pelvic rotation were susceptible to measurement error when concomitant pelvic motion occurred around other axes. When rotation values were corrected using correction factors derived from liner regression modelling, average RMSE across all sequences was: 3.64° (2D – Frontal), and 1.62° (2D – Sagittal). RMSE for the 3D measurements was 1.37°. Although both 2D methods enabled accurate measurement of pelvic rotation, the sagittal plane method demonstrated better accuracy and was comparable to 3D motion measures. Clinicians using 2D methods to measure linear and angular change should ensure that images are calibrated for distance from the camera, and cameras are set up orthogonal to the subject in both frontal and sagittal planes to enable for correction related to motion along and around other axes.

CONCLUSIONS

This study has shown that a 2D method can accurately measure axial pelvic rotation without the use of an overhead camera. This method has direct application in clinical settings as the technology required is readily available.

INTRODUCTION

In a context of musculoskeletal disorders prevention, movement analysis can provide a better understanding of subject exposure to biomechanical factors. In laboratory studies, these analyses are realized using optoelectronic motion capture systems, which are currently considered as a reference regarding their accuracy of measurements. As for "in the field studies", movement analysis using these systems is more challenging due to the difficulties related to volume calibration and marker occlusions. For these reasons, an emerging approach, using magneto-inertial measurement units (MIMUs), could be appropriate for a use in the field movement analysis. Several studies focused on the acquisition of upper limb kinematics using MIMUs. Some studies analyzed the impact of sensor placement and calibration on joint angles estimation [1, 2], while another study [3] underlined the importance of sensor placement and specific calibration, using a scapula locator, for the scapulo-thoracic movement estimation. However, this last study only investigated the scapula-thoracic kinematics during anteflexion and adduction movements.

To broaden these first results, this study aimed at estimating various shoulder movements using MIMU data on the upper limb with and without a numerical scapula sensor calibration. Furthermore, both scapulo-thoracic and gleno-humeral joint angles were investigated and compared with the same joint angles using an optoelectronic system.

METHODS

Nine healthy subjects with no history of upper limb complaints participated in the study. Five wirelesses MIMUs (MTw, version firmware 2.0.8, Xsens, Enschede, The Netherlands) were placed on the thorax, on the right scapula, right upper arm, right arm and right hand [2]. MIMUs' calibration consisted in maintaining a standing pose with the upper arm along the body, elbow flexed at 90°, in neutral forearm pronation-supination. Two specific scapula calibration are proposed: numerical readjusted calibration (addition of 18° around the axis representing the superior border of the scapula) (MIMU1) [3] and general physical calibration (MIMU2).

An optoelectronic system (Eagle 4, Motion Analysis Corporation, USA) was used as the reference measurement system for the kinematics (REF). Generally used marker set [4] and acromial marker-cluster [5] were considered.

Joint angles were estimated for MIMU1, MIMU2 and REF for four separate movements and posture: maximal amplitude of shoulder flexion/extension (ShoFmax); maximal amplitude of shoulder abduction/adduction (ShoAmax); a circular movement in the transverse plane (wheel) and a "T pose" (standing pose with the arm at 90° in abduction, elbow and wrist in neutral position). Each movement/pose was repeated 5 times in 3 different sessions. The statistical analyses looked for the accuracy (near to the reference) and the fidelity (repeatability) for the proposed calibrations. The differences between MIMU1 and REF and MIMU2 and REF were considered as variables. They were performed with a statistical mixed model with three variance components: subject, between-sessions and within-session.

RESULTS AND DISCUSSION

The mean differences for flexion/extension angle of the scapulo-thoracic joint estimated using MIMU1 varied between 3.12° (wheel) and 10.63° (T pose). As for MIMU2, these errors varied between 6.75° (wheel) and 16.85° (T pose) (Figure 1).

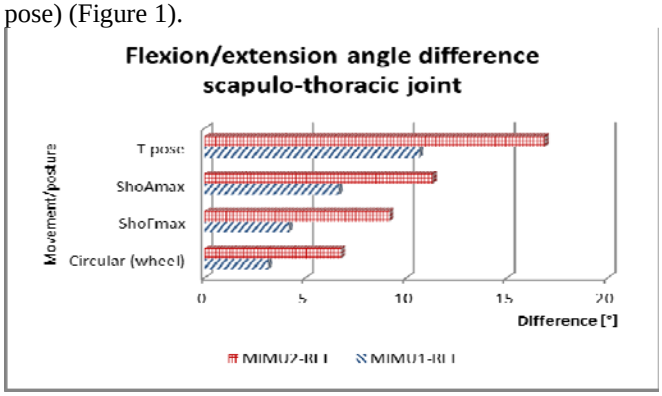

Figure 1: Flexion/extension angles differences between MIMU1 and REF and MIMU2 and REF for the analyzed movements/posture for scapulo-thoracic joint.

The mean differences for flexion/extension angle of the gleno-humeral joint estimated using MIMU1 varied between 17.57° (wheel) and 47.13° (ShoFmax). Considering MIMU2 these errors varied between 12.57° (wheel) and 42° (ShoFmax). For abduction/adduction angle estimation the specific scapula sensor calibration had no influence and the mean differences varied between 4.78° (wheel) and 12.88° (T pose) for the scapulo-thoracic joint and between 4.27° (wheel) and -20.05° (T pose) for gleno-humeral joint. It is interesting to mention that, for both MIMU1 and MIMU2 the between-subjects variability (i.e ShoFmax: Sd= 5.14) is smaller than the within-session variability (i.e ShoFmax: Sd = 9.54).

CONCLUSIONS

The results showed the importance of modifying the scapula sensor calibration for improved scapulo-thoracic and gleno-humeral movement estimation. This study confirms the necessity of defining the axis of the scapula by an appropriate anatomical calibration if the analysis of the movement of the scapula with regard to the thorax is needed.

RELIABILITY ANALYSIS OF SHOE-TYPE 3D INERTIAL MEASUREMENT UNIT SENSOR AND MOTION CAPTURE SYSTEM ON PARKINSON'S DISEASE PATIENTS

Myeounggon Lee, Changhong Youm, Minji Son and Hwayoung Park
University of Dong-A, Busan, Korea

INTRODUCTION

Parkinson's disease (PD) is a degenerative neurological disorder that can induce tremor, rigidity, bradykinesia, and postural instability. These characteristics cause PD patients to experience gait impairment, which may lead to increase a risk of falling. Previous studies have analyzed the gait of the healthy elderly subject using an accelerometer and an inertia measurement unit (IMU), which are inexpensive, portable, and simple to use. Furthermore, there have been studies on the reliability of a 3D IMU sensor and motion capture system during treadmill walking [1], but not with PD patients. Therefore, the purpose of this study was to investigate the reliability analysis of shoe-type 3D IMU sensor and motion capture system during treadmill walking on PD patients.

METHODS

We recruited 17 PD patients (64.6 ± 7.4 years, 1.59 ± 0.09 m, 64.5 ± 9.7 kg) using the following inclusion criteria: no history of orthopedic surgery, neurosurgery, and neurophysiological problems in the preceding 6 months; a Mini Mental State Exam (MMSE) score of >24 points; and a PD stage of 2-3 on the Hoehn and Yahr (H&Y) scale.

The 3D IMU sensor, comprising the IMU-based gait analysis system (DynaStab, USA) and shoe-type data logger (Smart Balance, USA), and the motion capture system (Vicon, MX-T10, UK) comprising nine infrared cameras were used to collect the treadmill walking data.

Thirty-nine reflective markers were attached to the participants according to the plug-in gait full-body model for capturing motion. All PD patients took the anti-parkinsonian medication at least 3 hours before test, and they performed the treadmill walking with their self-preferred speed. The resultant linear acceleration was calculated from the net acceleration of the X, Y, and Z axes on the left and right sides during a 1 minute treadmill walking. The root mean square error (RMSE) and percent error between the IMU sensor and motion capture system were calculated over the total signal for the resultant linear acceleration [2]. The cadence, step length on the left and right side, and the stride length on the left and right side were calculated during a 1 minute treadmill walking.

Pearson′s product-moment correlation analysis was used to compute the correlation between the 3D IMU sensor data and the motion capture system data. Furthermore, paired sample t-test was used to compare the cadence, step length, and stride length between IMU sensor and motion capture system. The statistical significance was set at 0.05.

RESULTS AND DISCUSSION

The analysis of the correlation between the resultant accelerations of the 3D IMU sensor and the motion capture system indicated that there was a strong correlation on the left ($r = 0.950 \pm 0.018$) and right sides ($r = 0.937 \pm 0.020$). The RMSE was indicated that the left sides was 1.99 ± 0.63 m/s^2 (the percent error: 6.87 ± 1.56%) and the right sides was 2.01 ± 0.58 m/s^2 (the percent error: 7.00 ± 1.39%), respectively. The analysis of the correlation indicated that there were strong correlation for cadence, left and right step length, and left and right stride length. There were no significant difference for cadence, left and right step length, and left and right stride length between the IMU sensor and motion capture system (Table 1).

Table 3. Reliability between IMU sensor and motion capture system

	IMU sensor (M±SD)	Motion capture system (M±SD)	Correlation coefficient (*r*)	Paired sample *t*-test (*t*), *p*
Cadence (step/min)	110.29±20.12	111.35 ± 21.50	0.988*	1.264, 0.224
Left step length (cm)	22.18±13.32	20.88±12.16	0.974*	1.833, 0.085
Right step length (cm)	22.18±12.83	22.00±12.60	0.975*	0.253, 0.804
Left stride length (cm)	44.24±25.51	44.35±25.40	0.999*	0.621, 0.543
Right stride length (cm)	44.29±25.30	44.41±25.50	0.999*	0.356, 0.727

M±SD is mean and standard deviation; * is significant difference, $p<.05$

CONCLUSIONS

The resultant linear accelerations and the cadence, step length, and stride length measured by the 3D IMU sensor and the motion capture system were indicated high correlation coefficients during the 1 minute treadmill walking. These results suggest that the shoe-type 3D IMU sensor may simply use for gait analysis in the clinical environment.

TEXTILE-BASED WEARABLE SENSORS FOR HUMAN MOTION CAPTURE

INTRODUCTION

Smart fabric sensors are made of fibers that add sensing properties, e.g. by knitting conductive yarns with nonconductive yarns. Structural deformations of the electrically conductive textiles change the fabric electric resistance making them employable, for instance, as motion sensors. Thus, textile-based sensors can be used as wearable devices to detect movements of a subject wearing them and can be developed for rehabilitative and biomechanics purposes. The aim of this study is to evaluate the employability of conductive textiles as knee-angle sensors by recording knee flexion-extension with a customized tracking system and the fabric electrical resistance variation with a dedicated supply and measuring circuitry.

METHODS

The electrical properties of the knitted conductive sample used in the study (SP29 made of 20% stainless steel and 80% polyester) were previously investigated during cyclic loading on an Instron tensile machine [1]. The same specimen was subsequently sewn along the knee joint of a pair of leggings with 18% elastane to be tested in a real application, with a participant performing cyclically knee flexion-extension in an upright position.

The knee angle tracking system used in this research consisted of a camera and red, green and blue markers appropriately placed on the thigh, knee and shank respectively. A MATLAB algorithm was used to distinguish and track the colored markers, with the actual location in 2D space being provided instant by instant. By knowing the coordinates of the center of the markers it was possible to calculate the knee angle as the angle between the lines connecting the thigh-knee and the knee-shank markers.

To measure the fabric electrical resistance of the conductive textiles embedded on the supporting garment a four-wire resistance measurement was chosen and a constant current supply method employed by a purposely manufactured electronic circuitry. To gather the electrical signal from the conductive area of the fabric, two copper tapes were sewn on the top and bottom of the specimen with a stainless steel thread. Such conductive contacts, between which the fabric was gripped in correspondence of the knee joint, collected the voltage across the specimen and the current provided to the sample with the controlled current generator. By dividing the voltage across the specimen by the current provided the fabric resistance was calculated. The knee angle and fabric resistance were acquired simultaneously by a data acquisition system (NI USB-6003), post processed in MATLAB and filtered with a Savitzky-Golay filter.

RESULTS AND DISCUSSION

The outcome of the study is represented in Figure 1, which describes the filtered fabric resistance, knee angle and hysteresis during three cycles of knee flexion-extension. The range of motion depicted varies from 155° (i.e. maximum extension during the test, with 180° being the reference for full extension) to 115° (i.e. maximum flexion). The maximum fabric resistance is measured at maximum knee extension which corresponds to the minimum elongation of the fabric. Conversely, the minimum fabric resistance occurs at maximum knee flexion corresponding to the maximum elongation of the textile. Both phenomena are consistent with [1] and in agreement with the Holm's contact theory and Ohm's Law. In fact, at maximum knee extension (and minimum fabric elongation), a decreased contact pressure in the yarn caused an increase of the contact resistance and, therefore, of the overall fabric resistance. On the other hand, by increasing the knee flexion (and the fabric elongation), a better contact between the strands of yarn resulted in an increased conductivity and, thus, a decreased resistance.

The hysteresis graph shows that the fabric behavior is non-linear, making the immediate estimation of the knee angle from the measured resistance not straightforward.

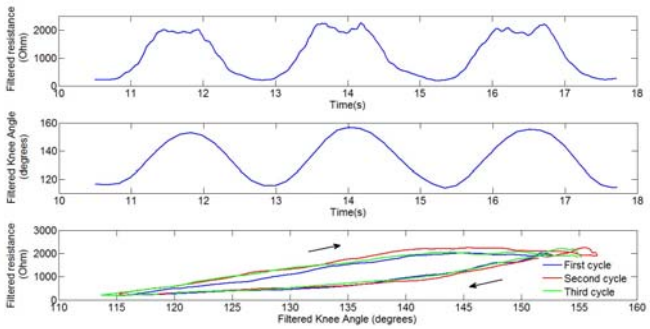

Figure 1: Filtered resistance, filtered knee angle and hysteresis during three cycles of knee flexion-extension.

CONCLUSIONS

The work described the preliminary feasibility study for a wearable sensor based on knitted conductive textile for human motion capture. In particular the knee flexion-extension and the corresponding sensing behavior of the conductive fabric under deformation were investigated. Further studies will consider systematic knee movements and will compare the performances of samples with different patterns embedded into leggings with different compositions.

ACKNOWLEDGEMENTS

USING A SINGLE ACCELEROMETER TO PREDICT LOWER EXTREMITY JOINT RANGE OF MOTION

[1,2] **Lauren C. Benson**, [1] Stephen C. Cobb, [3] Allison Hyngstrom, [1] Kevin G. Keenan, [1] Jake Luo and [1] Kristian M. O'Connor

INTRODUCTION

Falls are a major problem for stroke survivors, with higher incidences of falls than the general elderly population [1]. Individuals recovering from a stroke typically exhibit abnormal joint kinematics that could limit foot clearance [2]. Insufficient clearance between the foot and the walking surface may result in a trip, one of the greatest causes of falls [3]. Foot clearance is dictated by the sagittal plane range of motion (ROM) of the ankle, knee and hip [4,5].

The gold standard for quantifying joint kinematics requires the use of motion capture technology, typically found in research labs. However, the frequency of falls for stroke patients within the first six months following discharge from rehabilitation highlights the need for gait supervision when patients are ambulating on their own [6]. Although there have been several efforts to quantify joint kinematics outside of a research or clinical setting using wearable devices, most methods require the placement of several sensors on multiple body segments [7,8], which may be difficult for the general population to effectively adopt. The purpose of this study was to use machine learning techniques to predict lower-extremity joint angles based on a single accelerometer signal.

METHODS

Thirty-five participants with a range of walking abilities were included in this study: young adults (N=10), older adults without a history of falls (N=10), older adults with a history of falls (N=10), and stroke survivors (N=5). All participants walked overground (20 strides) and on a treadmill (6 minutes) at self-selected speeds while bilateral 3D joint kinematics of the ankle, knee and hip were recorded. Additionally, a 3D accelerometer was worn on the ankle, just above the malleolus. For each stride, the sagittal plane hip, knee and ankle ROM was determined. Time- and frequency-domain features of the accelerometer signal were also computed for each stride [9].

A correlation-based feature selection method was used to reduce the number of accelerometer features associated with each joint ROM [10]. The linear regression algorithm in Weka was used to predict each joint ROM of a single stride [10]. Performance of the linear regression model was evaluated using ten runs of 10-fold cross validation, measured as the correlation between the actual and predicted angles. The linear regression performance was averaged across all repetitions of training and testing for each of the ROM angles.

RESULTS AND DISCUSSION

The predicted knee angle ROM had a strong correlation to the actual knee angle ROM, while there was only a moderate correlation for the hip ROM and a weak correlation for the ankle ROM (Figure 1).

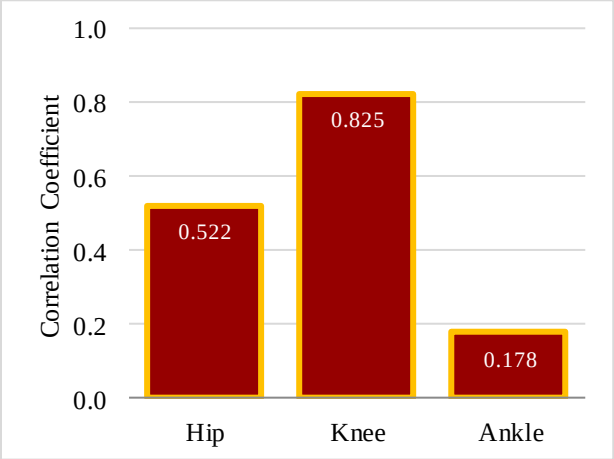

Figure 1: Correlation between actual and predicted joint range of motion.

Placement of the accelerometer on the distal joint segment appears beneficial for ROM prediction. As the ankle angle is calculated as the displacement of the foot relative to the shank, the placement of the accelerometer was not conducive to predicting ankle ROM. Similarly, the shank is not one of the segments determining the hip angle, which likely explains why the hip ROM prediction was worse than the knee. With the accelerometer on the distal segment of the knee, the knee ROM prediction was more successful. Additional sensors may have improved prediction accuracy, however, the goal was to accomplish kinematic prediction using a single sensor, which was done for knee ROM.

CONCLUSIONS

A single wearable device can be used to predict knee ROM. Being able to quantify joint ROM with a wearable device may help identify when individuals are at risk for falling in real-world settings.

HAND-HELD PROBE FOR OBJECTIVE INTRA-OPERATIVE ASSESSMENT OF OSSICULAR MOBILITY

[1] **Takuji Koike**, [1]Kai Takakuwa, [1]Yuuka Irie, [1]Sinyoung Lee and [2]Sho Kanzaki

INTRODUCTION

The ossicular chain, which consists of three ossicles, plays an important role in hearing. If the ossicles become fixed somewhere, hearing loss occurs. In order to improve the level of hearing, the fixed part of the ossicles must be sufficiently recovered or replaced. Evaluating the mobility of the ossicles is important during the tympanoplasty surgery, because the ossicular mobility affects the prognosis for the improvement of the hearing level. However, an objective measurement of the ossicular mobility has up to now been rarely performed during a surgery, and the assessment of ossicular mobility is made by palpation by the otologic surgeon in most cases. Palpation is inherently subjective and may not always be reliable, especially in milder degrees of ossicular fixation. We have developed a mechanical, hand-held probe that can provide an objective and quantitative assessment of the mobility of each ossicle during middle ear surgery [1,2]. In this study, the reliability and practical performance were evaluated by the measurements of artificial ossicles and cadavers.

METHODS

Our newly developed measuring system is shown in Fig. 1(a). The hand-held probe consists of a force censor, an actuator and an ear pick, which is usually used in ear surgery. The end point of the ear pick is attached to the piezoelectric force sensor (PS566, Mechano Transformer), which, in turn, is connected to the high precision piezoelectric actuator (MTKK10S100F30-S1, Mechano Transformer). The probe is connected to a computer-driven control unit. When the tip of the ear pick contacts an object like an ossicle, the actuator vibrates the ear pick at a frequency of 20 Hz. The load or reaction force generated by the ossicle is detected by the force sensor. A fixed ossicle is expected to generate a greater load (reaction force) than one that is mobile. The equivalent spring constant of the ossicle is calculated from the relationship between the load and displacement of the tip and is displayed on the computer screen. Each measurement takes 0.7 seconds.

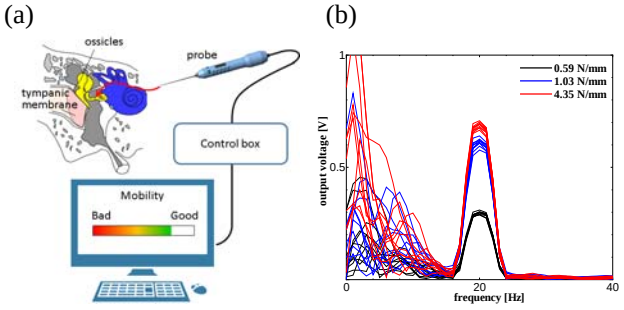

Figure 1: Measurement system for ossicular mobility (a) and frequency components of the output signal from the force sensor when the three artificial ossicles with different spring constant were measured (b).

The measurements were performed on artificial ossicles and fresh cadavers. The spring constants of the artificial ossicles were determined based on the results which were preliminary measured with the previous version of the probe [2] in patients during surgery.

RESULTS AND DISCUSSION

Figure 1(b) shows the frequency components of the output signal from the force sensor when the artificial ossicles with different spring constant were measured. The frequency components of 20 Hz were well detected regardless of the spring constant. The amplitude of the 20 Hz component increased with increasing the spring constant. This result suggests that the spring constants of the ossicles can be determined based on the amplitude of the 20 Hz component. By contrast, random frequency components were observed at the low frequency region below 15 Hz. These components are thought to be generated by hand trembling and are clearly separated from the 20 Hz component. This results shows that the ossicular mobility is measurable without being influenced by hand trembling.

The ossicle is considered as a rigid body, and the ossicular chain is supported by the ligaments and tendons in the tympanic cavity. The spring constant measured with our system therefore reflects the stiffness of the ligaments and tendons. Assessment of the degree of ossification of the ligaments and/or tendons is important for selection of a better surgical method and for improving the prognosis after surgery. Our device can provide valuable information of the status of the ossicles to the surgeons.

CONCLUSIONS

In order to evaluate the ossicular mobility during surgery, a measurement system was constructed. Our system can provide useful information of the status of the ossicles to surgeons. We are trying to use our system during actual surgery as a next step.

INTRODUCTION

Current approaches towards subject-specific FE modelling and virtual testing would benefit from easy-to-use personalization and positioning tools. The PIPER project aims to provide these tools for full human body FE models used in automotive safety as an open-source, easy-to-use software framework that is independent from both model and FE code. In this context the positioning of the spine is of particular interest, while remaining complex because of its high number of dofs. This abstract presents the development of a spline based spinal posture predictor tool relying on linear interpolation between known physiological postures, and its implementation within the PIPER tool.

METHODS

The PIPER tool allows to personalize and position complex full human body FE models through a range of geometry and physics based deformation methods. The tools can also provide additional a-priori knowledge to the user, in the form of quantitative data, targets or constraints. These can help to ensure that subjects or postures generated by the tool are both statistically representative and physiologically acceptable.

The spine predictor tool was coded in Octave and was interfaced with the PIPER toolbox within the SOFA physics simulation environment (www.sofa-framework.org). A generic spine positioning workflow consists in (i) importing and translating any FE model in its original posture in a PIPER model format (defined only once for a given FE model by defining model-specific Metadata), (ii) extracting and fitting a spline on the vertebral Coordinate Systems (CS); (iii) registering the spline on a reference posture; (iv) applying a weight-based linear interpolation to the spline's parameters between two selected physiological end-postures to build a target spline, (v) reconstructing the vertebral CS on the target spline and, (vi) applying the transformation towards the targets on the PIPER model and the resulting deformation on the FE model. The application of the target is performed through lightweight physics simulation [1] of the PIPER model. This simulation allows accounting for possible collisions between bones and provides a plausible transformation of the surrounding soft tissues.

Hobby [2] splines were chosen to model the cervical and thoracolumbar spine segments as two continuous splines, which positions and shapes are fully controlled by seven parameters. Continuity between vertebral CS orientations during postural transformations was ensured by maintaining the relative orientation between the local spinal axis system [3] and local spline CS.

The database of 6 physiological spinal end-postures used for the interpolations was built based on previously published upright MR imaging data on 9 volunteers [4] in the supine, standing erect, seated driving and forward flexed postures, complemented by published clinical data in the standing erect, seated erect and seated slouch postures.

RESULTS AND DISCUSSION

Figure 1 shows an example of a spline prediction and associated transformation of the PIPER model.

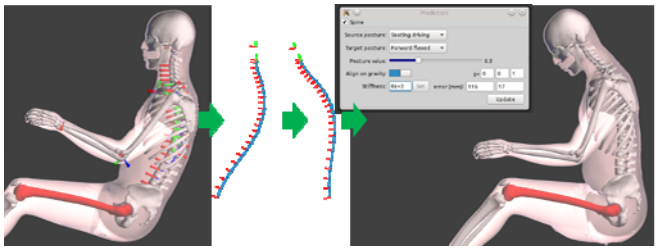

Figure 1: Splines, vertebral CS and lightweight physics model before and after transformation (shown here with the GHBMC M50 model, www.ghbmc.com).

Further to its use within the tool, the database also allowed (i) to validate the precision of the spline fitting method (mean error between target and fitted vertebral body centers = 0.24 ± 0.78 mm) and, (ii) to perform an evaluation of the precision of the predictive transformation by comparing the actual and predicted target posture for a given subject. The approach is currently limited by the posture database and is intended to be used as a pre-positioning tool, as it may require further positioning (e.g. to orient the head, or for out-of-the-plane postural predictions) through provided forward or inverse kinematics tools [5].

CONCLUSIONS

A simple spline based approach was used to build an easy-to use spinal postural predictor in the sagittal plane. It allows an almost real-time pre-positioning of human body models, accounting for physiological spinal postural solutions. The approach could be further extended by augmenting the content of the available end-postures database.

A COHESIVE ZONE BASED FINITE ELEMENT MODEL FOR INVESTIGATING ROTATIONAL CUTTING IN NEEDLE BIOPSY

[1]**Chi-Lun Lin** and [1]Guan-Jhong Lan

INTRODUCTION

The rotational cutting method, which drives a hollow needle to perform tissue removal with rotary and linear motion, is utilized by the majority of vacuum-assisted biopsy (VAB) tools to retrieve breast tissue samples for cancer diagnosis. The rotary motion introduces a tangential force, in addition to the axial needle forces, at the cutting surface of the tissue. As a result, the axial needle force can be significantly reduced such that larger volume of tissue samples can be obtained as the they are less deformed while being removed. Understanding how the rotary cutting speed affects the cutting force is crucial to the design improvement of VAB tools. Existing studies provided limited experimental data that only investigated a fixed, relatively low linear speed combined with different rotational speeds [1].

The cohesive zone (CZ) modeling technology was used in past studies to simulate needle insertion and other tissue damage behavior [2, 3], but a success of simulating the rotational cutting method has not been found. We present a CZ based finite element (FE) model that uses to simulate the progressive tissue damage occurred in a rotational cutting process.

METHODS

We developed a 3D FE model that includes a rotational hollow needle and a cylindrical tissue specimen. A cohesive crack path was predefined for the tissue. A constraint was applied when necessary to ensure the needle tip stayed on the path during the cutting process. The needle was a 12-gauge regular wall cannula with a length of 15 mm and a circular cutting edge at the tip. The tissue had a radius of 25 mm and a depth of 15 mm. The tissue was assumed homogenous and isotropic with a linear elasticity of 20 kPa. The Poisson's ratio was set to 0.495 due to the incompressibility. A general contact algorithm was used in the entire model. Friction was assigned to the contact between the needle and the tissue using the Coulomb friction model, where μ_s was 0.6 and μ_k was 0.2. The linear speed of the needle was set to 2 mm/s and a tangential-axial speed ratio (slice-push ratio) ranging from 0 to 5 was used such that the rotational speed was from 0 – 200 RPM. The distal surface of the tissue was fixed in the axial direction of the needle and the outer surface of the tissue phantom was prevented from moving in the radial direction. The simulation was performed using the Explicit solver of ABAQUS 6.14. The model settings were specifically made the same as an experimental study [1] for comparisons and validation.

RESULTS AND DISCUSSION

The axial needle force predicted by the CS model matched the result of the previous experiment. The force ramped from 0 to a similar end value (0.6 N) with an approximately equal slope. The average difference through the cutting process (0 – 12 mm depth) was within 10%.

Increasing the slice-push ratio would decrease the axial needle force and thus improve the cutting result. On the left-hand side of Figure 1 are three cross-sectional views, which represent the cases of 0 (top), 32 (middle) and 200 (bottom) RPM. The tissue was found largely compressed when the needle had no rotation, while the compression was trivial when the slice-push ratio reached to 5. On the right-hand side of Figure 1, the axial needle force reduced rapidly when the slice-push ratio increased, especially in its lower value range.

With this fixed linear speed (2 mm/s), the optimal rotational speed was about 80 RPM, which provided an optimal balance between the motor power requirement and axial needle force.

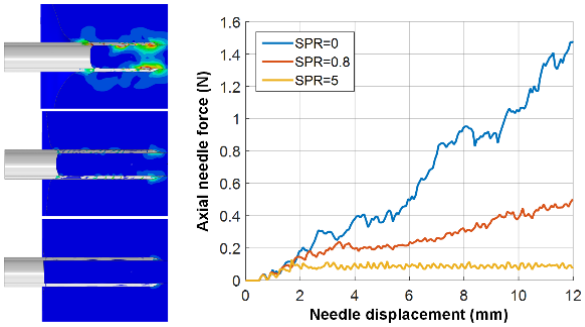

Figure 1: Visualized tissue compression and predicted axial needle force under different slice-push ratios.

CONCLUSIONS

A CZ based FE model that simulates the rotational cutting method of VAB tools was developed. The model was validated by comparing with an existing experimental study. The effect of the increasing slice-push ratio on the axial needle force also agreed the current findings. With this success, the validated model can be used to perform large-scale parametric studies to include more design parameters and cutting conditions, such as needle geometry, tissue properties and cutting speeds. The results will help build comprehensive understanding of the rotational cutting method and provide insight for new tool design innovation.

INTRODUCTION

Ophthalmic anesthesia is a very important preparation process for ophthalmic surgery. Since 1990 the gold standard technique of local anesthesia for eye surgery is a retrobulbar block [1], but there still are problems with training of new physicians. Retrobulbar block requires a lot of experience during injection anesthesia to approach the target area behind the eye ball globe. Mistakes from retrobulbar block are able to cause many complications such as retrobulbar hemorrhage, and brain stem depression. Normally, the training program of ophthalmic anesthesia is based on cadavers, but it is a blind practicing procedure. The correct anesthetic procedure is dependent on only the expert physician's opinion, but without any evidences to guarantee correct placement. Therefore, many simulators have been developed to facilitate the training procedure [2]. Nevertheless, all systems have limitations in providing position, if the needle tip is blinded by eye-muscle which overlaps the area with the retrobulbar target because of the principle of the tracking method. Our previous system was developed to detect the needle tip in the workspace of the retrobulbar block even it locates behind eye muscle by a magnetized based system [3] as in Figure 1a. However, in our previous work we have errors from localization because of the mismatch between the workspace of the sensors and that of the retrobulbar operated space.

This work presents a simulation of Hall Effect sensors to cover the retrobulbar block pathway in a training system by considering the mechanics of eye anatomies.

METHODS

A manikin 3D model was developed using human CT scans. The workspace between the Hall Effect sensor and magnetized needle was measured by using a robot arm, which is at a 13 mm perpendicular distance to the sensor. However, the average globe radius of the human is 10.5-13 mm [4], so the distance of the orbit to the target area almost reaches the maximum workspace of the sensor. A system is also required that has no electronic cables in the retrobulbar operation space. Additionally, each sensor requires 3 electronic cables. Therefore, a model was developed by placing a sensor socket only in the orbit structure. We rendered a simulation model of the sensor workspace to estimate numbers of sensors and socket positions in orbit. In order to detect the full pathway of the retrobulbar space a system was required with 24 sensors. All electronic cables were mounted to a printed circuit board (PCB) behind the orbit structure. An experiment was carried out on a prototype developed to verify the workspace of the sensor arrays. A magnetized needle was pointed to the edge of the retrobulbar operation space and target area, which consisted of touching along one side of the optic nerve, touching the inferior rectus (IR), touching beside the lateral rectus (LR), and the approached target area. During this experiment, the sensing data were recorded and analyzed with threshold classification on MATLAB.

RESULTS AND DISCUSSION

The activated sensing data were plotted with sensor position. The different positions in the workspace produced different sensors patterns as in Figure 1c. The system is able to roughly calculate the area of the needle in the system from the pattern of activated sensors with accuracy more than 90 % (n=50).

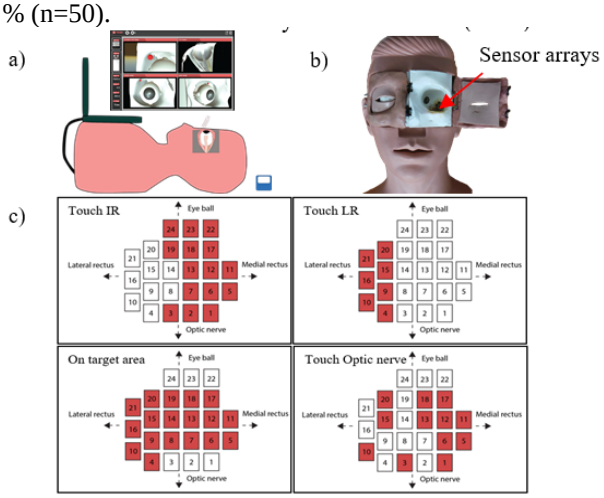

Figure 1: a) Conceptual designs of magnetic based retrobulbar block training system. b) The developed prototype of sensor position in manikin. c) Pattern of sensing data after passing threshold classification on MATLAB.

CONCLUSIONS

The developed magnetic based sensing system increased the sensitivity of sensor positions. The system is able to detect the needle in reference to the retrobulbar workspace as in the design step. However, the tracking system for needle position outside the retrobulbar workspace will be considered in the next iteration of the prototype.

ACKNOWLEDGEMENTS

This research cannot be success without support from national science and technology development agency (NSTDA). ORGANIZATION OF VIA-POSTURES DURING SIT-TO-STAND MOTIONS

[1] **Hiroshi R Yamasaki**, [2]Masato Iwami and [2]Hideyuki Tanaka

INTRODUCTION

Multi-joint coordination is a critical factor to ensure stable activities of daily life. As for sit-to-stand (STS) movement, a combination of joint angles at around the seat-off can be a boundary, namely via-posture, for optimal angular trajectory formation [1,2]. Spatiotemporal optimality of postures during STS, therefore, has been focused as a determinant of joint coordination [3,4]. However, knowledge on detailed mechanisms underlying organization of the via-postures is limited so far. Here, we aimed to investigate kinetic role of the via-postures during STS by examining task dependency of spatiotemporal position of the via-postures.

METHODS

Ten young male subjects (aged 21 to 26, height: 1.70 +/- 0.07[m], weight: 63.1 +/- 6.1 [kg]) without neurological and musculoskeletal disorders participated in this experiment after they gave the informed consent. The protocol was approved by the institutional review board. The subjects were instructed to perform STS motions from the height adjustable seat with preferred speed, crossing their arms in front of the chest. Four symmetric foot positions were tested: shank vertical (Vertical: V), foot-back (Near: N), foot-forward (Forward: F), and foot-far-forward (FF). The V condition positioned the ankle joint neutral, 90 degrees flexion of the knee joint. Fifteen degrees dorsiflexion and planter flexion of the ankle were set as the N and F conditions, respectively, and 20 or 30 degrees plantar flexion was selected for each subject for the FF condition. Seat height was adjusted so as to standardize the trunk and thigh positions in all trials. They performed six trials for each foot condition. The position of the right shoulder, hip, knee, and ankle were recorded by 3D motion capture system (VENUS3D, Nobby Tech, Japan). A force plate (Bertec 120Hz) was used to measure the ground reaction force from the seat. The angles of ankle, knee and hip joints, and the location of the center of mass (COM) were computed using the three-linked rigid body model in sagittal plane. Zero moment point (ZMP) relative to the ankle joint was also calculated. Data was normalized by the movement time (MT), i.e., the time interval during which the velocity of the COM exceeded 5% of its peak velocity. Details of via-posture computation were described elsewhere [4]. Briefly, candidate values for the via-points on the minimum angle-jerk trajectory were selected from the averaged data for each task and subject. Optimal timings of the via-points were obtained as a result of angle-jerk minimization. Two via-points that yield trajectory closely resembling the measured trajectory were identified using the fmincon function embedded in MATLAB.

RESULTS AND DISCUSSION

Figure 1 shows patterned trajectories of joint angles, ZMP position, and variability of ZMP. Timings of the first and second via-postures were computed (squares in the figure) at before the maximum hip flexion, and at around maximum knee flexion, respectively, irrespective of foot conditions.

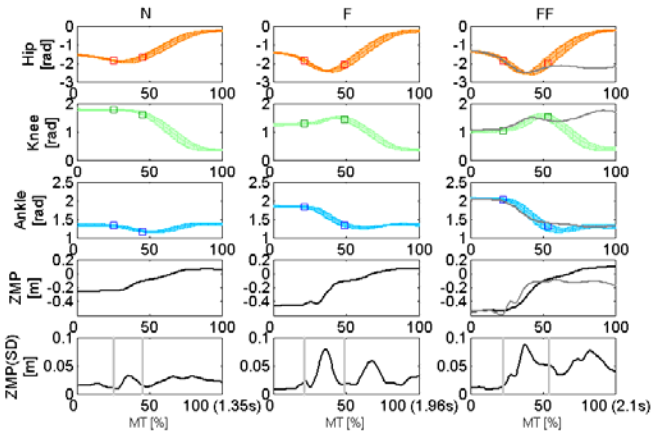

Figure 1: Example of normalized trajectories of joint angles, ZMP, and standard deviation of ZMP for Near, Forward, Far-Forward conditions from a subject. Squares: positions of the via-posture. Gray curves in the FF condition: a failed trial. Vertical bars in the bottom: timings of the via-postures. Brackets in the bottom abscissa: averaged MTs of the subject.

Timings of the via-postures were corresponded with temporal aspect of two predictors of failed STS in the subjects with Parkinson disease, i.e., horizontal peak velocity (20-30%MT) and vertical peak velocity (45-60%MT) of COM [3]. The first increment of standard deviation of the ZMP coincided with the phase between the via-postures (vertical lines in the figure), suggesting kinetic requirements to via-posture organization. Angular trajectory for a failed trial in the FF condition shown in the figure indicates that the subject was unable to pass the second via-posture while he cleared the first one. The result suggests different kinetic role for two via-postures to accomplish STS.

CONCLUSIONS

The joint coordination during STS was manifested through spatiotemporal organization of the functional via-postures.

EFFECTS OF ROBOT-ASSISTED TRAINING ON THE IMPROVEMENT OF THE UPPER LIMB MOTOR FUNCTION IN PATIENTS WITH STROKE

INTRODUCTION

Robot-assisted training (RT) is an innovative intervention for stroke patients to facilitate the upper extremity (UE) motor function. Recently, some studies showed that the RT interventions were effective for improving the stroke patients' performances. It has been found that the RT can significantly improve UE motor function; however, all the studies still have some limitations such as without a control group or small sample size. In addition, there is no significant improvement on ADL functions after receiving the RT intervention [1]. It may be because the RT interventions are usually executed under the laboratory settings, not in real daily environment.

The present study used a randomized control trial study to demonstrate that the RT could improve UE motor function of stroke patients. This study used a new robotic arm system, Armeo®Spring, which comes with visual interaction interface and functional task training, to simulate more close to the real environment. In order to evaluate the process quality of motion, a motion capture system, which is more sensitive and objective, was used in this study. We hypothesized that the RT intervention by Armeo®Spring could provide more improvements on the patient's (1) UE motor function, (2) ADL function, and (3) qualities of motion than the conventional OT intervention did.

METHODS

Eighteen patients with stroke more than six months after onset were recruited and randomly assigned to the RT and CT groups. The inclusion criteria were UE Fugl-Meyer Motor Assessment (FM) score of 13–60, and no severe cognitive deficits. No severe spasticity at shoulder, elbow or wrist (Modified Ashworth Scale score ≤ 2) was noted.

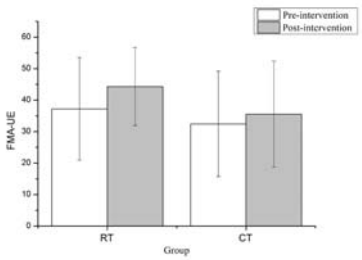
The robotic apparatus to be used in the RT group of the present study is Armeo®Spring (Hocoma Inc.). The Armeo®Spring is combined the robotic mechanism with the visual interaction interface and functional task training programs (e.g. reaching, grasp or moving for a specific target in some daily tasks).

The Fugl-Meyer Motor Assessment of UE part (FM) was used to assess the UE motor functions. This assessment has been clinically applied to measure the upper limb motor functions in patients with stroke. The Barthel Index (BI) and Manual Ability Measures (MAM) were used to evaluate ADL functions. Moreover, in order to evaluate quality of the movements of the upper limb, the electromagnetic motion capture system was used to measure the quality of motion. The parameters below were used to determine the quality of motion: movement unit (MU), path ratio (PR), movement time (MT), and arm-trunk coordination (ATC).

The assessments were carried out at the two time points: the initial evaluation and post-intervention. After receiving the initial assessment, the subjects were randomly divided into two groups, the RT and CT group. Each intervention includes 12 sessions, one hour per session and 2-3 times a week, lasting four to six weeks.

RESULTS AND DISCUSSION

In the RT group, there is a significant difference on the FM-UE score between pre- and post-intervention ($p = 0.008$), but no significant difference was found in the CT group. To compare the change of FM-UE scores (ΔFM-UE) between the RT and CT group, no significant difference was noted in this study. The FM-UE scores indicated the "ability of motor function" so that the results of FM-UE in this study showed that the RT might have effects for improving the motor function of the upper limb in the stroke patients.



After the intervention, both groups did not show significant improvement on the ADL function. Despite the improvement has been found in UE motor functions, these improved abilities did not effectively transfer to the performance of ADL functions. A previous study also indicated that and suggested a longer treatment period might be required [2]. Most kinematic parameters did not show the significant difference between pre- and post-intervention that might be due to the reasons of a small group sample size, and the short intervention period.

CONCLUSIONS

This study shows that the RT might be able to improve the stroke patients' UE motor function, which means that the RT could become an alternative strategy to help stroke patients improve the upper limb functions in the future.

The limitations of this study include a small sample size and a short intervention period. In addition, the measurement of kinematics cannot show the significant progress of the ability of UE motor functions. A larger sample size and longer intervention period might be suggested. For the kinematic measurement, more appropriate parameters for evaluating the quality of motion should be proposed in the future.

REDUCING LOAD CARRIAGE DURING WALKING USING A LOWER LIMB PASSIVE EXOSKELETON

[1] **Kurt L Mudie**, [2] Daniel C. Billing, [1] David J. Bishop, [3] Peter V.S. Lee and [1] Rezaul K. Begg

INTRODUCTION

Australian infantry soldiers are required to carry loads from approximately 20 kg to 60 kg [1]. Excess load carriage results in a greater mechanical load imposed on the musculoskeletal system. The implications for the solider include reduced task performance [2], decreased time to fatigue [2] and increased prevalence of overuse or chronic musculoskeletal injuries [1].

To minimise the strain on the musculoskeletal system, a passive lower-limb exoskeleton (~4 kg) has been designed to transfer a percentage of the backpack load to the ground. The aim of this study was to quantify changes in temporal characteristics of gait and insole force during exoskeleton assisted locomotion.

METHODS

One healthy male (age: 32 y; height: 1.82 m; mass: 76.8 kg), with no previous injury history, volunteered to participate in this study. Two walking trials were completed on an AMTI tandem treadmill wearing a 20 kg backpack. A force-measuring insole (F-Scan insoles, Tekscan, USA) was fitted to the participant, worn in the right shoe only, and data recorded at 50 Hz. Following a 30-minute familiarisation period wearing the exoskeleton, two five-minute trials were completed on the treadmill at 1.38 $m \cdot s^{-1}$ and a 0% gradient. The first trial was completed wearing the exoskeleton connected to the backpack (EXO). The second trial was completed without the exoskeleton and only carrying the backpack (control). A 10 minute rest period was ensured between conditions to minimise the risk of fatigue. Insole data were recorded for 30 seconds between the 4–4.5 minute mark and the final 10 strides recorded were analysed.

Force-time curves were exported as csv files (F-Scan Research 7.0) and anlaysed offline in Microsoft Excel. Heel contact and toe-off were determined as the first and last point ≥ 10 N, respectively. Temporal (stride rate, stance time and swing time) and kinetic (peak force during the loading and propulsion phases and rate of force development (RFD)) characteristics of gait were calculated for each right stride from the insole data. Mean ± SD of the final 10 strides were calculated for analysis.

Paired samples *t*-tests were performed to determine between condition differences for all dependent variables. Alpha levels were set *a prior* and significance accepted at $p < 0.05$. *Cohen's d* effect sizes were calculated and thresholds of 0.2 = small, 0.6 = moderate, 1.2 = large and 2.0 = very large used to qualitatively describe effect sizes.

RESULTS AND DISCUSSION

When wearing the exoskeleton, stride rate significantly increased ($p < 0.001$; $d = 2.86$), and the duration of stance ($p < 0.001$; $d = -1.36$) and swing ($p = 0.001$; $d = -2.53$) phases significantly decreased compared to not wearing the exoskeleton. Increased stride rate when wearing the exoskeleton and walking at the same speed will consequently result in a decreased stride length. It is hypothesised the reduction in stride length will likely lead to a decrease in peak anterior/posterior (sheer) braking forces. Over an extended period of time exposure to sheer forces caused from the foot striking the ground in-front of the body's COM has been identified as a risk factor for chronic lower-limb injuries. Thus, a potential decrease in sheer braking forces due to a decreased stride length may lead to a reduction in injury risk. However, changes in spatiotemporal characteristics may impose an increased metabolic cost.

Peak force during the loading phase tended to be lower when wearing the exoskeleton compared to not, with a moderate effect size ($p = 0.064$; $d = -1.08$) and mean difference of -45.51 N (4.64 kg). There was no significant difference and a small effect size in the peak force during the propulsion phase ($p = 0.708$; $d = -0.20$) and RFD ($p = 0.433$; $d = 0.39$) when wearing and not wearing the exoskeleton. These results indicate the current exoskeleton design was effective in reducing load carriage only during the first half of the stance phase (loading). However, wearing the exoskeleton will likely lead to an increase in peak force due to the mass of the device. Therefore, reducing the exoskeleton mass may result in a greater reduction in peak force.

CONCLUSIONS

The findings of the current study demonstrate the potential of an un-powered passive exoskeleton to reduce the load-carrying burden of the dismounted soldier. However, future research needs to extend to larger sample sizes and address design limitations using a multi-disciplinary approach between experts in human movement and engineering.

AN ARTICULATED, INSTRUMENTED NECK FOR A PARAMEDIC TRAINING MANNEQUIN: PROOF-OF-CONCEPT DESIGN AND TESTING

[1,2,3]**Claire F Jones,** [2]William SP Robertson, [1]Margaret Gayen, [1,3,4]Brian JC Freeman

INTRODUCTION

Neck immobilisation manoeuvres are performed by paramedics and emergency room clinicians when moving patients with suspected cervical spine injuries. These manoeuvres may mitigate further harm to the spinal column and spinal cord [1]. Existing paramedic training mannequins do not have realistic neck articulations and are not instrumented to provide the user with feedback regarding mannequin neck motion. Thus, the efficacy of immobilisation manoeuvres and devices cannot be easily assessed in the research setting, and paramedics' individual ability to perform these manoeuvres cannot be quantitatively assessed in the training setting. The aim of this project was to design, manufacture, and test a proof-of-concept low-cost instrumented and articulated neck for an existing paramedic training mannequin.

METHODS

The neck comprised three custom 3D-printed ball-and-socket articulations and four "vertebrae" with intervertebral motion limiting tabs and spring attachment points. Extension springs provided passive intervertebral stiffness (Figure 1B). A Stewart-Gough platform arrangement of six linear slide potentiometers (Bourns, UK) with custom push-rods, was used to measure the position of the head with respect to the torso, across the three articulations (Figure 1C). Aluminium adaptor plates and locking mechanisms were designed to interface the neck with existing attachment points without modification of the mannequin (Ultimate Hurt, Laerdal). The potentiometers were attached to these plates with custom joints (Figure 1C). To calculate head position from the six potentiometer outputs, forward kinematics were solved with a Newton-Raphson algorithm in a custom LabView/Mathscript program on a myRIO data acquisition device (National Instruments). A user interface provided real-time feedback and sampled data at 10 Hz.

The accuracy of the measured angles was tested using a motion capture system (Optotrak Certus, Northern Digital). Markers were rigidly attached to the adaptor plates of the isolated neck and the upper plate was manually rotated about each anatomical axis for 4 cycles. The range of motion (ROM) about each anatomical axis [flexion (F), extension (E), lateral bending (L), axial rotation (AR)] was measured by physically manipulating the mannequin head with the neck *in situ*. Finally, full mannequin head- and shoulder-hold log-roll manoeuvres (×3) were performed by a trained paramedic and assistants to determine the head-to-torso rotations and translations likely to occur during use.

RESULTS AND DISCUSSION

The rotations and translations of the superior platform relative to the inferior platform were accurate to within 2° and 2 mm, respectively, within reasonable ranges of motion. However, near the limits of the ROM, the error increased up to 10° or 6mm, suggesting that mechanical laxity in the potentiometer assembly allowed the superior platform to move independently of the sensors at their full extension.

The ROM were limited by the potentiometer assembly rather than the intervertebral tabs: F: 34°; E: 32°; LB: 29° (L), 28° (R); AR: 74° (L), 64° (R). The ROM matched physiological ROM well for LB (22-45°) and AR (44-79°), but were low for F (36-64°) and E (49-85°) [2,3]. The AR ROM asymmetry was due to the potentiometer push-rod arrangement. During the log-roll trials, the peak deviations from initial position were: F: 9.6°, E: 10.0°; LB: 11.5° (L), 11.8° (R); AR: 19.9° (L), 21.9° (R); translation: 29.5 mm (anterior), 12.4 mm (posterior). This indicated the ROM is likely adequate if the initial position is within ±15° of neutral in any direction.

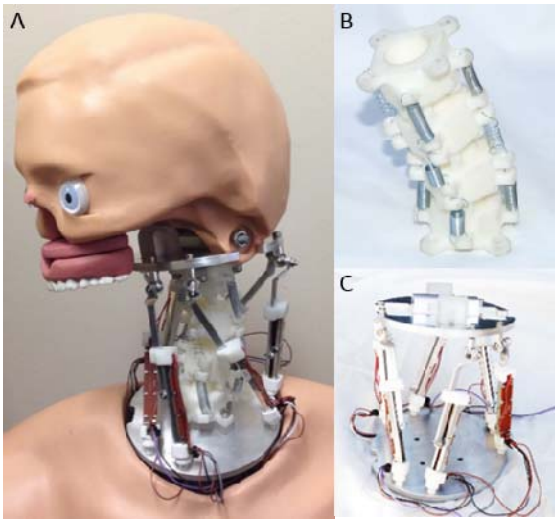

Figure 1: (A) Prototype installed in mannequin (jaw and head/neck "skin" removed); (B) "vertebral" elements with passive stiffness springs; (C) linear potentiometer assembly.

CONCLUSIONS

The neck had appropriate ROM in LB and AR, but limited ROM in the F-E direction. It allowed accurate measurement of head rotation and translation relative to the torso, and allowed motion within the envelope likely during immobilization manoeuvres. Improvements are required to reduce laxity and subsequent measurement inaccuracy at the extremes of motion, and to increase F-E ROM.

USE OF TISSUE INDENTATION METHOD FOR THE EVALUATION OF RESIDUAL LIMBS

[1] **Wei Xu**, [2]Abdo Haidar and [3]Jianxin Gao
[1]University of Surrey
[2]The London Prosthetic Centre
[3] TWI Ltd

INTRODUCTION

In developed countries, more than 90% of limb amputees achieve their mobility through the use of prostheses. Since the amputees will have to wear a prosthetic limb for the rest of their life, the comfort of a prosthetic limb attachment is the primary consideration for both manufacturer and service providers, as they are keen to help the prosthetic limb users to regain a good quality of life.

In order to achieve optimized design of a socket for an individual amputee, it is important to understand the biomechanical behavior of the soft tissue of the residual limb. In current clinical practice, this is done by a prosthetist via a touch-and-feel approach. Apparently this approach is subjective, and only provides qualitative information about the stump. To improve the accuracy of soft tissue evaluation, an indentation device is developed, which is able to record the dynamic response of the stump. By analyzing these dynamic data, more quantitative biomechanical characteristics can be obtained. Results of healthy subjects and above knee amputees were also compared.

METHODS

Indentation was a widely used for material characterization [1,2]. To measure the dynamic response of the soft tissue of human limbs, a specific tissue indentation device was developed where a force transducer and a displacement encoder were integrated, enabling to record the load-displacement curve during an indentation test. Silicone samples were first used to validate the device, where the results were in agreement with those obtained from an Instron mechanical testing machine, confirming that the indentation device is reliable and accurate.

Thirteen healthy volunteer subjects have been tested using the indentation device. Among them 5 are female and 8 are male, with age between 25 and 57. At the beginning, the length of the subject's leg was measured, which is the distance between the greater trochanter and the front surface of the knee when the knee is bent by 90°. Then 12 points were marked on the leg at predefined locations so that the results from different subjects can be compared. When the subject found a comfortable position, he/she was required to keep the position during the test as stable as possible. Each measurement point was tested on a relaxed condition. Only two positions were also tested under a contracted condition where the subject was asked to flex the leg muscle as much as possible and keep stable for around 15-20 seconds so that stable force-displacement curves can be recorded by the device. Since such a contract condition is difficult to maintain, only limited contraction tests were performed.

The residual stumps of two above knee unilateral amputees were tested with the same procedure as described above. Unlike the healthy subjects where only one leg was test, for the amputees, both their residual leg and the normal leg were tested under relaxed and contracted conditions, during which the force-displacement curves were recorded.

RESULTS AND DISCUSSION

The force-displacement curves were analyzed by second order polynomial regression. Among the three coefficients, the quadratic one was found to be the proper index to characterize the soft tissue of the limb muscle. It is an indenter specific coefficient. Figure 1 shows typical indentation test results of a healthy subject.

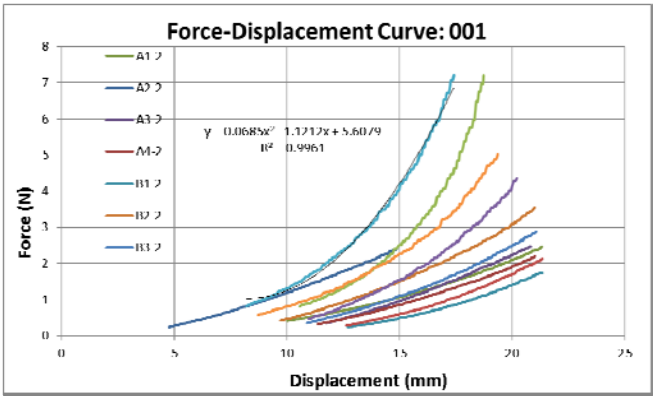

Figure 1: Typical indentation test results of a subject's leg.

Measurement results showed that at a specific location C3 of the healthy subject (age 57, male) at relaxed and contraction conditions, the index was 0.0685 and 0.0838 respectively, a difference of 22%. For an above knee amputee (age 40, male) at the relative same point C3, the index for the residual limb was 0.0248 (relaxed) and 0.041(contraction), a variation of 16%. For the normal leg, the index was 0.016 and 0.137 respectively, an 8-fold change. These results showed that compared with the healthy subject, the normal leg of the amputee is softer at relaxed condition but stiffer at contracted condition than that of the healthy subject. For the residual leg, the indices are both lower than that of the healthy subject, which reflects the partial loss of muscle control due to amputation.

CONCLUSIONS

Preliminary indentation measurement results showed that the quadratic coefficient of a second order polynomial regression for the force displacement curve is a proper index to quantify the muscle control loss of the residual limb. Further measurement tests and analysis are on-going.

THE EFFECT OF A PRE-HOP ON MUSCLE-TENDON INTERACTION DURING VERTICAL JUMPS

[1] **Jeroen Aeles**, [2] Glen Lichtwark, [1] Dries Peeters, [1] Christophe Delecluse, [1] Ilse Jonkers and [1] Benedicte Vanwanseele

INTRODUCTION

Due to the interaction between muscle and tendon, the muscle-tendon unit (MTU) can achieve power outputs that are far larger than possible from muscle contractions alone. Tendons can act to store energy by stretching and later return this energy during rapid shortening. This interaction between muscle and tendon can differ between movements and researchers are yet to understand what stimuli trigger these changes. In this study, we investigated the effect of adding a pre-hop to a squat jump, which was expected to stretch the medial gastrocnemius (MG) MTU prior to the upward motion.

METHODS

We compared the stretch-shortening behavior of the series elastic element (SEE) of MG during maximal vertical standard squat jumps (SSJ) and in squat jumps with a pre-hop (PHSJ) (fig. 1). Eleven well-trained athletes specialized in jumping performed both jumps on two force plates while a 3D-motion capture system was used to measure marker trajectories. A musculoskeletal model was used to determine muscle-tendon unit lengths during the jumps. B-mode ultrasonography of the MG was used to determine the fascicle lengths and pennation angles. By combining results of the muscle-tendon unit lengths, fascicle lengths and pennation angles, the stretch and recoil of the SEE of MG was calculated based on a simple geometrical muscle-tendon model [1]. A comparison between the jumps was made for the upwards motion, which was defined as the time between the lowest vertical position of the pelvis (based on pelvis marker just before vertical upward displacement) and toe-off, and for the total movement (length changes relative to fully erect standing position) (fig. 1).

RESULTS AND DISCUSSION

Joint angles at the knee and hip were not different between both jumps ($p > 0.076$). Jump height was not different between both jumps ($p = 0.099$). There was less stretching of the SEE during the upward motion of the PHSJ ($p = 0.002$). Consequently, muscle fascicles were able to shorten at lower maximal velocities, which could explain the higher ankle joint moment seen in the PHSJ as compared to the SSJ ($p = 0.028$ and $p = 0.025$ respectively). Although this was expected to result in a higher amount of total stretching of the SEE, this was not different between both jumps ($p = 0.320$).

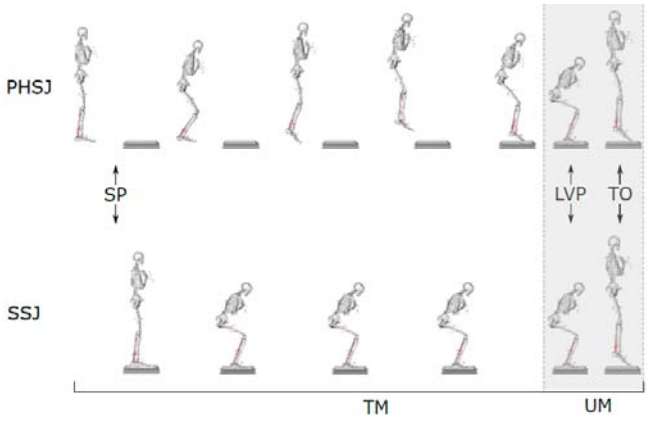

Figure 1: Illustration of the SSJ and PHSJ jumping motions and the respective phases. SP = standing position; LVP = lowest vertical position; TO = toe-off; UM = upwards motion; TM = total movement.

CONCLUSIONS

Even though the lower-limb kinematics were not different between both jumps during the upward motion, our results clearly show very different muscle-tendon interactions. The shift in stretching of the SEE is likely to come from the stretching of the MTU with active fascicle contractions at short fascicle lengths, induced by the pre-hop. This seems to improve the muscle mechanics as the fascicles shorten at lower maximal velocities and thus will be able to produce larger forces, as seen in the larger ankle joint moment. Although, these improved muscle mechanics did not result in increased jump height in the PHSJ as compared to the SSJ.

FASCICLE-TENDON INTERACTIONS DURING DROP LANDING

[1,2] **Enzo Hollville**, [1]Gaël Guilhem, [3]Antoine Nordez, [2]Jennyfer Lecompte and [1]Giuseppe Rabita

INTRODUCTION

In animal, it was shown that the tendon acts as a shock absorber to protect muscle fascicles during drop landing [1]. This is possible thanks to fascicle-tendon interactions, that have also been well described in humans [2]. However, Human studies were mostly focused on tendon function in performance enhancement while its protection abilities during damping activities have been relatively less explored. Thus, despite landing from a jump is a typical movement in many sports, fascicle-tendon interactions have never been analyzed during this task in vivo.

The present study was designed to analyze fascicle length changes during landing. We hypothesized that tendinous tissues (TT) of the medial gastrocnemius (MG) and vastus lateralis (VL) may increase their relative contributions to the whole muscle-tendon unit (MTU) lengthening as the drop height increase to protect fascicles from damage.

METHODS

Fifteen active men participated in this study. After a standardized familiarization session, they were asked to perform drop landings from 3 heights (25, 50 and 75cm), in a randomized order. VL and MG fascicles were measured at 1000 Hz using ultrafast ultrasound imaging (Aixplorer scanner®, Supersonic Imagine, Aix-en-Provence, France). 2D joint angles (i.e. hip, knee, and ankle) were calculated from lower limb kinematics obtained from 3D motion capture (Vicon, Oxford, UK, 250 Hz) and ground reaction forces (GRF) were measured at 1000 Hz over a force platform (Kistler, Wintertur, Suisse). Fascicles were tracked [3] throughout the landing to calculate the changes in length and lengthening velocities of the muscle fascicles, TT and MTU. Each landing duration was normalized with respect to time from the ground contact to the maximum knee flexion. Effects were determined using a one-way (height) ANOVA.

RESULTS AND DISCUSSION

For both muscle, changes in length of TT were much higher than for fascicles (Figure 1), demonstrating their important role in the energy dissipation during landing. Increases in drop height were associated with increases in both vertical GRF ($p<0.05$) and range of motion at the ankle, knee and hip joints ($p<0.05$). Regarding the peak lengthening velocities in muscle fascicles, the effect of drop height was significant in VL ($p<0.01$) and no significant in MG muscles ($p>0.05$). In the same time, TT and MTU peak velocities were different for the MG between DL conditions (25 vs 75 cm, $p<0.05$) while only MTU peak velocity increased in VL (25 vs 50, 25 vs 75 cm, $p<0.05$). The fact that MG fascicles velocity did not change as the height increases indicates that the Achilles tendon absorbs a greater amount of mechanical energy as the height increases while preserving MG muscle from high velocity eccentric contractions. On the contrary, VL fascicle lengthening velocities increased as height increased while VL tendinous tissues kept a similar behavior in all conditions.

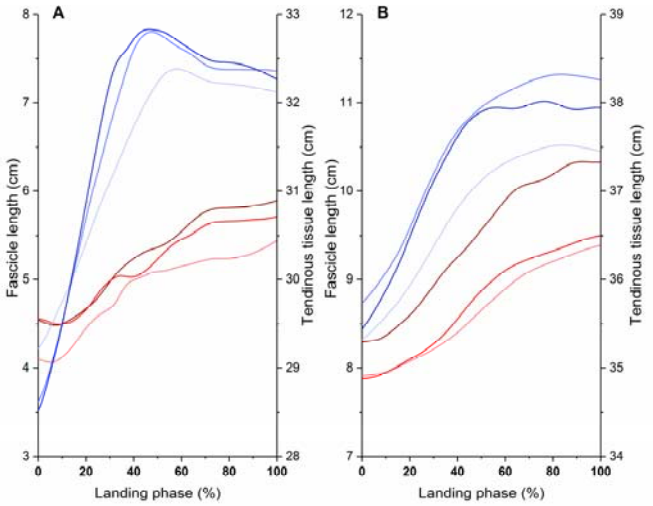

Figure 1: MG (A) and VL (B) fascicle (red) and tendinous tissue (blue) length upon normalized landing time from 3 DL heights: 25cm (light), 50cm (medium) and 75 cm (dark).

CONCLUSIONS

The present study demonstrates different behavior in muscle-tendon interactions between ankle and knee extensors during drop landing. Achilles tendon allows to protect the MG fascicles by avoiding a larger lengthening velocity as the drop height increases. At the opposite, the patellar tendon does not totally compensate the overall stretch of the VL MTU. Neuromuscular analyses must be carried out to fully understand the differences between MG and VL MTU.

ACHILLES TENDON WAVE SPEED TRACKS JOINT TORQUE AND MUSCLE ACTIVITY IN GAIT

INTRODUCTION

Understanding tendon tissue loading is crucial to the investigation of musculoskeletal disorders. Unfortunately, assessing *in vivo* loading remains challenging. Direct approaches are highly invasive [1], and modeling approaches rely on assumptions regarding muscle coordination and tissue geometry [2]. We are exploring the potential for using non-invasive wave propagation measurements to estimate tendon loads during dynamic movement. We recently found that a theoretical model for wave propagation in a tensioned beam predicts that shear wave speed in tendon is directly dependent on axial stress. A subsequent *ex vivo* study [3] confirmed this relationship, yielding a strong correlation between tendon stress and squared wave speed (mean $r^2 = 0.98$). The purpose of the current study was to investigate the potential for measuring *in vivo* Achilles tendon wave speed during gait, and to begin to examine the viability of using wave speed measures to assess tendon loading.

METHODS

Wave tracking. We constructed a custom device to generate and track transient shear waves in the Achilles tendon (Fig 1A). Waves were generated using a piezoelectric actuator (Thorlabs PK4JQP1, Newton, NJ, USA) housed in a 3D-printed enclosure strapped ~7cm superior to the calcaneus. The Achilles tendon was tapped in the transverse direction (20µm displacement) at 50Hz, with each tap sending a transverse (shear) wave along the tendon. Two single-axis accelerometers (PCB Piezotronics 352C23/NC, Depew, NY, USA) were positioned over the Achilles tendon 1cm and 2cm inferior to the tapping device. Transverse acceleration of the tendon was sampled from each accelerometer at 50kHz. Wave speed was calculated based on lag in wave arrival time between the two accelerometers (Fig 1B) after each tap, such that wave speed data were collected at 50Hz.

Gait analysis. Five subjects (3M, 2F) completed walking trials at a range of 5 speeds (0.75-1.75m/s) on a dual-belt, instrumented treadmill (Bertec, Columbus, OH). Ground reactions, lower body kinematics, medial gastrocnemius and tibialis anterior EMG, and tendon accelerations were collected synchronously for 8 seconds at each speed. Inverse kinematics and kinetic analyses were performed to determine ankle joint torque over the gait cycles. EMG data were rectified and low-pass filtered at 300Hz.

Wave speed analysis. Wave speed data were low-pass filtered at 12Hz. Agreement between squared wave speed and muscle activity was assessed visually. Correlation between squared wave speed and ankle torque was assessed using the coefficient of determination.

RESULTS AND DISCUSSION

Achilles tendon wave speeds varied from ~10-60m/s over the gait cycle, with peak speeds corresponding with push-off. There was excellent temporal agreement between wave speed, net ankle torque, and gastrocnemius muscle activity throughout stance (Fig 1C), with squared wave speed being highly correlated with ankle torque across the 5 subjects (mean $r^2 = 0.77$). There was a second distinct increase in wave speed during late swing, corresponding with passive tensioning of the Achilles as the tibialis anterior acted to dorsiflex the ankle in preparation for heel strike.

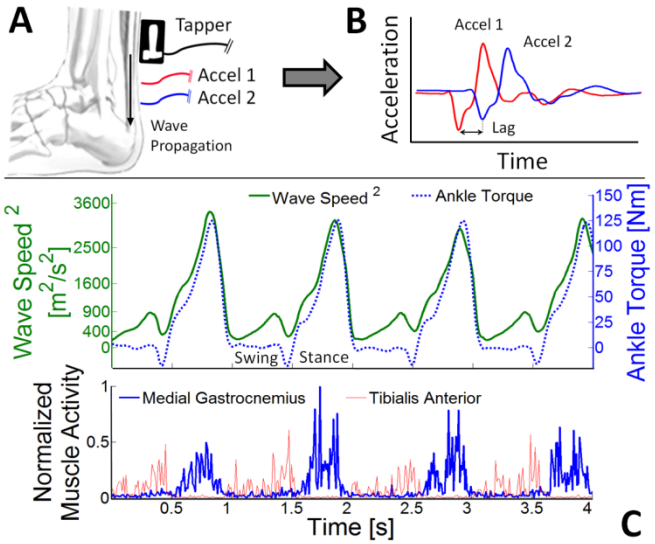

Figure 1: **A)** Schematic of wave speed measurement method. **B)** Example shear waves recorded via skin-mounted accelerometers. **C)** Squared Achilles tendon wave speed, ankle torque, and muscle activity during walking at 1.50m/s for one subject (M, 75kg).

These data establish the viability of using tendon wave speed measures as a proxy for *in vivo* loading. The observed relationships between wave speed, ankle torque, and muscle activity are in agreement with the expectation that squared wave speed will scale with tensile stress [3]. Crucially, we have shown that wave speed can be measured at a high rate using skin-mounted accelerometers, making the system usable for highly dynamic movements. Additionally, the unexpected finding of wave speed increases during swing highlights the potential for this method to reveal changes in tendon loading that can be omitted by traditional modeling approaches and EMG analysis.

CONCLUSIONS

We've shown that shear wave speeds can be measured and used to gauge *in vivo* tendon loading. Future work will focus on adapting the technology for use on other tendons, which could facilitate an array of clinical and research applications.

MUSCLE-TENDON CONTRIBUTION TO AN INCREASED RANGE OF MOTION FOLLOWING PASSIVE STRETCHING IN CHILDREN WITH CEREBRAL PALSY

INTRODUCTION

Stretching is often used to increase/maintain joint range of motion (ROM) in children with cerebral palsy (CP). An acute bout of stretching can increase ROM in children with CP[1], but during passive joint rotation of the ankle the tendon lengthens more and muscle less in children with CP compared to typical developing children[2]. This reduced stretching stimulus to the muscle might explain the negative and highly variable outcomes of long-term stretching interventions[3]. Therefore, this study aimed to determine the acute changes in muscle-tendon properties that contribute to increased ROM after a bout of stretching in children with CP.

METHODS

Eleven children with spastic CP participated (age:12.1±3y, 5/6 hemiplegia/diplegia, GMFCS level:7/4, I/II) in this study. Each child received 3 sets of 5x20 seconds passive, static dorsiflexion stretches separated by 30-sec rest, and 1-minute rest between sets. Stretches were applied by a physiotherapist. Pre- and immediately post-stretching, ultrasound (Telemed, Lithuania) was used to measure medial gastrocnemius fascicle lengthening (Figure 1) continuously over the full ROM and a ROM common to pre- and post-stretching. Simultaneously, 3D motion of 2 marker clusters on the shank and the foot was captured (OptiTrack, US) to calculate ankle angle according to ISB guidelines[4] and ankle joint torque was calculated from manually applied torques and forces on a 6DoF load cell (ATI mini45: Industrial Automation).

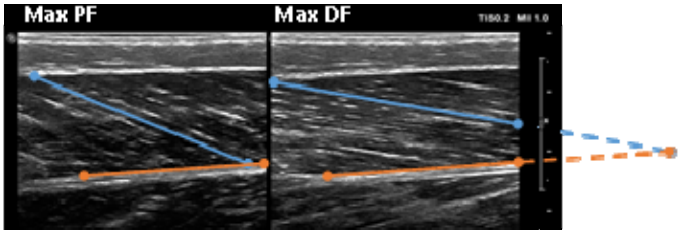

Figure 1: Example of ultrasound images at maximal plantarflexion (PF) and maximal dorsiflexion (DF). Fascicle length was tracked automatically through the full ROM.

RESULTS AND DISCUSSION

Total ROM increased by 9.9±12 degrees after stretching (p=0.016), of which 5.2±4.4 degrees showed in the dorsiflexion direction (p=0.004). At end ROM maximal ankle joint torque increased by 2.9±2.4 Nm (p=0.003) and over the full ROM fascicle lengthening was 2.8±2.4 mm greater (p=0.009). Over a common ROM there were no differences in fascicle lengthening or torque changes pre to post stretching. These results indicate that an acute bout of stretching did not alter the passive mechanical properties of the medial gastrocnemius muscle. This contrasts a similar study in typically developed adults[5] which found that stretching increased fascicle and muscle lengthening over a common ROM. The current lack of changes in muscle properties could possibly be explained by a smaller relative stretching stimulus to the muscles of children with CP, as reported previously[2].

The increased ROM and fascicle length at maximal dorsiflexion are most likely caused by an increase in manual torque applied to dorsiflex the ankle joint post-stretching (Figure 2). This may be due to an increase in the participants' tolerance to stretch, a mechanism that was first identified by Magnusson et al.[6]. Irrespective of the cause, we do see an acute increase in the stretching stimulus of the muscle fascicle after a bout of stretching.

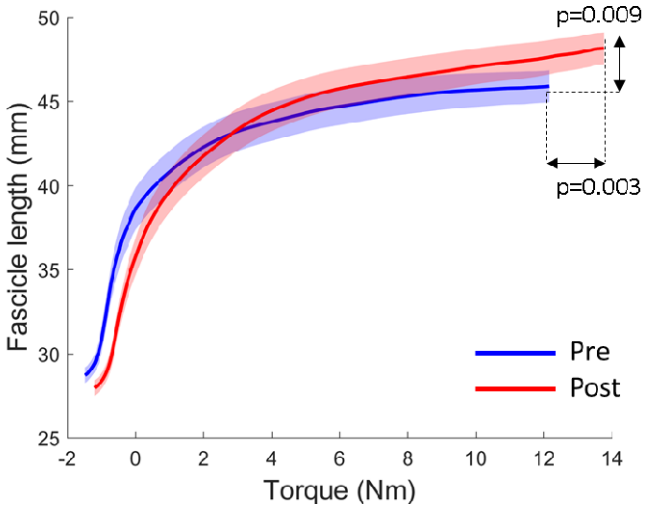

Figure 2: Medial gastrocnemius fascicle length relative to torque applied to dorsiflex the ankle joint before (blue) and after (red) an acute bout of stretching (mean and 95% CI).

CONCLUSIONS

A single bout of repeated stretches increased ankle ROM in children with CP, which was partially achieved by elongation of the muscle fascicles. However, the passive properties of the muscle fascicles remained unaltered by the stretching bout.

ARE ULTRASOUND-BASED ESTIMATES OF ACHILLES TENDON KINEMATICS CONSISTENT WITH THE EXPECTED BEHAVIOR OF A PASSIVE ELASTIC TISSUE IN SERIES WITH MUSCLE?

Emily S Matijevich, Lauren M Branscombe and Karl E Zelik
Vanderbilt University, Nashville, TN, USA

INTRODUCTION

The Achilles tendon (AT) is an important passive elastic structure that facilitates safe and economical human locomotion, and whose behavior informs the development of assistive technologies and rehabilitative interventions. However, quantifying AT kinematics and kinetics *in vivo* is challenging, leading to inconsistent estimates of length change, stiffness and hysteresis in literature [1]. Ultrasound imaging offers one way to non-invasively estimate AT kinematics *in vivo* during human movement, but critical questions remain about which ultrasound methods are most accurate, and if/when each method yields physiologically plausible AT estimates [2]. Two questions motivated this study: (I) Do commonly used ultrasound tracking methods yield similar estimates of AT length change? (II) Are these estimates consistent with the expected behavior of a passive elastic tissue acting in series with a contracting muscle?

METHODS

Three healthy subjects (20 ± 2 years, 75 ± 10 kg) performed various movement tasks, during which unilateral lower-limb kinematics (100 Hz, Vicon) and ground reaction forces (1000 Hz, Bertec) were collected synchronously with B-mode ultrasound (~60 Hz, 50 mm depth, Telemed). Subjects provided informed consent prior to participation. To address question (I), we compared AT length change estimates from two commonly used ultrasound methods. For the first method, termed *Indirect*, the ultrasound probe (7 cm linear transducer) was placed on the medial gastrocnemius (MG) muscle belly to track muscle fascicle length changes. Fascicle length was corrected for pennation angle to estimate total muscle length change. AT length change was then approximated indirectly as the difference between the overall muscle-tendon unit (MTU) length change (estimated from a regression equation using knee and ankle joint angles [3]) and muscle length change. For the second method, termed *Direct Muscle-Tendon Junction (MTJ)*, the ultrasound probe was placed over the MG-AT MTJ. Using optical motion capture and a custom-fixture attached to the probe to track its position, AT length change was more directly estimated as the linear distance between the calcaneus marker (AT insertion) and MTJ. MG muscle length change was also approximated using this method, by subtracting AT from MTU length change (from [3]).

To address question (II), subjects completed three simple tasks in which empirically-estimated AT length changes could be compared to the expected behavior of a passive elastic tendon acting in series with muscle. Tasks were chosen to test combinations of high/low MTU force and large/small MTU length changes. Tasks: (A) Restrained joint calf contractions were performed while seated with a rigid bar affixed above the knees, restricting ankle and knee rotation. Expectation: Small MTU length change and high MTU force would result in substantial AT lengthening, equal and opposite to MG shortening. (B) Heel raises involved contracting the calf muscles while standing to rise onto the toes. Expectation: Large MTU length change and high MTU force would result in AT lengthening. (C) Toe pointing required subjects to hold their foot in the air and plantarflex their ankle. Expectation: Large MTU length change and low MTU force would result in minimal AT length change. Each cycle began/ended with the MG relaxed and the foot in neutral position (i.e., perpendicular to shank).

RESULTS AND DISCUSSION

AT length change estimates were strongly correlated between the Indirect and Direct MTJ tracking methods. We found correlation coefficients of r = 0.82 ± 0.06, r = 0.89 ± 0.09, r = 0.75 ± 0.21 for tasks A, B, and C, respectively (N=3, Figure 1). AT length change estimates were qualitatively consistent with the expected behavior of a series elastic tissue during task A, which involved minimal changes in MTU length. However, AT length changes were drastically different from expectations for tasks B and C, in which the MTU underwent substantial shortening.

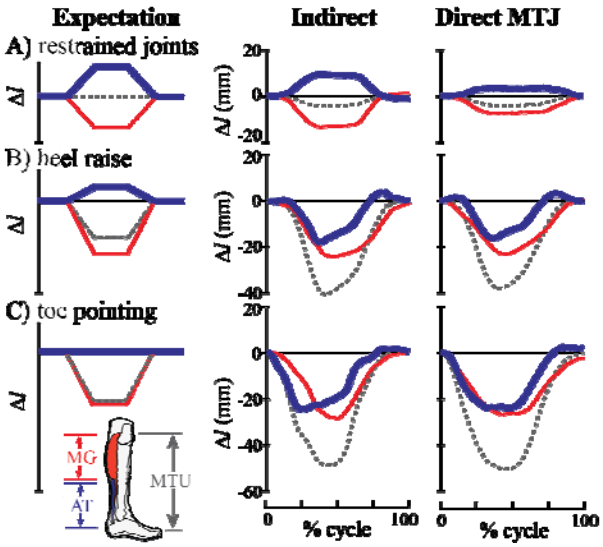

Figure 1: AT (thick blue), MG (thin red) and MTU (dashed gray) length changes for one subject during 3 tasks. Data averaged over 5 cycles. Δl = change from relaxed length.

CONCLUSIONS

Preliminary findings suggest that Indirect and Direct MTJ methods yield similar estimates of AT kinematics for the tasks tested. However, estimated AT kinematics were highly inconsistent with the expected behavior of a passive elastic tissue in series with muscle. In this ongoing study we seek to understand the reasons for and implications of this inconsistency.

THE IMPACT OF EXERCISE-INDUCED OSTEOARTHRITIS PAIN FLARES ON WALKING KINEMATICS, KINETICS AND MUSCLE CO-CONTRACTION

[1]Katherine A. Boyer and [1]Jocelyn F. Hafer
[1]University of Massachusetts Amherst
Corresponding author email: kboyer@kin.umass.edu

INTRODUCTION

Knee osteoarthritis (OA) is a chronic condition, yet symptoms (pain and stiffness) can fluctuate widely over a day or a week's time [1]. While alterations in gait mechanics have been found in relation to chronic OA pain [2], the response to acute pain flares is not clear. There is a need to understand the factors that contribute to acute pain flares as well as the potential consequences of pain flares on physical function and joint health. There is evidence for a role of mechanics in acute pain fluctuations as weight bearing exercise often exacerbates pain in patients with knee OA. Greater knee joint moments in combination with increased muscle co-contraction during gait are thought to contribute to greater joint loading and thus radiographic progression of knee OA [3, 4]. The aim of this study was to examine the impact of a bout of exercise on self-reported pain, walking mechanics and muscle co-contraction for participants with symptomatic knee OA.

METHODS

Thirty-seven adults (18 healthy older and 19 with mild to moderate symptomatic knee OA) were recruited for this study. Inclusion criteria were ages 50-75 years, BMI <35 kg/m^2, good general health, ability to walk unaided, and no history of cardiovascular or neurological disorders. Participants for the OA group met the American College of Rheumatology clinical classification criteria for OA in at least 1 knee and reported physician diagnosed knee OA. Prior to study activities, participants completed an IRB approved informed consent document and then the Physical Activity Readiness Questionnaire and Knee Osteoarthritis Outcome Score to assess risk factors for exercise participation and knee symptom severity. Overground walking mechanics and knee extensor and flexor co-contraction were assessed at the beginning and end of a 20 minute treadmill walk (20MTW).

Exercise Protocol: Participants completed the 20MTW at preferred walking pace. Perceived pain was evaluated on an 11 point verbal numeric pain rating scale (vNRS) in the first and final 2 minutes of the 20MTW. A change in pain ≥ 1 was considered clinically significant.

Data Collection: Immediately before and after the 20MTW, participants completed 5 walking trials at preferred pace over a 25 m walkway while kinematic and kinetic data were collected. External joint moments were calculated via inverse dynamics. Electromyography (EMG) was collected during the first and last minutes of the 20MTW. Electrodes were placed over the rectus femoris, vastus lateralis, vastus medialis, and biceps femoris and semitendinosus, according to SENIAM guidelines. The co-contraction between the knee extensors and flexors was determined using a modified co-contraction index (CCI) for terminal swing (last 15% of swing), loading response, mid-stance, and terminal stance. Due to technical difficulties, not all participants had complete datasets.

Statistics: OA participants were split into flare and no-flare groups based on change in vNRS in response to the 20MTW. One-way ANOVAs ($\alpha = 0.05$) were used to test for differences in the change pre- to post-20MTW between the OA flare, OA no flare and healthy control groups.

RESULTS AND DISCUSSION

Eight of nineteen OA participants had a significant flare response to the 20MTW (Figure 1). There were no significant differences between groups in the change in overground walking speed pre- to post-20MTW. Changes in heel-strike and toe-off knee flexion angles in response to the 20MTW were different between the no flare and control groups ($p = 0.02$ and 0.04 respectively). The changes in kinematics did not differ between the flare and control groups. There were differences in the changes in 2nd peak knee adduction moment, knee internal rotation moment and ankle eversion moment between the flare and no flare groups (p=0.04, 0.01 and 0.03, respectively). In addition there were differences or trends for differences in the change in the first peak knee adduction moment, knee internal rotation moment and ankle eversion moment between the flare and control group (p=0.09, 0.01, 0.03, respectively). A trend for a difference in the hip flexion moment between the no flare and control groups ($p = 0.06$) was also found. There were no significant differences in the change in CCI between groups.

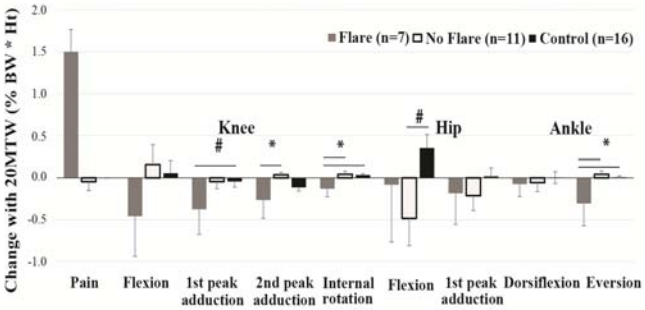

Figure 1. Mean and SE changes in self-reported pain and external joint moments in response to the 20MTW for the flare, no flare and control groups *p<0.05, #p<0.1.

CONCLUSIONS

The results of this study provide evidence in support of a gait response to acute pain flares in OA. The large variance in the gait changes for the flare group suggests there may be several different movement strategies adopted by OA participants in response to increased pain that merit further investigation.

INTRODUCTION

Tailored interventions that slow structural knee osteoarthritis (OA) progression are required. Knee muscle weakness [1] and altered muscle temporal activation is reported in people with knee OA [1,2]. Importantly, greater duration of medial knee muscle co-contraction has been associated with medial tibial cartilage loss in people with knee OA [3]. Therefore, duration of medial knee muscle co-contraction is a potential target for interventions to slow disease progression. Neuromuscular exercise is typically performed in functional weight-bearing positions and emphasises neutral frontal plane alignment, and may have greater potential alter temporal muscle activation than traditional quadriceps strengthening exercises. No studies have evaluated the effect of exercise on temporal knee muscle activity in people with knee OA. The aim of this study was to test the hypothesis that duration of medial knee muscle co-contraction would alter in individuals with medial knee OA following a 12-week neuromuscular exercise program compared to people with medial OA who followed a quadriceps strengthening program.

METHODS

This was a secondary analysis of data from a randomised controlled trial that compared the effects of a 12-week neuromuscular exercise program with a quadriceps strengthening program in medial tibiofemoral knee OA and varus malalignment [5]. Both exercise programs involved 14 physiotherapist-supervised exercise sessions (30-40 mins) over 12 weeks, and home exercise sessions four times/week. The neuromuscular program included functional weight bearing exercises, concentrating on trunk and lower limb position (particularly knee alignment) and quality of movement. The quadriceps strengthening program included non-weight bearing exercises with the main focus on gaining muscle strength. During gait, surface electromyography (EMG) data were acquired from the vastus lateralis, vastus medialis, biceps femoris, semimembranosus and biceps femoris muscles at baseline (0 weeks) and follow-up (13 weeks). Using an approximated generalized likelihood ratio method, the timing of muscle activation onsets and offsets were determined and expressed relative to initial heel contact as a percentage of stride cycle [4]. Duration of co-contraction was determined for medial and lateral muscle groups, as well as relative co-contraction duration (medial co-contraction duration relative to lateral co-contraction duration). Each was expressed as a percentage of stride cycle duration, and averaged across strides. Paired t-tests were used to determine within-group differences. Between-group differences were compared using ANCOVA, with baseline score as covariate.

RESULTS AND DISCUSSION

EMG data from 67 out of 100 were available for analysis. The neuromuscular exercise and quadriceps groups were comparable for age (62±7yrs vs 62±7yrs, respectively), sex (females: 60% vs 49%) and BMI (29.3±3.4 kg/m^2; 29.7±4.4 kg/m^2). There was no significant between-group difference in medial knee muscle co-contraction duration change during walking (mean difference 1.22 gait cycle; 95%CI (-3.23 to 5.67) *P*=0.29). There was also no between-group differences for any of the other measures assessed and no within-group changes were observed (Table 1). Several factors may explain why duration of medial co-contraction did not differ between groups. Notably, greater task specificity within the neuromuscular program may be required to alter temporal muscle activation during gait.

CONCLUSIONS

These exploratory findings suggest no difference between the exercise programs on the duration of medial knee muscle co-contraction using programs that differ in content, but do not provide specific feedback/education of co-contraction parameters. Further research is needed to confirm whether exercise can alter duration of medial knee muscle co-contraction, a potential predictor of medial tibial cartilage loss.

INTRODUCTION

Knee osteoarthritis (KOA) is the most common form of arthritis with an estimated lifetime prevalence of 44.7% (1). KOA is the leading cause of pain and limitations in activities of daily living and the chance of developing KOA rises after the age of 45.

The use of orthotic devices (knee braces, wedged shoes) is a generally accepted conservative therapy for KOA patients (2). Studies on the biomechanical effect of a newly developed ankle-foot-orthosis (AFO) for KOA patients are limited. A pilot study on 14 healthy patients showed promising results with a reduced external knee adduction moment (KAM) when using a prototype AFO (3). A biomechanical study of AFOs in KOA patients would be needed to further validate the effectiveness of this type of intervention. Therefore, the aim of the study was to observe the biomechanical effects of this orthosis in a larger sample of KOA patients.

METHODS

Fifty medial KOA patients (mean (±SD) age 58.6 (±10.4) years, height 1.73 (0.1) m, weight 83.8 (4.9) kg and BMI 27.8 (4.9) kg/m²), clinically diagnosed according to the ACR Guidelines, were recruited for the study. The patients performed a gait analysis wearing different interventions in a randomized order: control (own shoes), AFO (Agilium Freestep®, Ottobock, Germany), valgus brace (Unloader One Custom®, ÖSSUR, Iceland) and laterally wedged shoes (6º).

The KAM and KFM were retrieved from frontal and sagittal plane kinematics and kinetics and were used as the primary outcomes. Additionally, at the end of each gait analysis, all the patients rated the comfort of the orthosis or shoes using a scale from 1 to 5 (being 1 the most comfortable).

RESULTS AND DISCUSSION

Both peaks of the KAM were significantly reduced by 22% and 7% while using the AFO and 9% and 10% while using the wedged shoes (1st peak: AFO p = 0,00, wedged shoes p = 0,00; 2nd peak: AFO p = 0,047, wedge shoes p = 0,00).

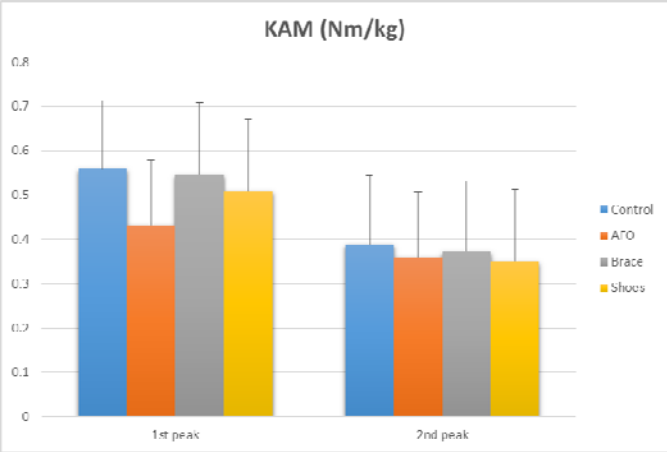

Figure 1: KAM using the different interventions.

Changes in the KFM were only significant while using the AFO (1st peak p = 0,001; 2nd peak, p = 0,045). We saw a 27% increase in the extension moment and a 30% reduction in the flexion moment.

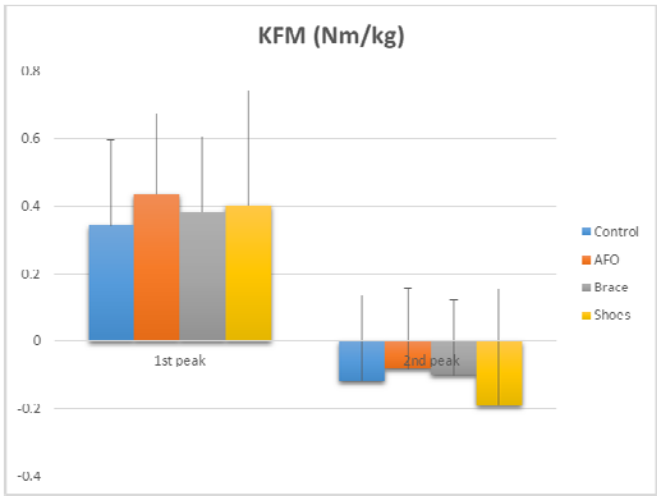

Figure 2: KFM using the different interventions.

90% of the patients found the AFO more comfortable when compared with the other devices. Average rates were: 2.2 for the AFO, 3.0 for the brace and 3.2 for the wedged shoes.

CONCLUSIONS

Both AFO and wedged shoes significantly reduced the KAM peaks by 15% and 10%, respectively, and therefore, reduced the load on the medial compartment of the knee. As previous studies showed that both KAM and KFM should be considered to get a complete description of knee loading in KOA patients (4), we also examined the KFM. The KFM seems to have significant difference only while using the AFO, increasing the 1st peak but also reducing the 2nd peak. The AFO showed a better effectiveness and a more comfortable way to reduce knee loading in medial KOA patients.

INTRODUCTION

Knee osteoarthritis (KOA), is a major burden to health care. Abnormal loading is believed to be a major contributor to the development and progression of KOA. Because KOA is most common in the medial side of the knee [1], methods such as gait modification training and lateral wedge insoles aim to unload the medial tibial compartment.

The effectiveness of these methods has commonly been evaluated as a change in external knee moments (*e.g.* KAM), but their relevance has been criticized [2]. Musculoskeletal (MS) modelling allows the estimation of muscle forces acting on the human body, but does not describe stresses in the cartilage. Finite element (FE) method enables the estimation of stresses in the cartilage, but requires force and moment input data to work. In this pilot study, we created a workflow, combining MS and FE models to study the effect of gait modification and insoles on a subject-specific level.

METHODS

The subject's (27 year-old female, m = 61.2 kg) gait was recorded using Qualisys motion capture system and Kistler force plates. A total of 39 reflective skin markers were placed at anatomical locations of the right leg, pelvis area and the trunk. The subject walked normally, with a 5° insole, a 10° insole, toes turned slightly inward ('*Toe in*'), and toes slightly outward ('*Toe out wide*'), all with self-selected speed. The bones were segmented from a full lower body MRI scan using Mimics software and the standard bone models of AnyBody MS software were morphed into the subject's bone geometry using the TLEM 2.0 model [3].

The marker trajectories and force plate data were used in an AnyBody v.6.0.5 inverse dynamics model. In the knee, a circle for each femoral condyle was fitted in the sagittal plane to the contacting contours of cartilage, segmented from a 3T MRI scan. The knee joint was defined as a hinge joint with an axis defined by the centers of the circles. Resulting forces, moments, and flexion rotation were exported and used as an input for the FE model. 5 trials of each technique were analyzed, and the most average ones of each technique were chosen as the input for the FE model.

The FE model was created in Abaqus v.6.13-3 using cartilages and menisci, segmented from the subject's detailed knee MRI. The soft tissues were defined as fibril-reinforced poroviscoelastics (FRPVE) [4] with element type C3D8P and ligaments as pre-strained linear springs.

RESULTS AND DISCUSSION

Toe in method reduced medial tibial reaction forces the most (Figure 1), but caused the highest stresses and strains in the contact area during heel strike and second axial peak force. *Toe out wide* caused highest stresses during the first peak force. Both insoles reduced stresses throughout the stance.

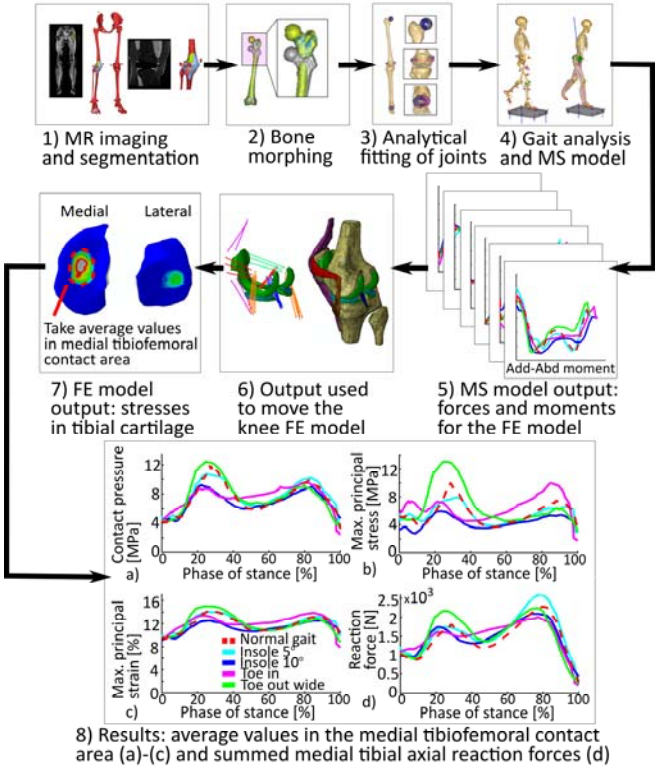

Figure 1: Study workflow from MRI through musculoskeletal (MS) model to finite element (FE) model.

Results indicate that the insoles might reduce stresses in the medial tibial cartilage. The effect of the 10° insole might be exaggerated because its stance phases were 10% longer than normal stances, as were those of *Toe in*. However, the length of stance in 5° insole trials was nearly identical to that of normal gait. A closer look revealed that *Toe in* and *Toe out wide* increased stresses because a shift in tibiofemoral contact reduced the medial contact area.

CONCLUSIONS

We established a novel, subject-specific method to study the effect of gait modification and lateral wedged insoles. Results indicate that the lateral wedge insoles show most potential at reducing stresses and strains in the medial tibial cartilage. However, in the future, these findings need to be corroborated with OA patients characterized by medial KOA.

CAN ALTERNATIVE MUSCLE RECRUITMENT STRATEGIES REDUCE THE FORCE TRANSMITTED THROUGH LOWER LIMB JOINTS?

INTRODUCTION

The breakdown of joint cartilage and underlying bone associated to widespread diseases such as osteoarthritis or rheumatoid arthritis leads to joint pain and reduced activity in daily life. Joint replacement is used as a final treatment, but due to its high impact and potentially limited life span, especially in physically active patients, there is growing interest in conservative treatments aimed to slow down joint degeneration and reduce pain. These treatments focus on the reduction of joint loads through exercise, reduced activity, weight loss and support equipment, as high loads have been identified as a risk factor for the development and progression of joint degenerative diseases. Targeted hip strengthening was shown to improve pain and physical function in people with medial tibiofemoral osteoarthritis [1] and an optimization study in musculoskeletal models suggested that alternative muscle force patterns can lead to a reduction in axial tibiofemoral force compared to physiological measurements [2]. However, the influence of alternative neuromuscular control strategies on the non-optimized joint loads remains unknown.

This study aims to explore the potential for alternative muscle recruitment strategies to reduce the hip and knee loads during gait and to show the influence of such patterns on the loads in the adjacent joints.

METHODS

Skin marker positions and ground reaction forces were measured for six gait cycles of a healthy volunteer (male, age: 28 yr., height: 1.90 m, mass: 82 kg) at a self-selected speed. Net joint moments, muscle lever arms and lines of action were estimated using the Opensim Gait2392 model with 13 degrees of freedom and 92 muscles [3, 4]. No muscle force-length-velocity relationship was included.

Three different muscle force patterns were obtained through three optimization strategies, implemented using the function *fmincon* in MATLAB (The Mathworks, Inc., Natick, MA), to alternatively minimize the sum of normalized muscle forces squared (minMusForce), the magnitude of the joint resultant force at the hip (minJRF hip) and at the knee (minJRF knee), while satisfying the equilibrium of net-joint moments. The muscle force pattern found through minMusForce served as an initial guess for both minJRF. The JRF for the hip, knee and ankle were then computed from these muscle force patterns.

RESULTS AND DISCUSSION

The JRF at the hip and knee was found significantly lower throughout the stance phase for the minJRF hip and minJRF knee, respectively, compared to the minMusForce (Figure 1). The peak JRF was 1.9 ± 0.1 BW and 2.6 ± 0.1 BW smaller for the hip and knee, respectively, both during late stance. For the knee, this result is in good agreement with previous findings [2]. The swing phase, where no significant reduction in JRF occurred, was not included in the analyses. For the minJRF hip, the ankle resultant force increased, while the knee resultant force remained similar compared to minMusForce (RMSE: 1.8 and 0.4 BW, respectively). For the minJRF knee, both the hip and ankle resultant force increased compared to the minMusForce (RMSE: 1.5 and 1.8 BW, respectively).

The current study is limited by the lack of comparison with in-vivo measurements. However, a minimization of knee JRF was previously shown to lead to lower JRF compared to measurements from an instrumented knee prosthesis [2].

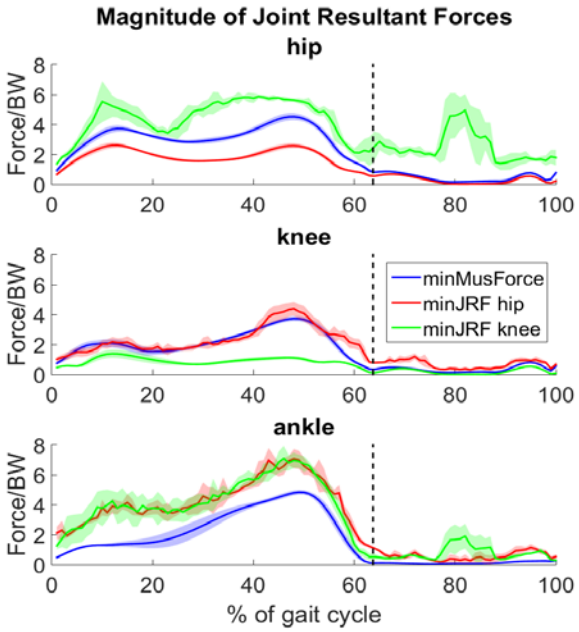

Figure 1: Magnitude of joint resultant forces (mean ± SD) in the hip (top), knee (middle) and ankle (bottom) of the left leg for the three different optimization strategies.

CONCLUSIONS

Alternative neuromuscular control strategies have the potential to reduce the loads in the hip and knee, but could simultaneously increase the loads in adjacent joints. Future research should further investigate this effect, for example through multi-objective optimizations as proposed by [5].

COMPUTATIONAL MODELLING OF BALLISTC CRANIAL WOUNDING USING SMOOTHED PARTICLE HYDRODYNAMICS FOR FORENSIC APPLICATION

[1]**Eryn Kwon**, [1]Simon Bickerton, [2]Michael Taylor and [1]Justin Fernandez

INTRODUCTION

Cranial ballistic wounding is highly fatal and the prevalence of a ballistic crime worldwide makes the computational and biomechanical study of ballistic evidence very important forensically. Of the variety of evidence types that can arise from a cranial ballistic impact, a type of forensic evidence called 'backspatter' is of particular interest. Backspatter is a fluid spatter originating from the entry site and travelling against the direction of the bullet, towards the shooter. The reverse directionality of the backspatter has specific evidential value, as it may establish a link between the victim and the shooter via transfer of biological matter as well as positions of the persons involved [1].

Due to ethical concerns, backspatter research requires a model of the human cranium to conduct research. The short duration of the event and severity of forces involved as well as the individual variation between persons (biodiversity) make the ballistic impact difficult to model. Currently, animal and physical models are used to model cranial ballistic wounding and backspatter. However, these models are of high cost and require long manufacturing and setup time.

With the advent of computational techniques and power, it is now possible for engineers to aid crime investigation by overcoming the ethical and practical issues associated with the animal and physical models. This study aims to deliver an accurate computational model, representing highly complex human anatomy, to be used as a surrogate cranial model to study gunshots, with specific interest to the backspatter problem.

METHODS

A computational model of a human cranium geometry based on a live female MRI scan has been developed. A typical sample female cranial MRI was digitised into three layers of scalp-skull-brain geometry. The geometry was meshed into small grids for the simulation (Figure 1).

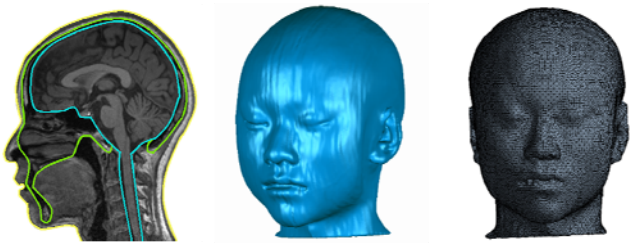

Figure 1: Computational modelling stages. MRI scan (left), digitized geometry (middle) and the meshed geometry (right) is shown.

The ballistic event was computationally simulated using smooth particle hydrodynamics (SPH) [2], a meshless particle based method, for a 115 grain 9 mm full metal jacket luger projectile shot from a distance of 1 m. The simulation result was validated against a ballistic experimental result of a matching physical model which had equivalent geometry and simulant materials. The physical models can be used by themselves to run forensic ballistic experiments as well.

RESULTS AND DISCUSSION

The simulation result was compared with a physical model ballistic experimental result. The high speed video was sampled at the same frame rate as the time steps of the SPH simulation.

Figure 2: Comparison of the physical experiment (left) with the simulation (right) at the same time after the impact.

The computational model successfully reproduced the forward spatter and backspatter, which compared well to the physical model experiment, as well as the surface skin layer deformation shape and size (Figure 2). The result of the ballistic simulation was integrated into a virtual crime scene.

This simulation demonstrated the potential of the computational models as a better alternative to animal and physical models. This work provides a basis for a more complicated, anatomically accurate geometric cranium model to further develop a reliable and robust simulation of cranial ballistic impact.

CONCLUSIONS

A computational model true to human anatomy was created, which successfully simulated a ballistic event using the SPH method. The simulation was able to reproduce realistic blood spatters which agreed in timing and quantity to experiment.

The computational model can be used as an economic and easy to customise surrogate to conduct research on a cranial ballistic impact.

CORRESPONDENCE RULES TO CORRELATE INTERSPECIES TRAUMATIC BRAIN INJURY

[1]**Robert N Saunders**, [1]X Gary Tan, [1]Amit Bagchi
[1]U.S. Naval Research Laboratory
Corresponding author email: robert.saunders@nrl.navy.mil

INTRODUCTION

The use of animals in the study of traumatic brain injury (TBI) is often beneficial so that controlled insult-injury correlations can be made. However the usefulness of these studies is not well established and due to ethical concerns, cost, test logistics, and insufficient data granularity, live animal data can be difficult to obtain. In this work, the development and validation of computational models of both a human head and pig are presented as an alternative. These models are then used to develop a framework for comparing TBI response between humans and pigs due to a blast overpressure loading. Such comparisons are developed through the correspondence rules to correlate the effects in multiple species, such as human and porcine subjects.

METHODS

High-fidelity computational models of the human head and porcine subject are based on high resolution CT and MRI scans. These medical scans were digitally segmented using an image-to-voxel transformation and then converted into a finite element (FE) mesh [1]. All major identifiable tissue components in the human head and porcine subject have been included in the models. The human model is based on a 50th percentile Caucasian male of 26 years age [2] and the porcine model is based on a ~30 kg mini-Yucatan pig [3]. Latest low-to-high strain rate data available in the literature has been used to define tissue component material behaviors with suitable constitutive functional forms. The human head model was numerically validated against four well-known experimental studies related to automotive accidents. Similarly, the porcine model was validated against available blast tube injury response data.

To develop a framework for human to animal correspondence rules, both the human and porcine computational models are subjected to identical blast overpressure loadings. The resulting TBI is predicted based on biomechanical measures such as pressure, stress and strain, and using injury thresholds from the literature. The overpressure, positive phase duration, and orientation of blast are varied in the numerical experimentation. The intent of this set of correspondence rules is to capture not only the species differences (e.g. weight, dimensions, skull thicknesses, etc.) but also the difference in response to different input insults.

RESULTS AND DISCUSSION

Initial results using a constant peak overpressure and duration blast wave from the front of the head have shown that the responses are intuitively expected, i.e., the proportionally larger skull of the pig protects the brain more than that of the human. The pig has a skull to brain volume ratio of about 3:1 whereas the human has a skull to brain volume ratio of about 1:2. Therefore, a blast impact that causes insignificant brain injury in the pig causes injury in the human head. Fig. 1 demonstrates this phenomenon using a 173 kPa pressure criteria for injury. This particular criterion was chosen in this instance as it showed the highest level of injury for the given blast overpressure. Likewise other criteria and injury levels can be utilized for exploring other biomechanical measures.

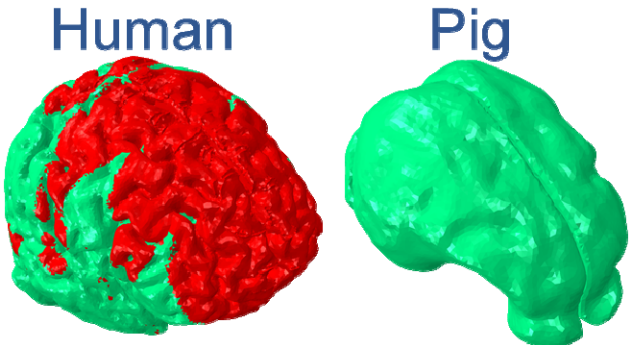

Figure 1: Spatial differences in predicted brain injury using a 173 kPa pressure injury criteria. Under identical conditions the porcine brain shows no injury where the human brain shows a substantial injury (region of the brain in red). Brains not shown to scale.

CONCLUSIONS

Initial results toward the development of interspecies correspondence rules have been shown. The results showed that the pig, with its proportionally larger skull, is better protected from a blast event. As additional threat scenarios are investigated, a more comprehensive correlation between the human and pig will be determined for blast-induced TBI.

INTRODUCTION

Traumatic brain injury (TBI), which was usually caused by an impact or a sudden change in the linear and/or angular velocity of the head, is one of the most common and serious injury in sports and traffic accidents. Therefore, it is important to study the intracranial tissue dynamic response during a collision. Woodpecker, which is famous for its excellent impact resisting system, has been researched for a long time. In recent years, researchers paid more attention on the protective effect of special head structures (hyoid bone, beak, etc.). However, there were no reported about the responses of woodpecker‘s brain under different direction of impacts. It was well known that the brain of woodpeckers could be good protected along the beak direction when it suffered from high-speed impact [1]. It is not yet known what will happen to woodpecker‘s brain during different directions of impact. In this study, finite element models were used to investigate the mechanical responses of woodpecker’s brain under four directions of impact.

METHODS

In this study, finite element method (FEM) was used to reconstruct the dynamic response of woodpecker’s intracranial tissue under four directions of impact. The impact was achieved through a rigid sphere with a certain mass hit different points of woodpecker’s head at a certain initial velocity (figure 1). The bone structure of woodpecker was scanned by Micro-CT. And the brain tissue was observed by Magnetic Resonance Imaging (MRI). The geometric shape of different parts were developed via software Mimics (Materialise Inc. Belgium). The 3D models were meshed and assembled in software HyperWorks (Altair Inc. USA). And numerical stimulation was performed in software ABAQUS (SIMULIA Inc. USA).Detailed mechanical parameters of intracranial tissue, such as equivalent stress, equivalent strain and strain rate, could be obtained by that simulation during whole collision duration time.

RESULTS AND DISCUSSION

According to the previous studies, Maximum principal strain rate (MPSR) were associated with concussion diagnosis and brain injury [2]. Figure 1 illustrated MPSR of brain tissue at the beginning of whole collision. Because of the effect of hyoid bone and beak, the beginning of brain’s responses caused by impact along the beak direction was delayed 0.5ms. The max MPSR for woodpecker’s brain under frontal and lateral impact in the beginning were 1.137ms^{-1} and 0.4877 ms^{-1} respectively. The max MPSR for impact from the rear side and the beak direction were almost the same (0.7538ms^{-1} and 0.7462 ms^{-1} respectively). MPSR of the frontal impact model distributed more widely than other model, while the beak impact model had the minimum MPSR distribution. The simulations reveal that frontal impact has led to more serious brain injury compared with other impact for woodpecker when it suffered the same impact energy. This result is also consistent with the anatomy experiments, which are in progress. The lateral and the back side of woodpecker’s skull have a dome shape, while the frontal of woodpecker’s skull is more flat. The domal structure is better to withstand the impact load than flat shell. The different geometry may be one of the factors that contributed to the mitigation of side and back impact. There were still some other factors (such as the arrangement of the trabecular bone, the distribution of skull’s thickness) that can be further studied.

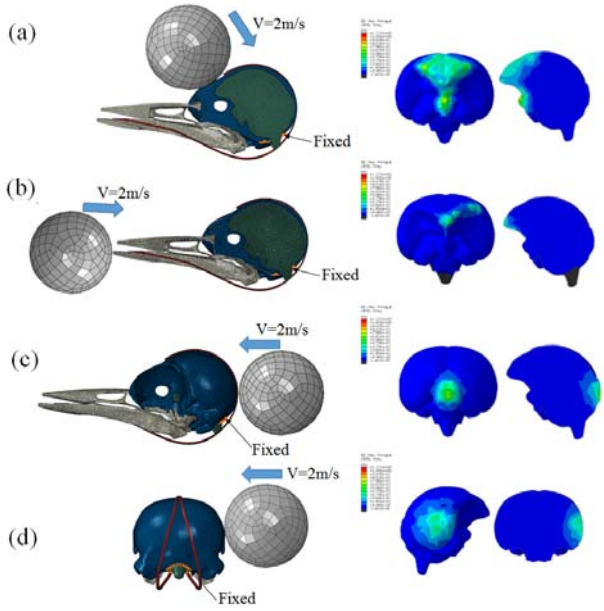

Figure 1: Simulation models and results. (a) Frontal impact and maximum principal strain rate (MPSR). (b) Beak impact and MPSR. (c) Back impact and MPSR. (d) Lateral impact and MPSR.

CONCLUSIONS

In this study, it has been find that brain tissue of woodpecker under frontal impact suffered more serious injury than the sample of other directions impact. The beak and hyoid bone delayed the impact pass to brain tissue, and reduced the risk of TBI.

POSTURAL SENSITIVITY FOR PELVIS FRACTURE DURING AN UNDERBELLY BLAST OF A MILITARY VEHICLE

INTRODUCTION

Underbelly blasts (UBB) due to improvised explosive devices have a devastating effect on the occupants of military vehicles as they can cause severe pelvic injuries, which are associated with high rates of morbidity and mortality [1]. There are numerous factors that affect the nature of these injuries, for example, initial body posture, seat design, torso-borne mass and loading severity. Amongst these variables, seating posture is believed to play an important role in the fracture pattern of UBB-induced pelvic injuries [1]. The finite element method (FEM), which offers a cost-effective tool in studies on human body responses, has been adopted in the current study to better understand the effect of different seating postures on UBB-induced pelvic injury patterns. Three commonly encountered seating postures: (1) normal, (2) upright, and (3) relaxed were evaluated using an FE human pelvis model. It should be noted that this FE model included compliance of the sacroiliac (SI) and coccygeal joints, which is particularly important in vertical loading and has not been previously considered.

METHODS

In this study, transverse cryosection images from the visible human database were used [2] for the construction of the FE male pelvis model. The model consists of the bony bilateral hip bones, sacrum, coccyges, as well as the abdominal mass. The model was assumed to have a 1-1.2 mm layer of cortical bone, which was meshed with three layers of wedge elements, while the trabecular bone was meshed with tetrahedral elements. All major ligaments were positioned according to anatomical texts and were modelled as both linear and non-linear springs. Contact between joints was modelled using a bed of compression-only linear springs. The bony structure was assumed to be an isotropic linear elastic material, whilst the abdominal mass was modelled with a Mooney-Rivlin hyperelastic material. All material properties were defined according to published data for a healthy human male. For the three seating postures considered (i.e. (1) normal, (2) upright, and (3) relaxed), a posterior pelvic tilt of 40º, 28º and 56º, respectively was used (Fig. 1). For each posture, the FE model was accelerated vertically to 2 m/s with a 10 ms time-to-peak, similar to cadaveric tests conducted by the University of Virginia [3]. The pelvic FE used in this study has previously been validated by the current authors against force and displacement histories of two sets of cadaveric tests.

RESULTS AND DISCUSSION

For all postures, the maximum principal strain in the sacrum exceeded 0.75% yield strain of the bone, indicating fracture at this location (Fig. 1). However, the upright posture (Case 2) was found to enhance load sharing between the sacrum and pelvis, with 30% more vertical force transmitted through the ischial tuberosities than the other seating positions. This redistribution increased strain in the ischial tuberosities and iliac wings, albeit below yield, and reduced the size of the predicted sacrum fracture. Consequently, a "vertical" or upright sacrum was found to reduce the risk of sacral bone fracture by distributing the compressive load through both the sacrum and pelvis more evenly than the other two postures.

CONCLUSION

The results of the current study suggest that a military occupant with a more upright initial sitting posture would have a lower risk of pelvic fractures compared to the other two postures due to increased load sharing between the pelvis and sacrum.

A PARAMETRIC STUDY OF FRACTIONAL ANISOTROPY AND THE EFFECTS ON BRAIN INJURY PREDICTION

[1]**Robert N Saunders**, [1]Anthony J Romano
[1]U.S. Naval Research Laboratory
Corresponding author email: robert.saunders@nrl.navy.mil

INTRODUCTION

Diffusion tensor imaging (DTI) and magnetic resonance elastography (MRE) studies have shown recently the spatial and mechanical anisotropy of brain tissue. The brain is essentially composed of oriented stiff fiber tracts and a surrounding isotropic extracellular matrix (ECM). It should be expected that these oriented fibers will affect the propagation of stress waves through the brain. Thus a computational model for the prediction of traumatic brain injury (TBI) should account for the anisotropic nature of the brain, however most consider the brain to be isotropic. This work will examine the consequences of modeling an isotropic versus anisotropic brain on brain injury prediction.

METHODS

A computational model of the human head which includes brain fiber tractography requires a combination of magnetic resonance images (MRI), DTI, and MRE data. The MRI data can be segmented digitally to give a geometrically high fidelity head model, which is then able to be exported to a finite element (FE) mesh [1]. DTI provides the orientation of the fiber tracts in the brain, represented by the fractional anisotropy (FA) value. The range of FA is between 0 and 1, with 1 being completely anisotropic and 0 being isotropic. Fiber stiffness is obtained via MRE data, which measures small strain shear wave propagation through the brain.

Ideally, DTI and MRE would be of the same subject as the MRI scans with the same resolution and taken simultaneously. However this is not the case for the current subject. MRI data was used to generate an FE model and not available at the time of acquisition of the DTI and MRE data. Thus a finite iterative closest point (FICP) algorithm was used to map the DTI and MRE data to the FE brain space. Additional tensor directions were interpolated using a Log Euclidean tensor interpolation. The efficacy of the FICP mapping is qualitatively shown in the top row of Figure 1. Note that we are only interested in FA values greater than 0.2, as all else will be considered isotropic ECM.

In this study, we will vary the range of FA that is considered isotropic. By varying the amount of the brain that is isotropic, the degree to which anisotropy effects the prediction of blast induced TBI can be determined. This study will not only vary isotropic FA range but also blast direction, blast peak pressure, and blast overpressure. Mechanical metrics suggested by the literature will then be used to estimate the resulting spatial and temporal injury to the brain as a result of the variation of these input parameters.

RESULTS AND DISCUSSION

Initial results using a constant peak overpressure and duration blast wave from the front of the head show that only two of the fifteen injury metrics suggest injury. Those are the 235 kPa pressure criteria and 5% principle strain criteria. The total volume of brain experiencing the two injury metrics over the duration of the simulation is shown in the bottom row of Figure 1.

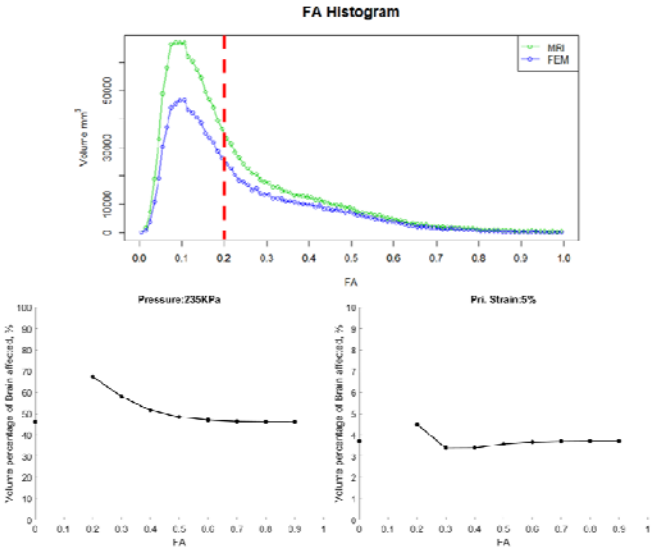

Figure 1: Top Row: Histogram showing the efficacy of the FICP method in mapping from MRI to FE space for values of FA of interest. Bottom Row: Total volume percent of the brain experiencing two suggested injury metric, 235 kPa pressure and 5% principle strain, as a function of FA.

It is interesting to note that the pressure criterion has the same trend as the FA histogram curve because pressure is not dependent on the shear stiffness in the brain. The strain based criteria, which is strongly dependent on brain constitutive behavior, does not exhibit the same behavior but instead shows a fluctuating response as FA is increased.

CONCLUSIONS

An initial study on the effects of FA on brain injury prediction has been shown. The results indicate that brain injury prediction is strongly dependent on the amount of FA included in the model. A continuation of this study is in progress to generate a full data set, which will be used to quantitatively analyze the effects of FA in the model.

UNATICIPATED CUTTING AND STOPPING TASKS DO NOT PREDICT THE SAME ACL INJURY RISK

[1]**Shelby A Peel**, [1]Lauren E Schroder, [1]Joshua T Weinhandl
[1]University of Tennessee, Knoxville
Corresponding author email: speel@vols.utk.edu

INTRODUCTION

Non-contact anterior cruciate ligament (ACL) injuries are traumatic injuries often occurring in female athletes involved in sports where running, landing, and cutting are the primary movements of the sport. Because these injuries occur at an extremely high incidence, much effort has been placed in developing predictive screening methods to minimize the chance of ACL injury [1].

These screening methods particularly target movement patterns (i.e. running, landing, cutting) that increase ACL loading. Two specific movements that may increase the risk of an ACL injury are unanticipated cuts and a quick, decelerating, stop. Unanticipated cuts have been shown to increase peak knee adduction moment, which increases the knee abduction angle; a characteristic of a high ACL injury risk movement pattern known as valgus collapse [2]. Quick, forward decelerating tasks increase anterior tibial shear force, which directly loads the ACL via anterior tibial translation, thus increasing ACL strain [3].

Although the cutting and deceleration tasks have been extensively studied individually, no study to date has determined if injury risk correlates between the two tasks. Specifically, it is currently unknown if individuals who demonstrate high knee adduction moments during cutting tasks also demonstrate high anterior tibial shear force during deceleration tasks. Therefore, the purpose of this study was to examine the relationship between peak anterior tibial shear force and peak knee adduction moment in an unanticipated deceleration task and unanticipated cutting task, respectively.

METHODS

Eleven female participants (22.0 ± 2.2yrs; 68.5 ± 9.8kg; 1.7 ± 0.1m) were recruited for the following study. All participants were free from lower extremity injuries at the time of testing. Prior to data collection, participants were informed of study procedures and provided written informed consent in accordance with institutional guidelines. Participants completed four randomized conditions: anticipated and unanticipated cutting, a straight run, and an unanticipated stop. All tasks were performed on the right leg with an approach speed for all tasks was 4.5-5.0 m/s. Five trials of each task were recorded.

For all tasks, three-dimensional marker coordinate data were collected at 200 Hz using an eight-camera Vicon motion analysis system. Synchronously, three-dimensional force data was collected at 2000 Hz using a Bertec force plate. Three-dimensional joint kinematics and kinetics were calculated for the unanticipated cutting and unanticipated stopping tasks. Peak knee adduction moment during the unanticipated cuts and peak anterior tibial shear force during the stops were extracted and normalized to body mass for further analysis.

Spearman rank correlation coefficient was calculated in MATLAB (MathWorks, Natick, MA) to analyze the relationship between peak knee adduction moment and peak anterior tibial shear force with an alpha level set to $p \leq 0.05$ and a rho value set to $\rho \geq 0.7$.

RESULTS AND DISCUSSION

There was a slight, negative, non-significant trend between peak knee adduction moment and peak anterior tibial shear force (p = 0.173). However, the two variables were not correlated (ρ = -0.45; Figure 1). The negative trend indicates that as peak tibial shear force increases, peak knee adduction moment decreases, therefore making the two variables independent of one another.

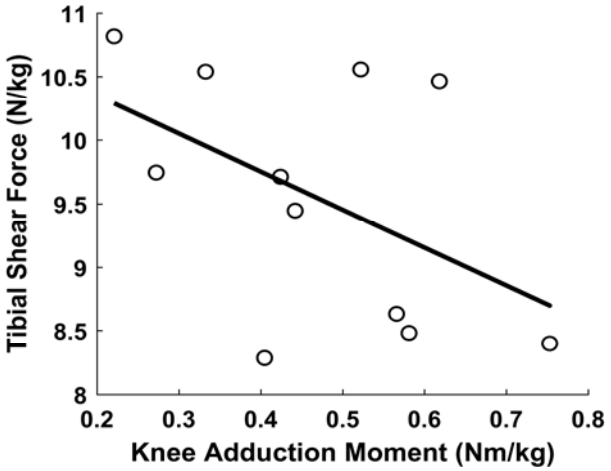

Figure 1: Relationship between peak knee adduction moment and peak tibial shear force.

Since the two variables appear to be independent of one another, screening methods may want to focus on cutting and deceleration tasks as separate entities when evaluating ACL injury risk. By analyzing these variables individually, identifying athletes at a high risk of an ACL injury may become more effective. Since sports require movements in multiple planes, these findings may also warrant a more comprehensive battery of tests, rather than the current approach of using a singular landing, cutting, or decelerating screening method.

CONCLUSIONS

Our findings suggest that peak knee adduction moment during an unanticipated cutting task and peak anterior tibial shear force during an unanticipated deceleration task are not correlated. These data can help future researchers and clinicians in better designing more effective ACL injury risk screening methods.

THE EFFECT OF TAPING ON KNEE KINEMATICS AND KINETICS DURING SIDE HOP

[1]**Kuang-Wei Lin**, [2]Yu-Lun Huang and [1]Chen-Sheng Chen
[1]Department of Physical Therapy and Assistive Technology, National Yang-Ming University, Taipei, Taiwan, ROC.

INTRODUCTION

Anterior cruciate ligament (ACL) injury is one of the most common injuries in sport. ACL protective taping has been developed and widely used to prevent ACL injuries by restricting knee joint movements. The effectiveness of the taping has been demonstrated with mechanical models [1]. However, the results of in vivo studies are still limited. Single leg hop tests are commonly used to evaluate functional performance after an ACL injury [2]. Therefore, in order to investigate if the ACL protective taping can provide a protective effect during functional tasks, the purpose of this study was to investigate the effects of the taping on knee range of motion (ROM) and moments in three different planes during the side hop test. We hypothesized that taping on knee during side hop would decrease knee ROM and moment.

METHODS

Ten healthy subjects (eight males and two females) volunteered to participate in this study. Each subject performed side hops with his/her dominant leg between two parallel strips of tape, landing on two force platforms. The distance between two parallel strips of tape was calculated using the height of the subject multiplied by 0.22. Subjects were asked to perform ten consecutive side hops in a trial. Subjects performed three trials in taping and non-taping condition while 3-minute break was provided between each trial. The Vicon T40 motion analysis system (Vicon Motion Systems Ltd., Oxford, UK) with ten infrared cameras to capture the 3D trajectories of the reflective markers with sampling rate 100 Hz was used. Two force platforms (Type 9287A and 9281B, Kister Instrument Corp., Winterthur, Switzerland) were used to synchronically record the ground reaction forces during the test. The sampling rate was set at 1000 Hz.

Twenty-one reflective markers were placed on the body segments including the thigh and shank clusters. A body-embedded orthogonal coordinate system was defined for each body segment using the markers, with the positive x-axis directed anteriorly, the positive y-axis superiorly, and the positive z-axis to the right. A static reference measurement was used to measure the locations of the markers (tibial tuberosity, fibular head and both medial and lateral epicondyle) with respect to the cluster markers and to define the neutral joint orientations. These four markers were removed for the dynamic trials. The joint moments at the knee were calculated using the measured kinematic and kinetic data by using the inverse dynamics approach. For statistical analysis, peak values of each moment component at the knee were extracted. Nine variables were studied and compared the differences between the testing conditions using paired *t*-test. The level of significance was set at .05.

RESULTS AND DISCUSSION

The results indicated that there was a significant difference between the means of the knee ROM in frontal plane in two conditions. Based on our results, the ACL protective taping restricted the frontal plane knee ROM by nearly 2° during the stance phase of hopping. However, no significant difference between the two conditions was observed in the knee moment (Figure 1).

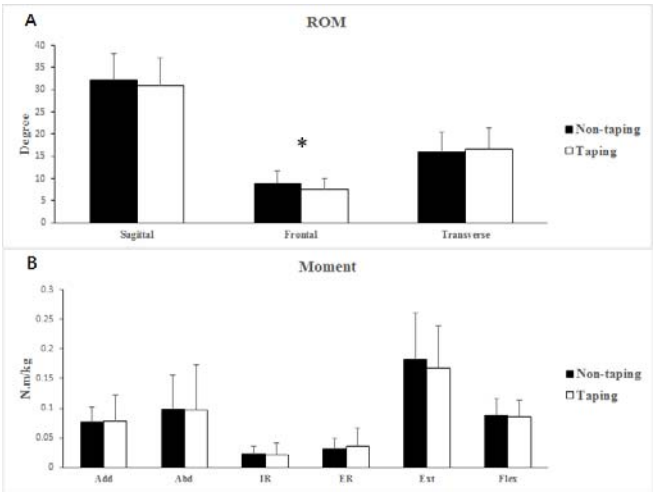

Figure 1: Average knee ROM (A) and moments (B) in three different planes during side hop (non-taping vs taping). Significant differences are indicated with an asterisk.

Increased knee joint abduction angles and abductor moments during landing may increase the risk ACL injuries [3]. In this study, we implemented a combination of two taping techniques, including rotary taping and collateral ligament taping, to provide a multidirectional support. According to the results, the knee ROM in frontal plane was significantly lower during the stance phase of hopping the taping condition. However, the change was trivial and not clinically meaningful. In addition, we recruited healthy participants instead of individuals with ACL injuries who have higher risk of ACL injuries. The effect of the ACL protective taping on reducing the risk of ACL injury is needed to be further investigated in future studies.

CONCLUSIONS

In summary, the ACL protective taping reduced the knee ROM in frontal plane in healthy individuals. However, the change was not clinically meaningful.

AN EXPLORATORY ANALYSIS CORRELATING FORCE PLATE FREE MOMENTS AND MULTI-COMPONENT KNEE MOMENTS DURING SIDESTEPPING

[1]**Mark A. Robinson** and [2]Cyril J. Donnelly
[1]Liverpool John Moores University and [2]University of Western Australia

INTRODUCTION

To mitigate an individual's anterior cruciate ligament (ACL) injury risk in sport, much biomechanics research has been devoted to mapping the internal (i.e., muscle forces) and external forces (i.e., ground reaction forces) that can load and damage the tissue during the weight acceptance (WA) phase of non-contact sidestepping and landing tasks. Inverse-dynamics is commonly used to estimate the three dimensional (3D) forces and moments applied to the knee as multi-component loading patterns are known to elevate ACL strain and injury risk of cadaveric knee models [3].

Although prospective evidence has identified links between ACL injury incidence and peak vertical ground reaction forces [4], there has been little exploration of possible links between rotational ground reaction moments (i.e., free moments) and multi-planar joint loading during sporting tasks with rotational on-line steering requirements e.g. sidestepping. This might seem surprising when the straight-line running literature has shown absolute peak free moments are related to the incidence tibia stress fractures [5].

As transverse plane rotational loads are characteristic of sidestepping sporting movements, the aim of this research was to verify if a mechanical relationship exists between peak free moments during the WA phase of sidestepping and time varying, multi-component knee moment vector fields.

METHODS

Sixteen male Australian Rules Football players completed an unplanned sidestepping protocol [2] with their preferred right limb. A 12-camera Vicon MX system recorded 3D kinematic marker trajectories at 250 Hz and 3D ground reaction forces and moments with an AMTI force platform at 2,000 Hz. Free moments were calculated as per Milner *et al.* [5] in Visual 3D. A custom lower-limb skeletal model with functional hip and knee joint centers and axes was used to estimate time varying, 3D knee joint moments during the stance phase of unplanned sidestepping [2].

The magnitude and timing of first peak free moment (Peak-Tz1) within the WA phase of sidestepping was obtained. Timing was expressed as a percentage of stance. It should be noted the vast majority of participants produced a positive free moment through stance, which would be interpreted to mean the free moment is rotating the foot towards the intended change of direction. Time varying 3D net knee moment vectors ($\mathbf{M}_{Z\text{-}X\text{-}Y}$) and 2D knee moment vector couples ($\mathbf{M}_{Z\text{-}X}$; $\mathbf{M}_{Z\text{-}Y}$; $\mathbf{M}_{X\text{-}Z}$) were obtained throughout stance. Canonical Correlation Analysis (CCA)[6], the SPM vector-field equivalent of linear regression, was used to examine the correlation between Peak-Tz1 and the 3D moment vector-field $\mathbf{M}_{Z\text{-}X\text{-}Y}$ throughout stance. Post-hoc analyses of the knee moment couples ($\mathbf{M}_{Z\text{-}X}$; $\mathbf{M}_{Z\text{-}Y}$; $\mathbf{M}_{X\text{-}Z}$) were also calculated with CCA ($\alpha = 0.05$). M_Z, M_X and M_Y represent knee flexion/extension, ab/adduction and internal/external moments respectively.

RESULTS AND DISCUSSION

Peak-Tz1 occurred at 20±10.7% stance, which corresponded to, or immediately following peak extension (19±4.5% stance) abduction (18±4.5% stance) and internal rotation knee moments (16±4.3% stance). There was a significant correlation between Peak-Tz1 and the 3D knee moment vector-field ($\mathbf{M}_{Z\text{-}X\text{-}Y}$) within WA (6-8% stance) and through mid-stance (25-80%). Post-hoc analysis revealed the later relationship was primarily explained by the $\mathbf{M}_{Z\text{-}Y}$ and $\mathbf{M}_{X\text{-}Y}$ vector couples with My potentially being dominant. The momentary relationship seen during WA requires further confirmation. These analyses show that Peak-Tz1 can predict multi-component knee loading patterns and potentially ACL injury risk during sidestepping. There may be useful mechanical information within free moment waveforms to inform literature interested in mapping ground reaction force measures to ACL injury incidence in sport.

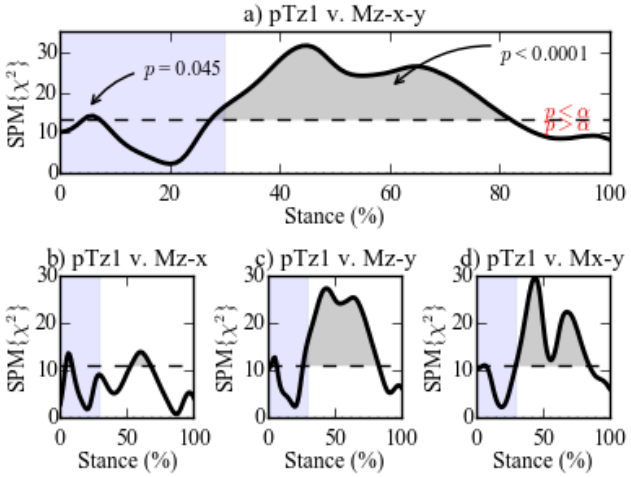

Figure 1: a) CCA of Peak-Tz1 and 3D knee moment vector-field $\mathbf{M}_{Z\text{-}X\text{-}Y}$ a significant relationship exists when the SPM{χ^2} statistic crossed the critical (dotted) threshold. The bottom panes are CCA's of Peak-Tz1 and knee moment couples ($\mathbf{M}_{Z\text{-}X}$; $\mathbf{M}_{Z\text{-}Y}$; $\mathbf{M}_{X\text{-}Z}$). The shaded blue area indicates WA phase of stance.

CONCLUSIONS

Peak-Tz1 during unplanned sidestepping was predictive of multi-planar knee moments during WA and through mid-stance. Further research with larger cohorts is currently being undertaken to assess whether this mechanical relationship is population, task and/or laboratory specific.

RUNNING AND STOPPING IN SPORT: IMPLICATIONS FOR INJURY

Gillian Weir, Carl Jewell and Joseph Hamill
Biomechanics Laboratory, University of Massachusetts Amherst
Corresponding author email: gweir@umass.edu

INTRODUCTION

Team based sports require athletes to perform dynamic movements in response to external stimuli. These external stimuli require rapid and precise reactions in order to gain possession of a ball, evade an opponent or carry out a team tactic. Time constraints associated with these dynamic movements may cause unplanned anticipatory adjustments and, as a consequence, lead to altered joint mechanics [1]. Gait termination (GT) is a transitional motor task that requires an athlete to transfer from a dynamic state of motion to a static position [2]. This requires the central nervous system to control and decelerate the COM within the base of support (BOS). Rapid deceleration during sport such as in GT and sidestepping have been associated with knee and ankle injuries [2, 3]. It is therefore important to understand how stopping is controlled and performed in order to identify strategies that may reduce risk of injury. Understanding these mechanics has implications for a number of deceleration movements in sport (i.e. stopping, cutting and landing). The aim of this study was to investigate the effect of anticipation on kinematics during running GT. Our secondary aim was to understand the role of the termination and stabilization steps in controlling forward momentum and terminating running gait.

METHODS

Five male (25.4 ± 4.2yrs, 1.77 ± 0.05m, 72.7 ± 6.4kg) recreational team sport athletes were asked to complete a series of anticipated and unanticipated straight line run and run-stop tasks. Participants were instructed to run at 4.5m/s along a runway and stop upon reaching a force plate with their right limb (termination step) with final GT on a second force plate with their left limb (stabilization step) (Figure 1). During these tasks, a large television screen either displayed a stop signal at initiation of the run (anticipated), or the stop signal appeared at ipsilateral limb toe off (unanticipated). 3D full body marker trajectories were captured with a 12 camera Qualisys motion capture system at 240Hz.

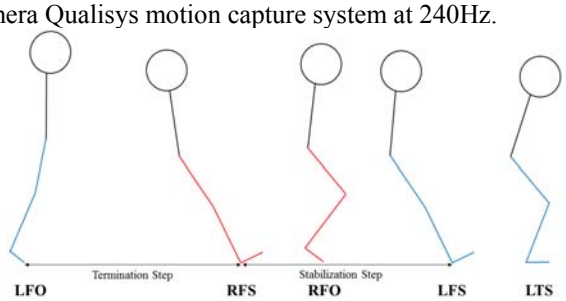

Figure 1. Stopping task.

Kinematic data were low pass filtered at 14Hz and analyzed during the stance phase for both limbs. Termination and stabilization step lengths were scaled to height. Comparisons between conditions and limbs were made with two-way ANOVAs ($\alpha = 0.05$).

RESULTS AND DISCUSSION

Athletes experienced significantly higher knee and trunk flexion range of motion during the termination step of anticipated and unanticipated GT in running ($p<0.001$) (Table 1). Knee flexion angles at foot strike were low during both steps in both conditions. Knee flexion angles less than 20° at foot strike have been observed during video analysis of ACL injury events [3] and have been associated with elevated ACL strain [4]. Greater peak trunk COM deceleration in the horizontal plane was observed in unanticipated compared with anticipated run-stop tasks during the termination step ($p=0.012$). Greater trunk COM acceleration away from the stance limb in the mediolateral plane and inferiorly in the vertical plane were observed in the termination step as compared with the stabilization step. These results suggest that forward momentum of the trunk during running is modulated during the termination step in order to achieve quiet stance during the stabilization step. As there is a large solution space for kinematic strategies during sporting tasks, the addition of muscle activation and kinetic data may better explain differences in postural adjustments in response to time constraints.

Table 1. Kinematics during stance for right and left limbs during anticipated and unanticipated run-stop tasks. COM velocities are positive in medial (toward stance limb), anterior and superior directions.

		Anticipated Stop	Unanticipated Stop
Termination step (right limb)	Knee flexion at foot strike (°)	14.3 (7.2)	12.6 (7.8)
	Knee flexion RoM (°)	79.7 (10.9)	83.8 (11.5)
	Trunk flexion RoM (°)	15.0 (3.6)	16.1 (3.0)
	Peak trunk COM acc M(+)/L(-)	-9.3 (1.6)	-9.3 (1.7)
	Peak trunk COM acc A(+)/P(-)	-16.0 (3.2)	-17.2 (3.5)^
	Peak trunk COM acc S(+)/I(-)	-10.9 (1.8)	-11.7 (1.1)
	Step length[a]	0.7 (0.2)	0.8 (0.2)
Stabilization step (left limb)	Knee flexion at foot strike (°)	13.4 (2.8)	11.9 (4.9)
	Knee flexion RoM (°)	39.1 (8.6)*	37.8 (7.8)*
	Trunk flexion RoM (°)	5.4 (2.2)*	6.0 (3.3)*
	Peak trunk COM acc M(+)/L(-)	-3.5 (1.1)*	-3.5 (0.8)*
	Peak trunk COM acc A(+)/P(-)	-14.8 (3.9)	-16.0 (3.2)
	Peak trunk COM acc S(+)/I(-)	-5.9 (2.3)*	-9.2 (2.4)^
	Step length[a]	0.6 (0.1)	0.6 (0.1)

*Significantly different from right limb ($p<0.001$); ^significantly different from anticipated stop ($p<0.05$); [a]scaled to height.

CONCLUSIONS

The termination step during running GT plays a significant role in modulating forward momentum in both anticipated and unanticipated conditions. These results have implications for coaches where both implicit and explicit cueing during stopping drills and strength training should focus upon: 1) dynamic trunk control; and 2) knee flexion during the termination step in GT.

SYNERGISTIC STRATEGIES FOR SUPPORTING DIRECTION SPECIFIC KNEE JOINT LOADS

INTRODUCTION

Due to their anatomical orientation, the major muscles crossing the knee can effectively oppose external loads in the sagittal plane. However, the roles of knee joint muscles in supporting frontal and transverse plane loads remain unclear. Therefore the aim of this study was to identify muscle synergies as they relate to internal knee joint moments in the sagittal, frontal, and transverse planes.

METHODS

A weight-bearing isometric force-matching task required 22 healthy adults (10 females) to modulate horizontal ground reaction forces, thus eliciting various combinations of sagittal, frontal and transverse plane internal net joint moments at the hip, knee and ankle [1]. Activities of ten lower limb muscles were measured with surface electromyography (EMG) normalised to maximum voluntary isometric contraction. Concatenated non-negative matrix factorization (CNMF) extracted muscle and moment synergies [2]. CNMF input combined EMG and internal knee joint moment data in order to map activation patterns to principal moment direction(s) [3]. The number of synergies that could reconstruct >90% of variance accounted for (VAF) in the original data was extracted.

RESULTS

Six synergies were extracted to account for 92.9% of VAF. Each moment synergy was dominated by one moment direction: extension (Ext), flexion (Flex), abduction (Abd), adduction (Add), internal rotation (IR), external rotation (ER) (Fig. 1). Muscle synergies associated with Flex and Ext moments were respectively accompanied by dominant hamstring and quadriceps muscle synergies. Co-activation was observed in muscle synergies associated with knee adduction, internal and external rotation moments. The muscle synergy associated with knee abduction moments was dominated by gluteus medius.

DISCUSSION

Muscle synergies help to reduce the computational complexity of a redundant human musculoskeletal system. Yet, considering muscle activation alone limits the ability to map a synergy to its "functional role" [3]. Our analysis included moment data so muscle synergies could be related to their role in supporting the knee. In doing so, extracted muscle synergies related to specific moment directions.

Synergies related to internal knee adduction and rotational moments were accompanied by substantial co-activation of the major knee joint muscles. Since external abduction loads coupled with rotation is a major mechanism of ACL injury [4], we consider these synergies to be important stabilizing components, co-contracting to increase compressive forces and joint stiffness. Supporting Srithnan et al [5], knee abduction was related to activation of the gluteus medius and tensor fascia latae, indicating hip abductors have an important role in regulating frontal plane knee loads. Results provide important insight into neuromuscular mechanisms of knee joint stability.

EFFECTS OF LAXITY ON SUBJECT-SPECIFIC CARPAL KINEMATICS AND KINETICS

Michael J Rainbow

Human Mobility Research Centre, Department of Mechanical and Materials Engineering, Queen's University, Kingston, ON, Canada

michael.rainbow@queensu.ca

Given the debilitating effects of scapholunate advanced collapse and current variable outcomes in scapholunate ligament reconstruction, there is vast room for improvement in the treatment, early detection, and prevention of degenerative changes in the wrist. To properly diagnose pathology and evaluate whether a given treatment has restored healthy carpus function, a comprehensive understanding of normal carpal architecture and function is essential. Previous 2D studies of carpal bone kinematics have shown that there is a spectrum of carpal mechanics that varies between row-type motion and column-type motion as a function of wrist laxity. More recent three-dimensional (3D) studies have suggested instead that carpal bone motion is consistent across individuals. The purpose of our work is to use three-dimensional kinematic and kinetic methods in vivo, and in vitro mechanical testing to determine whether carpal kinematics in stiffer wrists differ from carpal kinematics in wrists with higher laxity, and ultimately, whether we can restore subject-specific healthy carpal mechanics following scapholunate ligament reconstruction.

We use three different but complimentary approaches to tackle this problem – *in vivo* and *in vitro* three-dimensional carpal kinematic analyses, in vitro mechanical testing, and *in silico* modeling. Each approach yields insights into the function of the intact, pathological, and reconstructed wrist.

In our recent *in vivo* work, we have found that the component of radial-ulnar deviation of the scaphoid during wrist radial-ulnar deviation depends on the relative laxity in the wrist. Our mechanical tests on intact and dissected cadaver wrists confirm these findings. Preliminary results of our predictive carpal model – a forward model constrained by cartilage contact and non-linear ligaments – also demonstrates that carpal kinematics vary as a function of ligament stiffness. Whether these findings are clinically important remains to be determined. To address this question, we are currently examining how carpal mechanics are affected when the scapholunate ligament is reconstructed with tissue replacements more similar to the native scapholunate interosseous ligament.

ANATOMICAL VOLAR AND DORSAL RECONSTRUCTION (ANAFAB) FOR SCAPHO-LUNATE DISSOCIATION

MICHAEL SANDOW

Wakefield Orthopaedic Clinic, Adelaide, Australia
Corresponding author email: msandow@woc.com.au

INTRODUCTION

The carpus is a complex mechanical linkage that is well adapted to perform a wide range of grasping, manipulative and propulsive functions. Previous work from our group, detailed the concept of a stable central column of the carpus which is a theory aimed to explain the identified computationally derived isometric constraints.

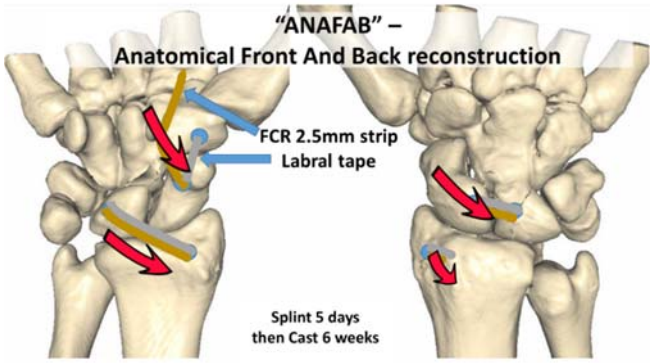
The process was to develop and then present a theoretical basis of wrist motion, identify the deficit in a particular pattern of injury, and then propose a solution based on the theoretical understanding of the cause of the biomechanical failure. This is then applied to injured patients to validate the proposition, and more importantly the theory of wrist biomechanics.

Scapho-lunate dissociation usually leads to excess scaphoid flexion, scapho-lunate diastasis, proximal scaphoid dorsal subluxation, plus pathological extension and ulnar translation of the lunate. This study reviews the efficacy of a reconstruction, based on the Stable Central Column Theory (SCCT) of Carpal Mechanics (reference), which aims to correct this disruption using a volar and dorsal approach with a hybrid tendon / synthetic tape weave (ANAFAB)

The purpose of this paper is to present the initial outcome indicating a successful translation of biomechanical theory into clinical solution.

METHODS

The reconstruction was performed using a distally based strip of FCR tendon, supplemented by a synthetic tape that was passed from the volar trapezium to the scaphoid tuberosity, trans-osseously to the scaphoid dorsum, trans-osseously from dorsal to volar through the lunate and then volarly to the radial styloid where it was secured with an interference screw. Patients were immobilised in a cast for 6 weeks, but no stabilising wires were used.



RESULTS

Ten patients have undergone the reconstruction and were assessed prospectively, including Scapho-Lunate (S-L) gap, pain, grip strength and carpal alignment.

At a minimum 6 month follow-up, the ANAFAB repair has achieved excellent realignment of the carpus, with correction of the S-L gap to (median) 3mm. Carpal realignment in most patients was within the normal range, and there has been a recovery of more than 75% grip strength and range of motion. Review is ongoing, with those patients followed the longest achieving further improvements in grip and motion.

DISCUSSION

The ANAFAB procedure, based on the SCCT, has achieved a consistent recovery of carpal stability and grip strength, without significant loss of motion.

This is a theory driven, defect correction based reconstruction that aims to restore the anatomical mechanical constraints on both volar and dorsal aspects of the carpus. However, further clinical experience is required to assess if this approach will provide a better long term solution than we currently can offer our patients.

Introduction

The dorsal capsulo-scapholunate septum (DCSS) is a thikening of the dorsal capsule, linking the dorsal side of the carpal crest of radius, the dorsal intercarpal ligament (DIC), and the scapholunate interosseous ligament (SLIOL). It appears to play a crucial role in the stability of the scapholunate articulation. The purpose of this study was to investigate the role of the DCSS in maintaining scapholunate stability.

Material and Methods

The DCSS and the dorsal portion of the SLIOL and the DIC were identified arthroscopically and were serially sectioned in 10 fresh cadaveric wrists. Scapholunate stability was assessed before and after each ligament was sectioned under arthroscopic control. The scapholunate stability was also assessed using fluoroscopic control in static and axial loading after each ligament was sectioned in the posterioanterior and lateral planes. All arthroscopic findings and radiological angles were recorded.

Results

We observed that sectioning of only the DCSS causes scapholunate instability that could be seen arthroscopically with no radiological changes. Additional sectioning of the dorsal part of the SLIOL worsens pre-dynamic instability but does not produce static instability. The pre-dynamic instability pattern observed arthroscopically was seen to increase discreetly on axial loading. The additional sectioning of the DIC resulted in an instability pattern seen arthroscopically and a significant dynamic instability pattern on axial loading of the wrist joint but an inconsistent

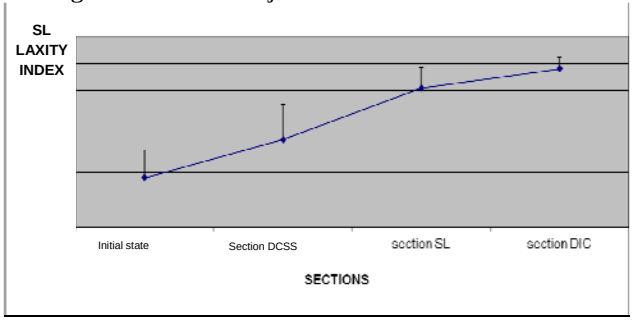

Figure 1 : Correlation between section of SL complex components and SL laxity index

Discussion

An isolated sectioning of the DCSS produces only an occult or predynamic instability pattern of the scapholunate articulation that could only be observed arthroscopically with no radiologic changes. Subsequent sectioning of the dorsal aspect of the SLIOL resulted in scapholunate dissociation that was a more advanced than the predynamic pattern. This type of instability pattern associated with sectioning of the DCSS and the dorsal part of the SLIOL resulted in a subtle radiologic static and dynamic instability pattern seen on axial loading of the wrist joint. A combined sectioning of the DCSS, the dorsal part of the SLIOL and the DIC resulted in a complete scapholunate dissociation seen arthroscopically. Sectioning of the DIC in addition to the DCSS and the dorsal part of the SLIOL also resulted in radiologic signs of complete scapholunate dissociation. However, the instability pattern seen on sectioning of all the three ligaments appeared to differ from that seen with isolated section of the dorsal part of the SLIOL. Isolated SLIOL sectioning produced an increase in the radiologic scapholunate gap on the posteroanterior view without any change in the scapholunate angle on the lateral view. A sectioning of the DIC however, resulted in a change in the scapholunate angle in the lateral plane without any remarkable increase in the scapholunate gap in the posteroanterior plane. These results might indicate:

1) A role of the dorsal aspect of the SLIOL in maintaining scapholunate stability especially in the transverse plane.
2) A role of the DIC in maintaining scapholunate stability in the sagittal plane.
3) A role of the DCSS on maintaining scapholunate stability in the predynamic phase.

Conclusion

An understanding of the role of each of these ligaments in maintaining scapholunate stability is of clinical relevance in decision making directed towards the treatment of these challenging injuries.

EFFECT OF EXTENSOR CARPI ULNARIS TENDON LOADING ON SCAPHOID PRONATION DURING DYNAMIC WRIST MOTION IN THE INTACT AND UNSTABLE WRIST

[1]**Frederick W. Werner**, and [1]Walter H. Short
[1]SUNY Upstate Medical University, Syracuse, New York, USA
Corresponding author email: wernerf@upstate.edu

INTRODUCTION

Several studies have examined the force patterns of various forearm muscles at different wrist positions [1,2]. Salva-Coll et al [3] demonstrated that the ECU (extensor carpi ulnaris) muscle causes scaphoid pronation especially in wrists with scapholunate advanced collapse (SLAC). Based on their study using static tendon loading, the authors suggested in the presence of SLAC, one should avoid ECU muscle contraction. The purpose of the current study is to examine scaphoid pronation during dynamic wrist motions in the intact wrist and following sectioning of those ligaments which provide scapholunate stability. Our hypothesis was that following ligamentous sectioning greater ECU forces would be required to achieve the same wrist motions and that scaphoid pronation would also be greater.

METHODS

Data from 22 fresh cadaver wrists (average 65 years, 11 male, 11 female) previously tested in a computer controlled wrist joint motion simulator were analyzed. Each wrist was prepared by identifying five wrist tendons (ECU, ECRB, ECRL, FCR and FCU). By pulling on these tendons with individual servo actuators, each wrist was cyclically moved through a flexion/extension motion, a radioulnar deviation motion and a dart throwing motion. Electromagnetic motion sensors were attached to the scaphoid, lunate and third metacarpal so that the motion of each bone was recorded during each motion. Data was acquired with the wrist intact and following sectioning of the scapholunate interosseous ligament (SLIL), the scaphotrapezial ligament and the radioscaphocapitate ligament and 1000 cycles of repetitive motion to simulate SLAC. During each motion the tendon forces required to achieve each motion were also acquired. During the 4th cycle of each motion, at every 12 ms, the percent ratio of the ECU force of the sum of all tendon forces was determined. The average ratio over the cycle and the ratio at the maximums at each extreme of motion were determined. Similarly, for each motion the amount of scaphoid and lunate pronation relative to the third metacarpal pronation was determined. Differences between the intact wrist and following ligamentous sectioning were compared using a paired test.

RESULTS AND DISCUSSION

With ligamentous sectioning, greater percentage ECU forces were required to achieve the same wrist motion (table 1). During both wrist flexion-extension and radioulnar deviation motions a greater force was required at maximum extension ($P<0.027$). During both the wrist radioulnar deviation and dart throw motions, greater average forces were required ($P<0.008$). At maximum flexion during the dart throw motion more force was also required ($P<0.002$).

With ligamentous sectioning the amount of scaphoid pronation increased during each motion (table 1). During the flexion/extension and dart throw motions, scaphoid pronation increased on average and at the extremes of motion ($P<0.04$). During radioulnar deviation, it increased at maximum radial deviation ($P=0.001$). Only in maximum wrist flexion during the flexion/extension motion was there a significant increase in lunate pronation ($P=0.001$).

CONCLUSIONS

Greater ECU forces are required after ligamentous sectioning to cause the wrist to go through the same dynamic wrist motions. Similarly, the scaphoid pronates more. These results may provide a reason why SLAC repair methods which repair the dorsal SLIL have limited success due to the forces causing the scaphoid to pronate and pull away from the lunate.

GROUND REACTION FORCE ACROSS THE FIRST TRANSITION DURING SPRINT ACCELERATION

INTRODUCTION

The transitions during human maximal effort accelerated sprinting have been kinematically investigated [1,2]. The breakpoint of the first transition, located around the 4th step after cleared blocks, was identified with the height of whole body center of gravity (CG) [1,2], while an argument about the existence of the first breakpoint is still left open [1]. Whereas the kinematic features of the first transition during accelerated sprinting have been investigated, characteristics of changes in ground reaction force (GRF), the source of CG acceleration and deceleration, across the first transition have never been shown. Step-to-step changes in GRF would provide clear evidence of the existence of the first transition during accelerated sprinting. The purpose of this study was to elucidate the existence of the first transition as phenomena of the abrupt changes in GRF.

METHODS

Fifteen male athletes (mean ± SD: age, 20.5 ± 1.1 y; stature, 1.73 ± 0.03 m; body mass, 65.5 ± 3.4 kg) who belonged to university track club performed three to five maximal effort 60-m sprinting, during which the step-to-step GRFs for 50-m was recorded using 54 force platforms (Tec Gihan, Uji, Japan; 1000Hz). From the GRF signals, step-to-step changes in braking, propulsive, net anterior–posterior and vertical impulses, as well as vertical impulses during braking and propulsive phases, were calculated by integrating the respective GRFs. Moreover, mean forces for the respective impulse variables were computed by dividing the impulses by the corresponding durations.

As a criterion for detecting the breakpoint at the transition step, vertical impulse during the braking phase (IMP_{Vert1}) was adopted, because of the clear trend of abrupt increase in the value, which can be visually identified (Figure 1). Based on the detected breakpoint step, values from three steps before and three steps after the breakpoint step for each variable were extracted for each participant. The respective variables for all trials of each participant were averaged out.

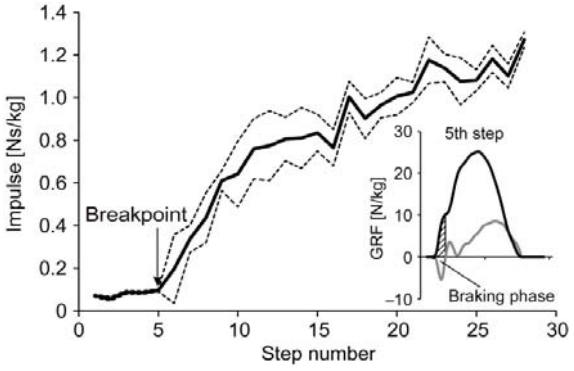

Figure 1: Example of step-to-step changes in IMP_{Vert1} during accelerated sprinting and the breakpoint of the first transition. The small panel shows horizontal and vertical GRFs at the 5th step. Value at each step is the mean of five trials for a typical participant.

Using the extracted individually averaged data around the first transition step, one-way analysis of variance with repeated measures was performed to examine the changes in variables with acceleration. When a significant difference was detected, data were analyzed using the Bonferroni post hoc test. The significance level was set at $P < 0.05$.

RESULTS AND DISCUSSION

Based on the changes in IMP_{Vert1} as a criterion (Figure 1), the breakpoint representing the first transition during accelerated sprinting was detected at the step of 5.6 ± 1.3 from the start for all participants. The abrupt and acute increase in IMP_{Vert1} demonstrates a clear evidence of the existence of rapid adaptation of locomotor pattern as a transition. Statistical analyses have revealed that there was no significant difference in IMP_{Vert1} and mean force during the braking phase, as well as the braking duration, until the breakpoint step, while significant step-to-step increases in values were detected for corresponding variables after the breakpoint step. These results indicate that the rapid increase in IMP_{Vert1} just after the breakpoint step probably results from increases in both vertical force during braking phase and the duration of braking. The step number of the detected breakpoint in this study (5.6 ± 1.3) was slightly larger than that (4.4 ± 0.9) in the previous study [2]. Although the difference in detection procedures (using IMP_{Vert1} in this study versus CG height in the previous study) possibly resulted in this discrepancy, difference in the performance levels could be another cause (relatively low level in this study compared to the previous study). Nagahara et al. [2] reported that the foot abruptly starts contacting on the ground in front of the CG just after the breakpoint step, and this would lead to rapid increase in IMP_{Vert1}, supporting the findings of this study. The mean propulsive force decreased to the breakpoint step, and it was maintained afterward. These results show that the decrement of the propulsive force at the breakpoint step would be the trigger of the abrupt adaptation of locomotion at the next step of the breakpoint step. Conversely, changes in running speed and net anterior–posterior impulse did not show atypical changes in values around the breakpoint step, suggesting that the first transition during accelerated sprinting does not relate to the performance.

CONCLUSIONS

In conclusion, the current results demonstrated that there is most likely the transition at the step of 5.6 ± 1.3 from the start during accelerated sprinting which can be detected by the acute increase in vertical impulse during the braking phase. The transition phenomenon may relate to the decrement of propulsive force at the breakpoint step. The findings of this study would help deeper understanding of human bipedal locomotor system.

RUNNING MECHANICS AND PERFORMANCE IN TRAINED MIDDLE-DISTANCE RUNNERS

[1] **Danielle Trowell**, [1]Elissa Phillips and [2]Jason Bonacci
[1]Australian Institute of Sport
[2]Deakin University
Corresponding author email: Danielle.Trowell@ausport.gov.au

INTRODUCTION

There are clear and observable differences in running technique of athletes that compete in races across different distances. Recent research has begun to distinguish middle-distance runners (800m – 3000m) from long-distance runners (>10km) [1, 2], but there remains a lack of knowledge related to the specific running technique of middle-distance runners. To improve current training programs among middle-distance runners there is a need to enhance our understanding of the biomechanical factors associated with performance. Therefore, this study aimed to identify movement patterns most related to performance among trained middle-distance runners.

METHODS

The relationship between running mechanics and performance (1500m race time) was examined in 11 national-level male runners (age: 22.3 $\pm$ 5.1 years, body mass: 67.7 $\pm$ 6.1 kg, height: 181.8 $\pm$ 5.4 cm). The average 1500m race time was 3:49.66 $\pm$ 6.08 min. Running mechanics were collected using a VICON motion analysis system (Oxford Metrics Ltd, Oxford, UK) and 8 consecutive in-ground Kistler force plates (Kistler, Winterthur, Switzerland). Athletes completed trials at a representative race pace (7.24 $\pm$ 0.34 $m \cdot s^{-1}$). Sixty-four sagittal plan kinematic and kinetic variables from the right lower limb were included in the analysis. A Partial Least Squares Regression (PLS-R) was used to reduce data to a subset of variables with the best predictive power for 1500m race time. This variable subset was analyzed using a multiple regression to determine the strength and predictive power of the model.

RESULTS AND DISCUSSION

Faster males showed a smaller total range of hip motion during swing (R^2 = 0.60, p = 0.01); less forward lean of the thorax at toe-off (R^2 = 0.50, p = 0.02); a larger range of vertical oscillation during stance (R^2 = 0.49, p = 0.02); a smaller range of sagittal plane knee motion during swing (R^2 = 0.46, p = 0.02); a slower peak knee flexion velocity during swing (R^2 = 0.44, p = 0.03); a larger maximal vertical GRF (R^2 = 0.41, p = 0.03); and a smaller ankle plantarflexion angle at contact (R^2 = 0.34, p = 0.08).

The multiple regression model revealed that three biomechanical measures could explain 96% of the variance in 1500m race time (Adjusted R^2 = 0.94; p < 0.01). Hip flexion/extension angle range during swing, the thorax flexion/extension angle at toe-off and the plantar/dorsiflexion ankle angle at contact added significantly (p < 0.05) to the prediction of race time; with the root mean square error (RMSE) was 00:01.2min (Figure 1).

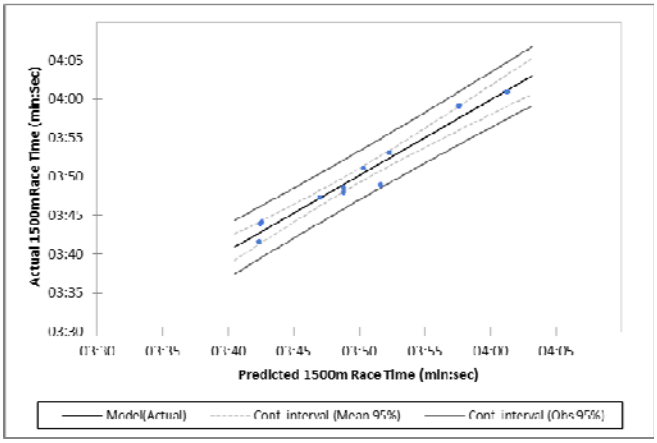

Figure 1: Plot of actual versus predicted 1500m race times for males (R^2 = 0.96).

These findings suggest that male middle-distance runners make initial ground contact with their ankle and foot in a more optimal position relative to the rest of their body. A larger plantarflexion angle observed among the slower runners appears to be the combined result of a more posterior global tibia angle (-1.76 $\pm$ 3.66, p = 0.05) and plantarflexed foot at contact (-88.30 $\pm$ 4.35, p = 0.11). The angle of the tibia increases when the knee is situated posterior to the ankle at contact. This occurs when the landing foot makes contact with the ground too far ahead of the vertical projection of the center of mass –otherwise known as overstriding. To compensate athletes seem to increase trunk inclination to maintain the anterior-posterior distance between their center of mass and center of pressure.

To the best of our knowledge, overstriding with a plantarflexed ankle and foot hasn't been examined previously. However, it seems possible that this technique may result in similar effects to those that occur during dorsiflexed overstriding, such as greater braking forces.

CONCLUSIONS

This was the first investigation of the relationship between running mechanics and performance in highly-trained middle-distance runners that used three-dimensional motion analyses during over-ground running. The results of this research show that superior runners appear to run with a more upright posture, facilitated by foot contact occurring closer to the body and less thoracic lean.

RELATIONSHIP BETWEEN THE LENGTH OF THE FOREFOOT BONES AND PERFORMANCE IN MALE ENDURANCE RUNNERS

[1] **Hiromasa Ueno**, [1]Tadashi Suga, [1]Kenji Takao, [1]Takahiro Tanaka, [1]Jun Misaki, [1]Yuto Miyake, [1]Akinori Nagano, and [1]Tadao Isaka
[1] Faculty of Sport and Health Science, Ritsumeikan University

INTRODUCTION

The magnitudes of lower limb joint moments are closely related to superior running performance. Of those, larger ankle plantar flexor moment plays a more important role in achieving better running performance, as compared with other lower limb moments [1]. Metatarsophalangeal (MTP) joint moment in the foot contributes to plantar flexor moment, thus indicating that the magnitude of MTP joint moment may potentially improve running performance, despite being a relatively small joint. In a recent study, we demonstrated that the forefoot bones were longer in sprinters than in non-sprinters [2]. Moreover, we found that longer forefoot bones were related to better sprint performance [2], possibly by increasing plantar flexor moment during sprinting, which is derived from enhanced MTP joint moment. Based on these findings, we hypothesized that longer forefoot bones may also contribute to superior running performance in endurance runners, but this remains unclear. Thus, in the present study, we compared the length of forefoot bones in endurance runners and untrained subjects to understand the characteristics of the forefoot bones in endurance runners. In addition, we examined the relationship between the length of the forefoot bones and performance in endurance runners.

METHODS

The lengths of the forefoot bones of the big and second toes in 45 male endurance runners and 45 male untrained subjects were measured using magnetic resonance image. For the forefoot bones of the big toe, the lengths of the distal phalanx, proximal phalanx, and metatarsal were measured. For the forefoot bones of the second toe, the lengths of the distal phalanx, middle phalanx, proximal phalanx, and metatarsal were measured. In addition, the lengths of mid-foot bones, including the medial cuneiform, intermediate cuneiform, and navicular, were measured.

RESULTS AND DISCUSSION

The forefoot bones of the big toes normalized to FL were significantly longer in endurance runners than in untrained subjects (47.1 ± 1.2 vs 46.0 ± 0.9 % of FL, $P < 0.001$). Moreover, second toes normalized to FL were significantly longer in endurance runners than in untrained subjects (52.2 ± 1.4 vs 51.3 ± 1.0 % of FL, $P < 0.001$). In contrast, the lengths of mod-foot bones did not differ significantly between the two groups. This suggests that long-term mechanical stress on forefoot bones during running may lead to specific bone development in the foot, potentially by up-regulation of growth factors [3].

As expected, the length of forefoot bones of the big toe, but not of the second toe, were significantly correlated with personal best 5000-m race time in endurance runners (**Figure 1**). The MTP joint serves to absorb energy during stance phase [4], and this elastic energy can partially utilize the enhancement of plantar flexor moment during push-off phase [5]. Thus, longer forefoot bones may increase utilization of elastic energy, which is related to endurance performance by contributing to good running economy.

In a recent study, we demonstrated that the forefoot bones of the big and second toes were longer in sprinters than in untrained subjects [2], as in the present findings. In addition, we showed that the length of the forefoot bones of the second toe, but not of the big toe, correlated with performance in sprinters [2]. However, the present study found a positive correlation between the length of the forefoot bones of the big toe, but not of the second toe, and performance in endurance runners. These findings indicate that the superior value of longer forefoot bones may differ between events. Sprinters use a toe-strike pattern, and the peak loading in this pattern is greater in the second toe than in the big toe [6]. In contrast, most endurance runners use a rearfoot-strike pattern, and the peak loading in this pattern is greater in the big toe than in the second toe [6]. Thus, such differences in foot-strike patterns between events may explain the discrepancy between the findings in the present and previous studies.

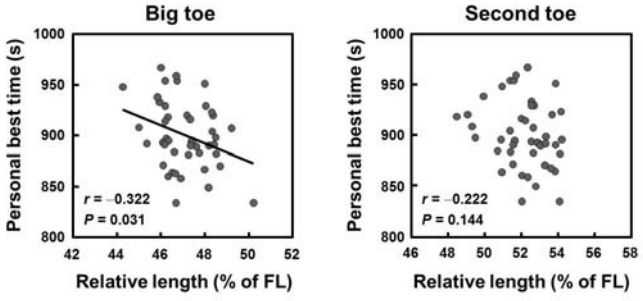

Figure 1: Relationships between the lengths of the forefoot bones of the big and second toes and personal best 5000-m race time in endurance runners

CONCLUSIONS

The present findings showed that the forefoot bones of the big and second toes were longer in endurance runners than in untrained subjects. Furthermore, longer forefoot bones of the big toe, but not of the second toe, were related to better running performance in endurance runners. Thus, we suggest that longer forefoot bones may be advantageous in achieving superior performance in endurance runners, similar to that in sprinters.

SEX-SPECIFIC RELATIONSHIPS BETWEEN AGE AND RUNNING KINEMATICS

JJ Hannigan, Peter Shen and Li-Shan Chou
University of Oregon
Corresponding author email: chou@uoregon.edu

INTRODUCTION

In recent years, both the number of older runners and the incidence of injuries in this population have increased [1]. Runners are more likely to sustain an injury as they age, with the average age for sustaining a running injury at 36 years old [2]. While several factors have been suggested to explain this phenomenon, few studies have investigated potential kinematic differences between younger and older runners [3].

Male and female runners display different kinematic patterns during running when both healthy and injured [4-5]. For this reason, when studying age-related changes in runners, it is important to analyze males and females separately. Most studies to date that have analyzed age-related changes in runners, however, have analyzed males and females together. Therefore, the purpose of this study was to examine the relationship between age and running kinematics in males and females independently.

METHODS

Thirty-nine reflective markers were placed on 23 female (age: 27.4 ± 10.0 years; range: 18-50 years) and 37 male runners (age: 30.0 ± 10.7 years; range: 18-51 years). Whole-body kinematic data were collected at 200 Hz using a 10-camera motion capture system (Motion Analysis Corp.) during continuous overground running.

Pearson correlation coefficients were used to assess the relationship between age and hip, pelvis, and trunk excursion during stance phase in all 3 planes of motion. In addition, independent t-tests compared college-age runners (ages 18-21) with older adults (ages 35+). For all tests, the family-wise alpha-level was set .05; thus, the per-comparison alpha-level was set to .006.

RESULTS AND DISCUSSION

In female runners, there was a significant, moderate, positive correlation between age and hip internal rotation excursion (r = 0.456, p = .001). There was also a significant difference in hip internal rotation excursion between college-age female runners (10.4 ± 5.9°; n=10) and older female runners (16.9 ± 5.4°; n=5), p = .006 (Table 1).

In male runners, there was a significant, moderate, inverse correlation between age and trunk flexion excursion (r = -0.357, p = .002). There was also a significant difference in trunk flexion excursion between college-age male runners (4.6 ± 1.5°; n=10) and older male runners (3.2 ± 1.5°; n=10), p = .005 (Table 1).

Excessive hip internal rotation has been found in female runners with patellofemoral pain (PFPS) [6], which is the number one injury in female runners overall [2]. The finding from this study could explain why female runners are more likely to develop a knee injury as they age [2].

An inverse relationship has been reported between trunk flexion and patellofemoral joint stress [7]. Less trunk flexion excursion in older runners could thus place more stress on the knee, and potentially help explain why knee injuries increase in males as they age [2].

CONCLUSIONS

Compared to their younger counterparts, older female runners displayed greater hip internal rotation excursion, while older males displayed less trunk flexion excursion. These findings may have injury implications related to the aging process. To better understand the relationship between age and running kinematics, longitudinal studies are needed on the same cohort of runners as they age.

ACKNOWLEDGEMENTS

The authors would like to acknowledge Dr. Jim Becker for his significant contributions in data collection.

ASYMMETRY DURING RUNNING AT PREFERRED AND NON-PREFERRED SPEEDS

INTRODUCTION

Running is a popular recreational sport worldwide, with large-scale events attracting thousands of participants; almost 50,000 completed the 2015 New York Marathon and the 10 km Dublin Women's Mini-Marathon consistently attracts 40,000 runners each year. It also composes a significant part of team sport and military fitness training. Group training is common, with members running at a similar pace. However, not everyone will be the same size or have the same preferred movement speed, meaning some will run faster or slower than they would consider optimal. Asymmetrical loading is often cited as a potential risk factor for development of injury, but is known to occur even in healthy individuals at discrete points in the stance phase during running at preferred speeds. It is unknown how modification of running speed affects this.

The aim of this study was to investigate asymmetry during running at preferred and non-preferred running speeds. Specific objectives were to investigate the effects of modification of running speed on between-limb kinetic asymmetry, determine if asymmetry occurs across the entire stance phase, and establish normative asymmetry in a group of healthy young males across the stance phase.

METHODS

Following university ethical approval, 15 healthy, recreationally active males (mean ± standard deviation; age: 27 ± 4.6 years, height: 1.81 ± 0.09 m, mass: 80.4 ± 12.4 kg) provided written informed consent to participate. All were injury-free in the preceding six months.

14 mm reflective markers (B&L Engineering, California, USA) defined the anatomical bony landmarks of both limbs, specifically the medial 1st metatarsophalangeal joint, lateral 5th metatarsophalangeal joint, superior distal hallux, calcaneus, medial and lateral malleolus and knee joint centre, greater trochanter, iliac crest, anterior and posterior iliac crests. Three-dimensional motion analysis (250 Hz, MX13, Vicon Motion Systems Limited, Oxford, UK; 12 Hz low-pass filter) and an AMTI force plate (2000 Hz, AMTI OR6, Advanced Mechanical Technology Inc., Massachusetts, USA) were used to acquire data for subsequent 3D inverse dynamics analysis in BodyBuilder.

The preferred limb was the limb preferentially used for kicking, single leg balance, and hopping. Three trials (within ±5% target speed) were acquired at each individual's preferred running speed (PRS), and ±20% of this speed (PRS-20%, PRS+20%). Support moment was calculated as the sum of the extensor moments at each % of stance [1]. Root mean square difference (RMSD) between the mean ensemble average curve of the preferred (P) and non-preferred (NP) limb support, ankle, knee and hip moments were calculated for each individual, with the absolute symmetry index (ASI) calculated as the absolute difference between peak P and NP limb values as a percentage of the average peak P and NP limb values.

RESULTS AND DISCUSSION

Average running speeds were 2.4 $m.s^{-1}$ (PRS-20%), 3.0 $m.s^{-1}$ (PRS) and 3.6 $m.s^{-1}$ (PRS+20%). Peak support moment increased with increase in running speed from 362 and 382 N.m (P & NP respectively) at PRS-20% to 440 and 461 N.m at PRS+20%, with comparable, small between-limb differences observed (ASI: 8 ±5%, 6 ±6% and 8 ±6% at each speed) and negligible timing differences (average absolute difference: 2-3%%). These increases are expected due to the corresponding increase in ground reaction forces and angular kinematics with increase in running speed. Across the entire stance phase, average support moment RMSD as a percentage of the average support moment peak was similarly low in all conditions (8 ±5%, 7 ±4% and 8 ±6%). These values are lower than the 10% upper boundary typically reported for potentially pathological gait.

Previous research has shown altered joint contributions to support with increased movement speeds, but not observed here (ankle: ~39%, knee: ~50%, hip: ~11%) possibly due to the small range of speeds tested. Small differences in percentage contribution to the support moment of each leg were observed at the ankle (~5%), knee (~5%) and hip (~3%), with no effect of condition. This indicates subtle differences in the role and contribution of each joint in each limb, suggesting within-limb compensation strategies occur to ensure overall gait symmetry. At joint level, asymmetry was observed at both peak moment and across the stance phase (Table 1), with no practical difference in the timing of the peak moments which occurred at 2-4% of stance. If ground contact time is also asymmetrical, this may indicate different rates of torque development in each limb. Smallest asymmetries were at the ankle, with larger asymmetry at the knee and hip; peak hip moment ASI but not RMSD was affected by running speed.

Table 1. Ankle (A), knee (K) and hip (H) kinetic asymmetry during running at preferred and non-preferred speeds

	PRS-20%			PRS			PRS+20%		
	A	**K**	**H**	**A**	**K**	**H**	**A**	**K**	**H**
ASI	7	13	16±	6	11	12	8	8	18
(%)	±4	±8	11	±5	±9	±12	±6	±9	±18
RMSD	7	11	12	7	13	12	8	10	11
(% peak)	±3	±4	±4	±4	±6	±5	±4	±5	±3

CONCLUSIONS

Observed support and joint moment asymmetry at both peak moment and across the entire stance phase was typically low, with negligible asymmetry in timing of peak moment. Differences in support moment (<8%) are smaller than those observed at the individual joints (A: <7%, K: <13%, H: 18%). There were small effects of running speed on the asymmetry of kinetics reported here, but further work is required to understand the potential effects these may have on potential running injury risk.

SEX DIFFERENCES IN HIP EXTENSOR MUSCLE ACTIVATION DURING THE LATE SWING PHASE OF RUNNING: IMPLICATIONS FOR ALTERED FRONTAL PLANE HIP KINEMATICS

[1] **Jia Liu**, [2]Hsiang-Ling Teng, [1]Chrostopher M Powers
[1]University of Southern California, Los Angeles, CA, USA
[2] California State University, Long Beach, CA, USA

INTRODUCTION

Excessive hip adduction during weight bearing tasks has been linked to various lower extremity injuries (eg. patellofemoral pain [1]). Compared to males, females have been reported to exhibit excessive hip adduction during both swing and stance phases of running [2]. Pilot data obtained in our lab has shown that during running, initial contact hip adduction is predictive of peak stance phase hip adduction.

It is possible that abnormal activation of the hip extensors during the late swing phase of running may contribute to excessive hip adduction at initial contact and therefore subsequent stance phase hip adduction. During the late swing phase, the hip extensor muscle group (gluteus maximus and hamstrings) is active to decelerate and prepare the lower limb for initial contact with the ground [3]. Over-activity of the hamstrings relative to the gluteus maximus could bias the hip towards adduction, as the gluteus maximus also functions as a hip abductor (upper fibers) whereas the hamstring group as a hip adductor anatomically.

Given the potential of the hip extensor muscle group to influence frontal plane kinematics, the purpose of this study was to evaluate sex differences in: 1) frontal plane hip kinematics during the late swing phase of running, and 2) the relative recruitment of the gluteus maximus and hamstring muscles during the same time period.

METHODS

Participants and Procedures: Seventeen recreational runners (rearfoot strikers, 18-45 yrs) participated in this study (9 men, 8 women). Participants were instructed to run at a controlled speed of 3.4 m/s along a 14-m runway. Three trials from each participant were collected. Surface electromyography (EMG) of the gluteus maximus, and medial/lateral hamstrings as well as kinematic data were obtained using a 10 camera motion analysis system (Qualisys Track Manager, version 2.10).

Data Analysis: Visual 3D (C-Motion, Rockville, MD) was used to calculate the peak hip adduction angles during the last third swing (i.e, late swing) phase. MATLAB (Mathworks Inc., MA, USA) was used to calculate the individual muscle's average EMG and activation ratio (i.e., gluteus maximus divided by the mean of medial and lateral hamstrings EMG) during the late swing phase. All EMG data were normalized to the maximum EMG obtained during maximum voluntary isometric contractions (MVICs).

Statistical Analysis: Independent sample t-tests were used to compare sex differences in the following variables calculated during the late swing phase of running: 1) peak hip adduction angles, 2) average gluteus maximus activity, 3) average hamstrings activity, and 4) gluteus maximus-hamstring ratio. All statistical analysis was performed using SPSS (Version 22; SPSS, Inc, Chicago, IL, USA), with significance level $p<0.05$.

RESULTS AND DISCUSSION

Kinematics:

The peak hip adduction joint angles during the late swing phase of running were significantly higher in females than males (12.8±0.6 vs 9.7± 1.4, p=0.032; Table 1).

Muscle Activation:

Female runners exhibited a significant lower gluteus maximus activation (9.6±1.2% vs 24.2±5.9%, p=0.018) and a significant lower gluteus maximus/hamstring activation ratio (0.3±0.0 vs 0.6±0.1, p=0.022) during the late swing phase of running, when compared to males (Table 1). No sex differences in activation of the medial and lateral hamstrings were observed. (Table 1).

Our results suggest that diminished gluteus maximus activation in females may bias the hip joint into greater hip adduction during the late swing phase of running. This finding is relevant as the position of the hip at initial contact is predictive of peak hip adduction during stance.

CONCLUSIONS

Compared to males, females demonstrated significant lower gluteus maximus activation during late swing phase of running, which may contribute to the observed greater hip adduction angles during the late swing phase of running.

EFFECT OF GAIT STRATEGIES ON THE KNEE AND ANKLE JOINT LOADS DURING STAIR DESCENT

INTRODUCTION

Gait is very essential for the independence in the activities of daily living. The researches related to the gait have been focused mainly on the level walking and running.

In case of running, the knee joint load increases as 3~4 times the body weight, which causes a great burden on the joint [1]. The strategy of initial contact was shown to affect joint load, i.e. the peak free-moment (rotational moment on the ground) was greater for the forefoot contact strategy (the forefoot contacts the ground first) as compared to the rear-foot contact strategy (the heel contacts the ground first). The increased free-moment subsequently burdens ankle and knee joints [2].

The most frequent locomotion pattern, secondary to the level walking and running, is the stair walking [3]. Approximately four times body weight was shown to be applied in the knee joint during stair descent [1]. However, there is little research on how to reduce the joint load during stair descent.

Therefore, this study aims to suggest gait strategies that can reduce the joint loads during stair descent, by investigating the net joint reaction force at the ankle and knee.

METHODS

Five young men participated in this study. Kinetic and kinematic data was acquired by eight 3D motion cameras (Vicon, Oxford, UK) with Plug-in-gait marker set and one force plate (Kistler, Winterthur, Switzerland) were used. The force plate was inserted in the second step of four-step-staircase.

Subjects were requested to descend stair on their own comfortable speeds but in three different strategies of initial contact, i.e., forefoot contact, midfoot contact, and heel contact. Three trials of each strategy were measured with rest inserted between trials to reduce the effect of fatigue. Joint reaction force and moment at the ankle and knee joints during stair descent were derived by the inverse solution of Nexus software (Vicon, UK).

RESULTS AND DISCUSSION

Fig. 1 shows peak joint reaction force in the normal direction at the ankle and knee during loading response. The normal direction was defined as the longitudinal axis of shank at the knee joint and the vertical axis (perpendicular to the heel-toe line of foot) at the ankle joint.

As expected, different strategies in initial contact resulted in different reaction force patterns in the loading response phase (0-16% of stance phase). Forefoot contact strategy showed monotonic force pattern at both joints. In contrast, midfoot and rearfoot strategies showed oscillating force patterns. Monotonicity of joint reaction force in forefoot contact may be associated with the power absorption maintained during the loading response phase at both joints.

Further investigations on the joint shear forces and joint moments are needed in the future.

QUANTIFICATION OF STRIDE-TO-STRIDE DEPENDENCY IN HUMAN GAIT

[1] **Peter C Raffalt** and [2]Jennifer M Yentes
[1]University of Copenhagen
[2]University of Nebraska Omaha
Corresponding author email: raffalt@sund.ku.dk

INTRODUCTION

The stride time pattern during continuous walking in healthy individuals has been shown to include stride-to-stride fluctuations exhibiting statistical persistence [1]. Thus, each stride depends on many previous strides with a stride-to-stride dependency that "*decay in a scale-free (fractal-like), power-law fashion"* [2]. The nonlinear methods detrended fluctuation analysis (DFA) and sample entropy (SaEn) have previously been applied to quantify the statistical persistence and predictability of gait patterns in different populations [1,2,3]. However, these methods do not return an outcome measure in a physiological or physical interpretable time scale.

Recently, entropic half-life (ENT½) was introduced as a novel measure that quantifies the time over which short-term temporal correlation in a time series deteriorate to an uncorrelated, random structure [4]. Applied to movement related variables, ENT½ could quantify how long time elapses before previous performed movements have substantially reduced their influence on future movements [5].

In the present study, we applied ENT½ to stride-to-stride time intervals recorded in healthy individuals during overground (OW) and treadmill walking (TW). In addition, we introduced an alternative method called statistical persistence decay (SPD) which evaluates how long successive strides are related to each other.

METHODS

Fourteen healthy subjects (7 males; 25.0 ± 4.2yr; 170.8 ± 11.9cm; 69.4 ± 16.9kg) completed two sessions of one hour OW and TW at self-selected walking speed. Stride time intervals were recorded using footswitches (Trigno™ 4-channel FSR Sensor, Delsys Inc., Natick, MA).

The stride time interval time series was reshaped 100 times by moving adjacent data points gradually further and further away in time with each reshaped time series. ENT½ is defined as the number of strides (reshaped time series) required to increase the normalized SaEn of the original time series to half the normalized SaEn of a time series of random permutation of the original time series (figure 1). SPD is the number of strides (reshaped time series) required to decrease the DFA scaling exponent below the 95% upper limit of the scaling exponents of 100 time series of random permutation of the original time series (figure 1).

Paired Student's t-tests (level of significance = 5%) were used to investigate statistical differences in ENT½ and SPD between walking conditions.

RESULTS AND DISCUSSION

There were no significant walking condition differences for ENT½ (OW: mean = 11.3 strides, median = 9 strides; TW: mean 14.6 strides, median = 8 strides) or for SPD (OW: mean = 51.4 strides, median = 64.5 strides; TW: mean 50.3 strides, median = 59.5 strides).

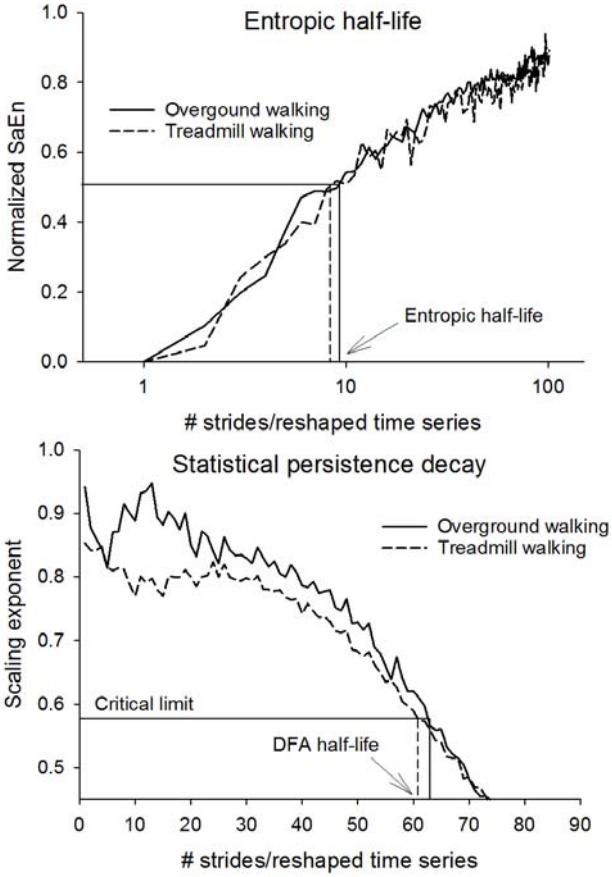

Figure 1: Representative results of ENT½ and SPD.

CONCLUSIONS

The present study quantified the stride-to-stride time dependency in healthy individuals on an interpretable scale. The number of strides required to reduce the influence of past strides on the present stride was quantified by ENT½ and SPD. While the predictability in stride-to-stride time intervals was halved after 11-15 strides during OW and TW, the statistical persistence in stride pattern was deteriorated to an uncorrelated noise after approximately 50 strides. ENT½ and SPD did not differ between walking conditions, suggesting that the applied motor control induced the same stride-to-stride time dependency during OW and TW.

LOCAL AND ORBITAL DYNAMIC STABILITY IN THE MUSCLE ACTIVITY DURING WALKING

[13] **Benio Kibushi**, [23]Shota Hagio and [1]Motoki Kouzaki

INTRODUCTION

The central nervous system can periodically control the muscle activity among various walking speeds, nevertheless control of muscle activity may be unstable as walking speeds get faster. However, the muscle activity changes nonlinearly when walking speeds are modulated. It is assumed that stability analysis in nonlinear system is useful to investigate inherent stability of the muscle activity. As a stability analysis in nonlinear system, local and orbital dynamic stability in kinematics during walking have been researched [1-4]. Local dynamic stability is calculated by the maximum Lyapunov exponent that quantifies how the dynamical system responses to small perturbation as a local divergence exponent [1]. Local dynamic instability connected with fall history [2], therefore local dynamic instability may indicate how an analyzed data includes risks of breakdown in walking motion. Orbital stability is calculated by the maximum Floquet multiplier that indicates the trend of the accumulated errors of each stride [3], in other words, maximum Floquet multiplier reflects periodicity of gait. We hypothesized that local and orbital stability in the muscle activity become unstable as walking speeds increase. Our purpose was to investigate how local and orbital stability in the muscle activity changes as walking speeds increase.

METHODS

Ten healthy men (23.3±0.9 years) walked on a treadmill at 14 various walking speeds (2.0-8.0 km/h and preferred walking speed) over 50 gait cycles. Surface electromyograms were recorded from 12 muscles in right lower limb and trunk. Three-dimensional position of 29 retro-reflective spherical markers were measured to calculate kinematic data. For the calculation of maximum Lyapunov exponents and Floquet multipliers, five dimensional time delayed coordinate systems were constructed [1, 2, 4]. A positive maximum Lyapunov exponent means that an analyzed data is unstable in terms of local dynamic stability. Maximum Floquet multipliers were calculated as eigenvalues of the Jacobian of the Poincare map [2, 3]. If maximum Floquet multiplier is less than 1, an analyzed data is stable in terms of orbital stability.

RESULTS AND DISCUSSION

All maximum Lyapunov exponents were positive, and maximum Lyapunov exponents increased as walking speeds got faster (Figure; top). It means that local dynamic instability of the muscle activity increased as walking speeds got faster. Increasing rate of maximum Lyapunov exponents in 5.0 ~ 8.0 km/h were larger than in 2.0 ~ 5.0 km/h. Because metabolic cost or joint power in fast walking is inefficient, it is suggested that walk to run transition is frequently observed around 7.0 km/h [5]. Our results indicated that not only metabolic cost but also local dynamic instability of the muscle activity might be factor for gait transition. We observed different increasing rate of maximum Lyapunov exponents among muscles. Rate of increase from 5.0 to 8.0 km/h in ankle planter flexors, rectus femoris and tensor fasciae latae were especially high. It has been reported that activation of rectus femoris during swing phase in walking was higher than running when treadmill speeds were over gait transition speeds [5]. High intensity of the muscle activity might relate to local dynamic instability. Contrary to maximum Lyapunov exponents, all maximum Floquet multipliers were < 1 (Figure; bottom), indicating that muscle activities were stable in terms of orbital stability even if walking speeds changed. It has been revealed that maximum Floquet multipliers in trunk motion were stable when walking speeds increased [4]. As well as orbital stability of trunk motion, the muscle activity might also be stable even if walking speeds increased. Periodicity of the muscle activity might be maintained even in fast walking.

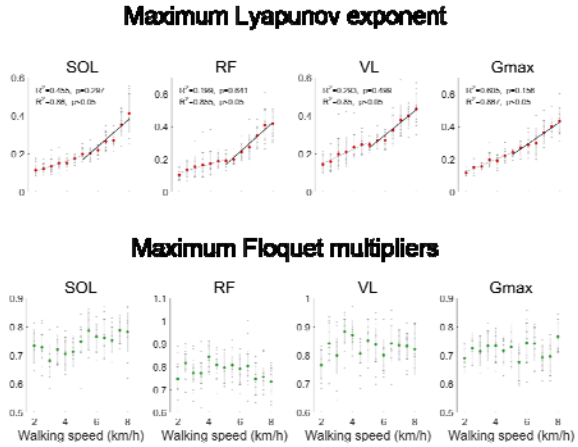

Figure 1: Maximum Lyapunov exponents and maximum Floquet multipliers in soleus (SOL), rectus femoris (RF), vastus lateralis (VL), and gluteus maximus (Gmax).

CONCLUSIONS

Local dynamic instability of the muscle activity increased as walking speeds got faster, whereas orbital stability was maintained. It suggests that orbital stability contribute to achieving fast walking that fall risks is high.

ASSESSING FACTORS RELATED TO INDIVIDUAL VARIABILITY OF THE NEGATIVE WORK OF THE KNEE JOINT DURING RUNNING

[1] **Satoru Hashizume**, [1] Hiroaki Hobara, [1] Yoshiyuki Kobayashi, [1] Akihiko Murai, [1] Mitsunori Tada, [1] Masaaki Mochimaru

INTRODUCTION

Runners are exposed to the risk of running-related injuries occurring on the lower extremities. A previous study reported that 20-79% of runners experience running-related injuries of the lower extremities [1].

Muscles around the knee joint are common regions of running-related injuries. Eccentric muscle contraction induces higher muscle damage compared with other muscle contraction types. The negative work of joint corresponds to associated eccentric muscle contraction [2]. The negative work of the knee joint, therefore, can be used to evaluate the potential risk of associated muscle injury.

It has been shown that running technique affected on kinetic and kinematic parameters [3]. Because running technique varies among individuals, the negative work and associated parameters of the knee joint may also vary among individuals. Clarifying the factors related to individual variability of the negative work of the knee joint may help to reduce the potential risk of injury occurring on muscles around the knee joint. The purpose of this study, therefore, was to examine the linear relationships between the negative work of the knee joint and the associated parameters.

METHODS

Fifteen young adult males without musculoskeletal injuries of the lower extremities (age: 26.5 ± 4.9 years old, body height 1.75 ± 0.04 m, body mass: 65.5 ± 7.4 kg) participated in this study. Retro-reflective markers were attached to right lower extremity. Subjects were asked to run on a 40 m straight runway at a speed of 3.0 ± 0.3 $m \cdot s^{-1}$. Three-dimensional coordinates of markers (200 Hz) and the ground reaction force (2000 Hz) were recorded using an optical motion capture system and force platforms, respectively.

The angular velocity of the knee joint was calculated by using the Cardan sequence. The inverse dynamics approach was used to calculate the moment of the knee joint. The power of the knee joint was calculated as the dot product of the moment and the corresponding angular velocity, and then the negative work of the knee joint flexion-extension movement was calculated as the time integral value of the negative power.

The multiple linear regression analysis was used to examine the relationships between the negative work of the knee joint and the associated parameters. The duration of the negative power, moment and angular velocity were assigned to the independent variables.

RESULTS AND DISCUSSION

The means and standard deviations (SDs) of the time-series power of the knee joint during the contact phase of running are represented in Figure 1. The negative work, moment, angular velocity and duration of the negative power were -38.8 ± 8.2 J, -70.0 ± 16.3 N·m, 3.32 ± 1.05 $rad \cdot s^{-1}$ and 113 ± 21 ms, respectively. As the result of the multiple linear regression analysis, the multiple correlation coefficient was 0.818 ($p < 0.01$). The standardized coefficients were -0.134 ($p = 0.732$), -1.103 ($p = 0.044$) and -1.080 ($p < 0.01$) for the moment, the angular velocity and the duration of the negative power, respectively.

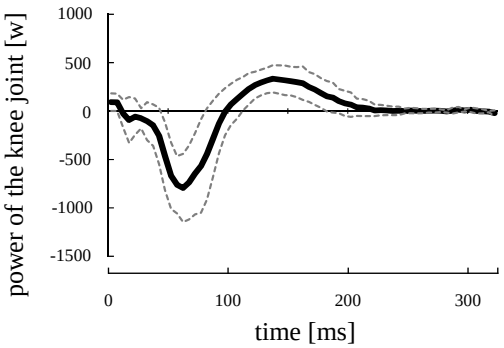

Figure 1: The time-series power of the knee joint during the contact phase of running. Solid and dotted lines represent mean value and SDs across all subjects, respectively.

The present results revealed that the individual variability of the negative work of the knee joint was not attributable to the individual variability of the moment but of the angular velocity and of the duration of the negative power. Both the angular velocity and the duration negatively correlated to the negative work. Decrease in the angular velocity and in the duration induced decrease in the angular displacement, and this resulted increase in the negative work. These suggest that runner can decrease in the potential risk of the injury occurring muscles around the knee joint by decrease in the angular velocity and in the duration.

CONCLUSIONS

This study examined the relationships between the negative work of the knee joint and the associated parameters by using the multiple linear regression analysis. The standardized coefficients were significant for the angular velocity and the duration of the negative power but not for the moment.

INTRODUCTION

Poor and static postures have been linked as a risk factor for obtaining back pain [1-3]. Back pain is a large financial burden on the suffering individual and on the economy with estimated direct and indirect annual costs amassing $1.02 billion and $8.15 billion respectively in Australia [4]. Wearable technology has become increasingly popular, with numerous devices available to give information on vital signs, monitoring of activity and diagnosis of various conditions [5-6]. There are currently several devices which focus on the improvement of the user's posture, including the ViMove (DorsaVi, Melbourne, Australia) and Lumo Lift (Lumo Bodytech Inc., Palo Alto, United States). These devices however are limited in either their price, methods of data collection, accuracy or information sent to the user.

The aim of the current study was to address some of these limitations of current posture tracking devices, by creating an inexpensive device capable of accurately measuring whole spine angular position and angular velocities.

METHODS

From a review of currently available sensors capable of measuring 3D rotations and velocities it was decided to create the device using inertial measurement units (IMUs). A SparkFun Razor 9DOF IMU (AU$115) was selected. To ensure the selected IMU was suitable for use in the device, its accuracy was compared to a number of other sensors on a Katana Robot 450 (Neuronics, Zurich, Switzerland). The other sensors consisted of an expensive IMU (AU$2900) (Lord MicroStrain 3DM-GX3-25, Williston, USA) and optical motion capture (OptiTrack Flex, NaturalPoint Inc., Corvallis, USA). The sensors were tested under six range of motion (ROM) conditions with variations in speed, axis of motion, and single- and coupled-axis motion. The sensors were also tested under random motion conditions, in which the Katana constantly changed speed and direction of motion for approximately 60 seconds.

The selected IMU was then used to implement a Spinal Motion Measurement device (SMM) which consists of three IMUs, two ADXL337 accelerometers and wireless, portable data acquisition capabilities, with a total cost of AU$560. The SMM was then used to track human posture and stance (standing and sitting) (Figure 1). Testing involved comparing the SparkFun Razor IMU in its ability to track posture and stance against a 12 camera (V8) VICON MX optical motion capture system using a marker-set to measure thoracic and lumbar motions [7] and extra markers on the lower limbs and hip. Six human participants (N = 3 male and 3 female) and 10 different movements, with variations in speed and direction, were used for this testing.

RESULTS AND DISCUSSION

Results from the Katana Robot 450 testing showed the SparkFun Razor IMU to be comparably accurate to other sensors during ROM testing at speeds ranging from 1-1.5 rad/s. At 1.5 rad/s, the root-mean-square errors (RMSE) for the orthogonal axes X, Y and Z (Up) were 4.39°, 0.67° and 4.73° respectively. At 1 rad/s, the typical self-selected speed of lumbar flexion [8], the RMSE value for the X-axis was reduced to 2.24° and during random motion testing the X, Y and Z axis RMSEs were 1.67°, 1.36° and 5.88° respectively. The results show the SparkFun Razor IMU to be accurate at measuring angular position, particularly around axes perpendicular to gravity and thus appropriate for the SMM.

Preliminary results of human testing (N = 1) using the SMM show it can measure the magnitude of flexion-extension with a RMSE of 2.00°. The SMM was also able to determine stance with a 100% success rate. The results show that the SMM device, which is substantially less expensive compared to other similar devices, is capable of accurately measuring spinal posture and determining stance.

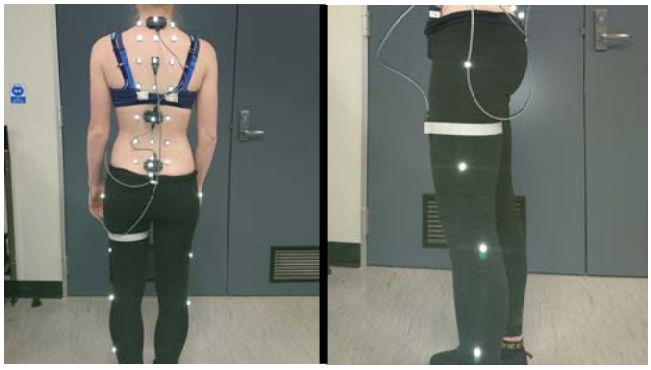

Figure 1: The Spinal Motion Measurement device (SMM) and marker set used for VICON data acquisition in testing.

CONCLUSIONS

The SMM has been shown to accurately measure the posture of the human spine and accurately predict the stance of the user. Due to its low cost and comprehensive data output capabilities, the SMM will have numerous implications for low-cost data acquisition of spinal motion, and posture and stance tracking of individuals.

FULL BODY KINEMATICS USING WEARABLE INERTIAL SENSROS

INTRODUCTION

The need to characterize human movement has consistently driven researchers to develop improved motion analysis systems. The primary measurement challenge is to design devices and algorithms that can accurately monitor movement regardless of the activity and testing location. Movement has typically been captured using optical, mechanical, or inertial sensing instruments. Although each system offers its own advantages, they all have unique limitations that may distract clinicians from their core responsibilities when deployed in a clinical environment. The current standard for measuring movement in a clinical environment involves instruments that have varying degrees of accuracy and complexity and may be administered differently depending on the user's biomechanical expertise.

Inertial sensors have been used to overcome the limitations of other motion systems. A typical inertial measurement unit (IMU) includes accelerometers to measure the translational acceleration in addition to gravity, and gyroscopes to measure angular velocities. We aim to develop an inertial system to provide joint kinematics similar to those provided by optical motion capture systems. The inertial system is more time efficient and easier to use in the clinic without the need for specialized equipment and personnel.

METHODS

Our inertial system uses 15 wearable IMUs attached to the head, sternum, sacrum, and lateral surface of the upper arms, forearms, hands, thighs, lower legs, and superior surface of the feet. The IMUs use wireless synchronization, which is critical for measuring joint kinematics and coordination. We developed a tracking algorithm to estimate joint angles during gait. The algorithm tracks 3D orientation of the head, trunk, pelvis, and upper and lower limbs. The algorithm provides estimates of the head and shoulder, elbow, wrist, hip, knee and ankle joint angles bilaterally. It also provides temporal measures of gait to assess the critical gait events that occur during a typical walking cycle. These events occur during specific phases of the gait cycle, and are considered an essential requirement for producing a normal walking pattern. Examples include a heel initial contact, existence of controlled plantar ankle flexion and knee flexion during loading response, ankle dorsiflexion during mid-stance, hip extension with a trailing limb posture during terminal stance, and rapid hip flexion with synchronous ankle plantar flexion during pre-swing.

We used an industry standard motion capture system as a reference to evaluate the performance of our inertial tracking algorithm. The validation study was conducted at Movement Disorders Laboratory at Oregon Health and Science University, which is equipped with a 12-camera motion capture system. We compared the inertial metrics with those obtained from the reference system in ten healthy adults.

RESULTS AND DISCUSSION

With IMUs and reflective markers attached to the relevant segments of the body, each subject walked at 2 miles/hour on a treadmill for 60 seconds. The inertial and optical data was processed after data collection to calculate the head and upper and lower limb joint angles. We use the mean absolute error to compare the angles from both systems. Table 1 shows the comparison results for one subject.

Joint	Flex/Ext		Add/Abd		I/E Rot	
	μ	σ	μ	σ	μ	σ
Hip	3.70	1.12	3.01	2.43	4.66	0.89
Knee	1.66	0.93	1.87	1.61	2.03	2.70
Ankle	4.27	1.12	6.03	4.14	3.82	3.85
Shoulder	1.51	1.08	2.97	1.87	4.42	2.60
Elbow	4.90	1.40	2.78	1.79	6.96	4.63
Wrist	1.52	0.94	2.43	1.92	3.58	2.10
Head	2.45	1.58	7.06	4.75	2.27	1.47
μ (σ)	2.86 (1.28)		3.74 (3.12)		3.96 (3.10)	

Table 1: Mean absolute error (MAE) between joint angles from the inertial and optical systems.

Despite the good agreement, we believe some of the estimation error might be attributed to misalignment of the IMU frame relative to the anatomical axes of rotation. When the IMUs are attached to different body segments, they are not perfectly aligned with the segment main axes of rotation. Therefore, we asked the study participants to remain stationary in a neutral pose for 3 seconds at the beginning of the recording to estimate the misalignment. This information is then used to realign the sensors data for analysis using matrix rotation before calculating the joint angles. While this addresses misalignment of the sensors relative to the anatomical axes, it assumes the participant can both remain stationary and adopt a truly neutral initial pose. Often individuals prevent them from standing in this neutral pose, and we hypothesize that this contributed to the larger errors seen in this group. We are developing other analytical and procedural techniques to address this potential issue.

CONCLUSIONS

Our findings suggest that it is feasible to use IMUs to measure accurately measure body kinematics. The system is portable and unobtrusive, and requires no lengthy setup or calibration; all of which makes the system well suited for use outside of a laboratory.

INTRODUCTION

Body segment parameters (BSPs) such as mass and moment of inertia are required for biomechanical analyses and simulations. While subject-specific BSP models using geometric methods of varying complexity are available, most studies use regression-based approaches which require far fewer subject measurements. Regression approaches can be appropriate for certain populations and certain activities and tasks, but do not provide reliable data in general.

The aim of this project is to develop a low-cost and convenient method for calculating subject-specific body segment parameters. In this work, Microsoft Kinect v2 sensors were used to obtain full-body 3D scans and volume-based approaches were used to calculate the masses of each segment. Data was also extracted for use with the Hatze [1] geometric model, and for comparisons against the regression models of Dempster [5] and Zatsiorski [6].

METHODS

Four Microsoft Kinect v2 sensors were arranged in a 4.5m × 4.5m square configuration, facing inwards, and were connected to a custom PC via four PCIe USB cards. The software library *libfreenect2* [2] was used to simultaneously interface with the Kinect sensors. The depth images from the Kinects were calibrated using the internal calibration factors to generate a point cloud, and a coordinate system orientation process was performed by placing three basketballs in the viewing volume to use as a global reference frame.

Participants (N=16) posed motionless with arms raised for approximately seven seconds, during which time three images were taken and averaged to reduce sensor noise. The merged and averaged point clouds from each Kinect were denoised, isolated from the ground and any other stray points, then meshed into a single volume using an Alpha Shape algorithm. The body volume was divided into 15 segments on the basis of virtual palpation of 28 standard anatomical reference points.

The mass of each segment was calculated from its volume using an assumption of constant density [3]. Each segment was virtually palpated to obtain anthropometric measures for calculating segment masses with Hatze's method [4]. Results from both approaches were compared against participant total body mass measured on scales. Body volume was compared to that determined by a commercial laser-based 3D body scanner. Two common regression methods using mass [5] and mass & height [6] were used for comparison of calculated segment masses.

RESULTS AND DISCUSSION

For a single participant, a volume difference of –4.5% was measured when comparing the Kinect system (75.8L) to the laser-based scanner (79.4L). For the Kinect system, a single participant scanned in four separate sessions resulted in an average 5.7% relative error to the mean, with larger errors resulting when point clouds could not be accurately merged.

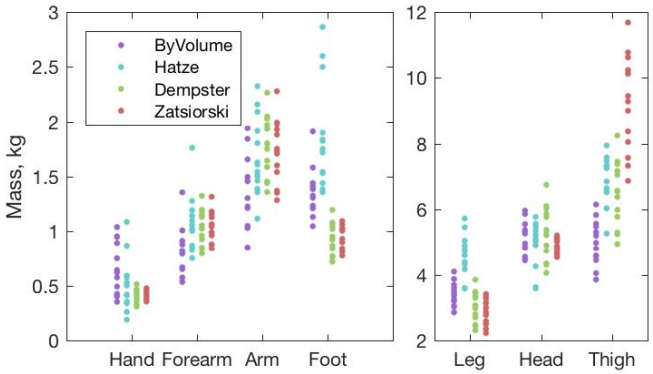

Figure 1: Left-limb segment masses calculated by scanned volume, scanned geometric, and regression methods. Right-limb results show similar trends.

Data from three subjects were omitted due to technical difficulties. The method of calculating segment mass using scanned volume with constant density predicted total participant mass with mean error –1.0% and RMS error 2.9%. The Hatze approach over-predicted total mass with mean error 19.1%.

Individual segment masses varied considerably (Figure 1). Between participants, the scan methods had similar variation for each segment as did the regression models. The largest relative variation in mass occurred for segments with the smallest volume. The foot in particular was over-estimated in comparison with the regression models. The arm, forearm, and head had the most consistent results between all methods.

CONCLUSIONS

A low-cost 3D body scanning system was developed using off-the-shelf Microsoft Kinect v2 sensors. The ability of this system to estimate body segment mass has been demonstrated using two algorithms; the volume-based method predicted total participant mass with less than 3.0% error.

INTRODUCTION

Kinect for Windows v2 (Microsoft, Redmond, US) is an RGB-D camera that features a markerless human pose estimation algorithm. Markerless tracking has generated considerable interest in the biomechanics community due to its low-cost and portability and has had applications in gait analysis, balance and postural assessment, and rehabilitation training. Several studies have assessed agreement between Kinect v2 markerless algorithm and marker-based optical motion capture systems. Average errors in joint centre coordinates can be as high as 207 mm (SD = 71 mm) during upright standing posture [1] and limits of agreement (LOA) equal to 28°, 46° are reported for peak knee flexion angle at a self-selected walking speed [2]. Shortcomings on the capacity of Kinect to provide accurate tracking have been associated with temporary self-occlusions of body parts, participant's orientation and distance from Kinect, noise in depth data, subject's body shape and limitations in the pose estimation algorithm [3]. Motion speed might also play a role, due to the low capture frame rate of Kinect v2 (30 fps) and to local alterations in depth measurements caused by moving objects [4].

To enhance the accuracy of Kinect v2 for motion tracking, an alternative tracking method (denoted as *KinEdge*) was developed, based on custom-made coloured markers and computer vision techniques. The aim of this study was to evaluate the accuracy of gait-related kinematic measurements obtained from this novel Kinect v2-based methodology.

METHODS

A novel real-time algorithm was developed to track spherical coloured markers (Ø38 mm) attached on the subject's body. Multiple data streams (colour, infrared and depth) from Kinect v2 were used as input and processed using OpenCV library and Kinect SDK 2.0.

A 12-camera Vicon (Oxford, UK) motion capture system sampling at 120 Hz was used as gold standard. Symmetric three-marker brackets were designed and 3D-printed. Each bracket held 2 reflective markers (Ø9 mm) on its extremities and a coloured marker in the middle. The centres of the three markers were coincident with a straight line. In this study, the agreement between the centre of the coloured marker (tracked by KinEdge) and the midpoint of the 2 reflective markers (tracked by Vicon) was assessed.

Twenty healthy participants were recruited. Three brackets were attached to the left iliac crest (*hip*), lateral epicondyle of the left femur (*knee*) and lateral left malleolus (*ankle*). Kinect v2 was positioned on the side of a treadmill, at 1.5 m distance from its midline. The following treadmill speeds were adopted: 0.83 m/s (slow gait), 1.31 m/s (fast gait), 2 m/s (slow run) and 2.5 m/s (fast run). Marker data were simultaneously acquired using Kinect v2 and Vicon over a 15 s period.

Vicon marker coordinates were transformed to Kinect v2 reference frame (X = posteroanterior, Y = superior, Z = mediolateral). Vicon and KinEdge data were synchronized using a custom iterative algorithm based on cross-covariance and resampled at 30 fps, to match Kinect v2 original framerate. A Bland-Altman analysis of agreement was performed for each marker coordinate and for the knee flexion angle at all treadmill speeds.

RESULTS AND DISCUSSION

The LOA between KinEdge and Vicon for marker coordinates ranged from 2.2, 9.6 mm for hip X during slow walking up to -20.3, 39.9 mm for ankle Z during fast running. In most cases, however, the LOA were narrower than -10, 10 mm. The hip marker exhibited almost constant LOA across all axes and for all treadmill speeds. In contrast, the ankle marker displayed a negative relationship between agreement and treadmill speed. This relationship was less evident for X and Y coordinates, with LOA up to -6.3, 9.2 and -15.2, 7.4 mm respectively during fast running, and stronger for Z. The knee marker showed an intermediate trend compared to the other two markers, with LOA up to -11.7, 9.1 mm along Z during fast running. LOA for knee flexion angle were within -1.4° to 1.7° for ambulation at all speeds (Figure 1).

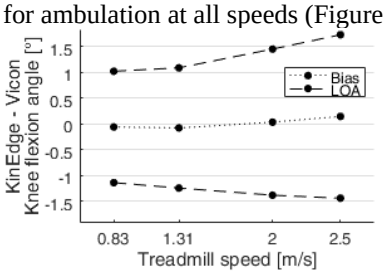

Figure 1: LOA vs. treadmill speed for the knee flexion angle.

CONCLUSIONS

A novel marker-based tracking method for the low-cost Kinect v2 system was introduced. Good agreement with a conventional marker-based motion capture system over a range of gait speeds demonstrates that the proposed hardware and software may represent a practical motion analysis alternative for research and clinical settings.

EXPLORING SEGMENTATION AND FEATURE EXTRACTION METHODS FOR CLASSIFYING RUNNING CONDITIONS USING 3D ACCELEROMETERS

[1]**Lauren Benson**, [1]Christian Clermont, [1,3]Sean Osis, [1]Dylan Kobsar and [1,2,3]Reed Ferber

INTRODUCTION

Accelerometers have been used to classify gait patterns during running [1], but classification accuracy depends on signal segmentation and feature extraction [2]. Segmenting running data into strides relies on identifying heel-strike events [2], and it has been shown that a fixed-size sliding window can be used for segmentation [3]. For each segment of data, either the entire waveform can be processed or discrete variables can be extracted from the accelerometer signal, each of which are then used to classify running conditions. While some stride-dependent features may assist classification, the stride-based segmentation may not be necessary for identifying running conditions. Therefore, the purpose of this study was to examine how different segmentation and feature extraction methods influence the classification accuracy of different running conditions.

METHODS

Twenty-nine runners (13 F, 16 M; 31.3 (11.5) yr; 1.72 (0.09) m; 68.1 (10.1) kg) were outfitted with a tri-axial accelerometer (Shimmer3 GSR+® ± 8g, Shimmer Inc., Dublin, IE), placed on the back near the center of mass. After a warmup on a level treadmill (Bertec, Columbus, OH, USA), participants ran for one minute under each of the following four randomized conditions: preferred speed, 25% faster than preferred, 25% slower than preferred, and preferred speed with a neoprene brace (McDavid Level 1 Elastic Knee Sleeve, Minnetoka, MN) over their right knee.

For both the speed (fast vs. slow) and brace (preferred vs. brace) conditions, 12 sets of features were extracted. For two feature sets, the accelerometer signal was segmented into strides, and normalized to 202 data points. The first set of features included all data points of each axis of the accelerometer waveform. The second set of features included 154 discrete variables extracted from the time and frequency domain of the accelerometer signal, including measures of magnitude and variability, frequency content, association between the axes, and stride-based variables [1,4-6]. For the remaining 10 feature sets, the accelerometer signal was segmented into windows of length 0.25 s, 0.5 s, 0.75 s, 1 s, or 1.5 s, each with 0% or 50% overlap [2]. The features extracted for each window were 114 of the same discrete variables from the second stride-based feature set, excluding 40 features that specifically relied on a stride segment. A feature selection algorithm reduced the dimensionality of each set of features. Each participant's data were classified separately for speed and brace using linear discriminant analysis and 10-fold cross validation. The classification accuracy was averaged across all participants for each feature set. For each classification, differences in accuracy across feature sets were determined using a repeated-measures ANOVA, with significance at $p<0.05$. Follow up t-tests compared the accuracy between the two stride feature sets and between the best stride feature set and the best window feature set.

RESULTS AND DISCUSSION

There was a significant difference in classification accuracy across feature sets for both the speed and brace classifications ($p<0.05$). The mean classification accuracy using the entire stride waveform was 62% for speed and 61% for brace, while performance was 90% for speed and 79% for brace using discrete variables selected from each stride. The best performance from the window feature sets was 1.5 s windows with 50% overlap, resulting in 90% classification accuracy for speed and 80% accuracy for brace (Figure 1). For stride-based segmentation, feature selection using discrete variables resulted in significantly better accuracy than using the entire waveform for both speed and brace classifications ($p<0.001$). However, no significant differences were found between stride-based discrete variables and segmentation using 1.5-s windows with 50% overlap.

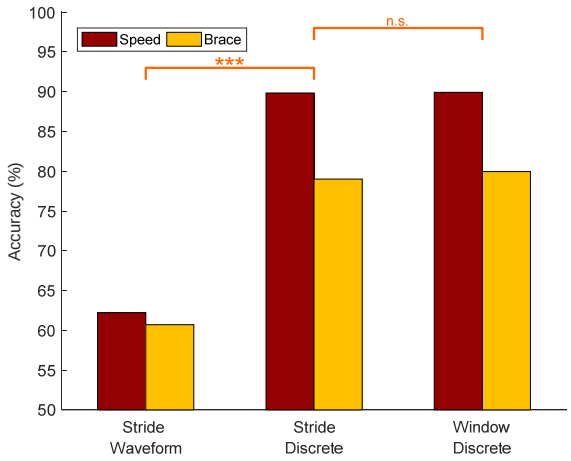

Figure 1: Classification accuracy for stride and window feature sets. (***$p<0.001$; n.s. = not significantly different)

CONCLUSIONS

Selecting appropriate features from accelerometer data is crucial for classification of running conditions. However, the segmentation method is less important, suggesting it may be possible to eliminate the methods involved with identifying strides and stride-related variables when classifying both speed and brace conditions.

CHOOSING BIOMECHANICAL VARIABLES FOR ASSESSING ROBOTIC LOWER LIMB EXOSKELETON PERFORMANCE

[1] **Daniel P Ferris**
[1]University of Florida
Corresponding author email: dferris@bme.ufl.edu

INTRODUCTION

Advances in robotic actuators, sensors, batteries, and computer processors have led to a proliferation of powered exoskeletons for assisting human movement [1]. These devices are often developed in academic research labs and for-profit companies aiming to create a commercially successful project. The exoskeletons are typically intended for one of three purposes: human performance augmentation, therapeutic rehabilitation, or assistive technology for individuals with disabilities. A search of the internet or news media will easily reveal dozens of devices featured in press releases or pitch videos for investors.

Despite the large number of robotic exoskeletons in mass media, there are relatively few experimental studies published in scientific journals evaluating users' performance with robotic exoskeletons. One of the reasons for a lack of robotic exoskeleton evaluation studies in the literature is a lack of biomechanical expertise and equipment within the engineering research labs designing and building the devices. Typically, engineers designing the devices are specialists in mechatronics or computer science, not biomechanics. Even when team members have sufficient biomechanics backgrounds and equipment, there is considerable debate and disagreement about what measurement parameters are the most important in assessing robotic exoskeleton performance. Over the last 18 years, my laboratory and I have conducted dozens of studies on humans using robotic exoskeletons. The results from these studies highlight the complexity of choosing appropriate biomechanical variables for exoskeleton assessment.

METHODS

We built and tested numerous robotic exoskeletons for assisting human locomotion. The devices include ankle, knee, hip, and whole leg robotic assistance. Actuators for the devices included artificial pneumatic muscles, pneumatic cylinders, or electromechanical motors. We studied neurologically intact healthy young subjects and individuals with incomplete spinal cord injury. Healthy subjects walked and ran over a range of speeds with different exoskeletons. In some studies, we tested multiple controllers on the same hardware and subjects to determine how the choice of exoskeleton controllers influenced the user's performance. The controllers included myoelectric control, feedforward handheld button control, footswitch control, and intrinsic dynamics state machine control. The amount of training varied depending on the study, from no training in some studies to multiple days in other studies. The biomechanical variables that we measured included kinematics, ground reaction forces, joint inverse dynamics, electromyography, and metabolic energy expenditure. Other physiological variables that we measured include heart rate, electrodermal activity, ratings of perceived exertion, and subjective preferences.

RESULTS AND DISCUSSION

Figure 1 shows an example of biomechanical experiments on a subject walking with multiple hip exoskeleton controllers. In this particular study, subjects walked with the hip exoskeleton under proportional myoelectric control and under intrinsic dynamics state machine control.

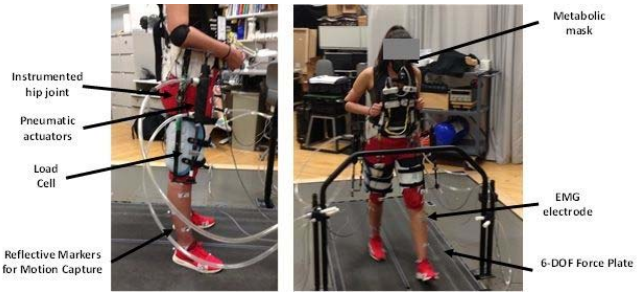

Figure 1: Example of testing of a young healthy subject walking with a pneumatically-powered, robotic hip exoskeleton.

The energetic cost of transport was generally the most robust parameter at identifying when a robotic exoskeleton was providing performance benefits during walking or running. However, there were instances where electromyography provided unique insight into changes to localized muscle recruitment that went against the trend in energetic cost of transport. For example, running with an elastic whole leg exoskeleton was able to reduce quadriceps muscle activity during running compared to running without the exoskeleton, but the energetic cost of transport increased by ~50-60% due to added recruitment of other muscle groups [2]. Studies using a robotic hip exoskeleton (Figure 1) also found that the subjects' subjective preferences for type of controller and type of torque assistance do not always concur with the conditions of lowest energetic cost of transport. Human subjects prioritize multiple variables related to their movement patterns when using a robotic exoskeleton.

CONCLUSION

Biomechanists evaluating the performance of a robotic exoskeleton assisting human locomotion need to be careful in choosing biomechanical variables that reflect the intended purpose of the exoskeleton assistance.

EFFECT OF ELASTIC ANKLE EXOSKELETON ASSISTANCE ON SOLEUS MUSCLE DYNAMICS DURING WALKING

Richard W. Nuckols, Gregory S. Sawicki
Joint Department of Biomedical Engineering at North Carolina State University and University of North Carolina - Chapel Hill
Corresponding author email: rwnuckol@ncsu.edu

INTRODUCTION

Unpowered exoskeletons that place intermediate stiffness springs in parallel with the human plantarflexors can reduce the metabolic demand of walking [1]. Exoskeleton stiffness above and below this 'optimal' value results in increased metabolic cost. The physiological mechanisms underlying this U-shaped trend are not completely understood. Proposed mechanisms include compensation at proximal joints, increased co-contraction around the ankle, and unfavorable muscle fascicle contractile conditions (*i.e.*, force-length (FL) or force velocity (FV) operating point) [1].

Research in our lab has begun to address changes in muscle fascicle dynamics due to exoskeleton assistance and the relationship to metabolic cost. In hopping with a spring-loaded ankle exoskeleton, we observed large reductions in metabolic cost, but no difference in soleus muscle mechanical power output. Exoskeletons reduced biological muscle force requirements but also increased fascicle excursion leaving muscle workload unchanged [2]. Our computer models indicate that this altered fascicle behavior may extend to walking as well, where stiff exoskeletons lead to decreased force but increased excursions in muscle fascicles [3], conditions that would exact a penalty due to the increased metabolic cost of rapid muscle shortening. The purpose of the current study is to make direct measurements of ankle plantarflexor muscle dynamics during walking elastic exoskeleton assistance and relate these findings to changes in joint and whole body mechanics and metabolic energetics. We hypothesize that the stiffest ankle exoskeletons alter muscle FL and FV contractile dynamics, and offset the benefits of decreased fascicle force, leading to suboptimal improvements in metabolic cost.

METHODS

We used an exoskeleton emulator to apply a range of ankle exoskeleton rotational stiffnesses to the user. The emulator provided torque from benchtop motors to the ankle exoskeleton through a Bowden cable transmission. We tested five exoskeleton stiffnesses (0, 50, 100, 150, 250 Nm/rad) applied across 3 walking speeds (1.25, 1.5, 1.75 m/s). Following an initial training day where subjects walked for 95 minutes, mechanics data were collected for each condition. Inverse dynamics analysis was performed by combining high speed motion capture (VICON) and GRFs from an instrumented treadmill (BERTEC). B-mode ultrasound images of soleus fascicle length changes were captured using a low profile ultrasound system (TELEMED) and were digitized to extract length change patterns [4]. Data have been collected on 9 subjects and full data analysis performed for one subject at the 1.25 m/s walking speed.

RESULTS AND DISCUSSION

Exoskeleton torque increased with exoskeleton stiffness and resulted in a concomitant decrease in biological moment and muscle-tendon unit force (Fig. 1, middle two panels). Viewed independently, the decrease in biological muscle force would have positive whole body metabolic benefit. However, our initial data suggest that isometric fascicle dynamics during mid-stance, typically associated with large stretch in the Achilles' tendon (*i.e.*, 'catapult mechanism), are disrupted when high stiffness exoskeleton assistance is applied. In the stiffest condition, during mid-stance, we found a 10% increase in avg. fascicle length (not shown) and ~x4 higher fascicle shortening velocity (Fig. 1, bottom, red vs. purple). These altered fascicle dynamics likely result in less economical force development (*i.e.*, reduced force per unit activation) and act to counter the metabolic benefit derived from reduced force requirements.

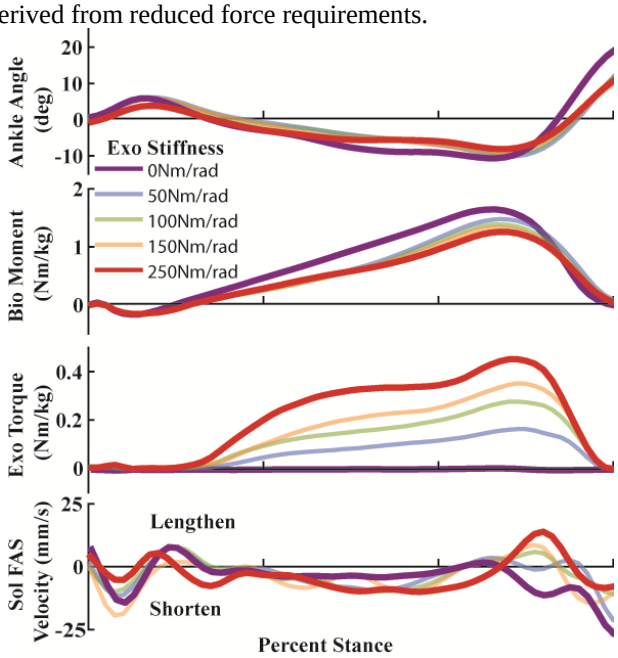

Figure 1: Ankle joint and soleus muscle fascicle dynamics resulting from application of bilateral elastic ankle exoskeleton assistance during walking at 1.25 m/s.

CONCLUSIONS

Design of wearable robots intended to reduce metabolic effort need to account for unintended changes in muscle contractile dynamics of the user. This is especially true for devices intended to assist joints with compliant muscle-tendon architecture, where the muscle fascicle length changes are inherently decoupled from joint kinematics.

ESTABLISHING NEUROMECHANICAL MAN-MACHINE INTERFACES FOR WEARABLE ASSISTIVE TECHNOLOGIES

INTRODUCTION

Human movement emerges from the coordinated interaction between the neuromuscular and the musculoskeletal systems [1]. Observations of movement neural function alone cannot explain how neural structures (i.e. motor neurons) elicit mechanical forces [1]. Similarly, observations of movement mechanical function alone cannot explain mechanical variables tightly connected to muscle co-excitation such as joint stiffness or compressive forces, which are central in the execution of movements [2]. A possible way to address this problem is given by neuro-mechanical modelling [1,2]. In this work we show how this methodology can be used to record muscle high-density electromyograms (HD-EMGs), extract underlying motor unit dynamics from noisy and high-interference recordings (i.e. via blind-source separation [3]), and reconstruct the non-linear transformations that lead to production of musculoskeletal mechanical forces. Furthermore, we present and discuss how this procedure can be used to establish intuitive real-time human-machine interfaces for controlling both upper limb and lower limb assistive technologies.

METHODS

The University Medical Center Göttingen Ethical Committee approved all experimental procedures. Four male intact-bodied participants and one transhumeral amputee who underwent the targeted muscle reinnervation procedure [4] volunteered after signing informed content forms. *Intact-bodied subjects:* Participant performed a series of isometric ankle plantar-dorsi flexion tasks that tracked monitor-displayed ankle joint moments spanning a range of plantar-flexion and dorsi-flexion maximal voluntary contraction percentages, i.e. 20%-90%MVC. HD-EMGs were recorded from ankle muscles synchronously to ankle joint angular moments and position dynamometer readings. *Amputee testing:* HD-EMGs were recorded using electrode grids located in correspondence of the residual upper arm frontal, lateral, and dorsal compartments to cover the targeted reinnervations. Data were recorded during dynamic trials involving mirrored bi-lateral motions that simultaneously articulated elbow flexion, forearm pronation, and wrist flexion, both in the intact and missing limb [3].

HD-EMGs were decomposed into the constituent motor unit discharges using the blind source separation algorithm based on Convolution Kernel Compensation method [3]. Motion data recorded during the static poses were used to build a personalized model of the musculoskeletal geometry that matched each individual's anthropometry via linear scaling in OpenSim [5]. The subject-specific geometry model was then used as part of an open-loop neural data-driven musculoskeletal modeling formulation [1,2].

RESULTS AND DISCUSSION

Figure 1 shows the process of neuro-mechanical transformation during which discrete spike trains are converted into continuous fiber activations and subsequently translated into mechanical tendon force. Figure 1 also shows how neurally controlled muscle-tendon forces, computed across all muscle-tendon units in the model, enable the blinded reconstruction of resulting net joint moments in intact limbs as well as in the amputee's phantom limb with substantial accuracy during validation trials. Squared Pearson product moment correlation coefficient (R^2) and the normalized root mean squared difference (RMSD) displayed favorable values across all joints and tasks for both intact-bodied ($R^2 = 0.96 \pm 0.03$, RMSD = 0.3 ± 0.02) and amputee ($R^2 = 0.8 \pm 0.2$, RMSD = 0.4 ± 0.1).

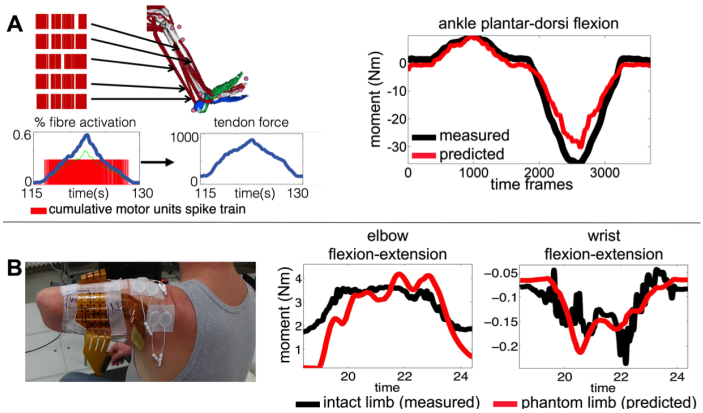

Figure 1: **A:** (left) Subject-specific musculoskeletal model with input cumulative spike trains (CSTs) used for muscle neural control. CST-based reconstruction of continuous whole-muscle activation and non-linear force transfer on the tendon. (right) Measured and predicted joint moments. **B:** Joint moments predicted in the missing limb are depicted together with those experimentally measured from the intact limb during a bi-lateral mirror task involving simultaneous elbow flexion, forearm pronation and wrist flexion.

CONCLUSIONS

This work proposes a clinically viable technique for interfacing with the human nervous system and for the concurrent real-time modelling of the resulting musculoskeletal mechanical function. This will enable understanding how neurorehabilitation technologies interact with the user. Moreover it will open new avenues for developing biologically inspired assistive technologies that can operate as a natural extension the own body and restore physiological neuromusculoskeletal function in impaired individuals.

EMULATING NEUROMECHANICAL LIMB PROPERTIES IN AN EXOSKELETON FOR SCI SUBJECTS

INTRODUCTION

Current exoskeletons replay pre-programmed trajectories at the actuated joints. To allow spinal cord injury (SCI) subjects to walk again, ultimately without additional support aids, we aim to emulate the neuro-mechanics of the limbs in a modular torque controlled wearable exoskeleton.

We employed a biologically inspired neuromuscular controller (NMC), which was based on the muscle-reflex model of Geyer et al [1]. This model encodes principles of legged mechanics through several local reflex loops that activate depending on leg-ground contact state. In simulations, the NMC resulted in steady-state human-like walking, reproducing human walking dynamics and leg kinematics. The controller also tolerated ground disturbances and adapted to slopes without parameter interventions. While the NMC has been implemented in a powered ankle prosthesis and shown to normalize gait for transtibial amputee subjects [2], these controllers have not yet been implemented in multi-dof devices that support locomotion.

Our aim is two-fold. First, we further validate and refine the NMC in the context of force perturbations, and second, we determine its efficacy for the control of wearable exoskeletons, in particular those that allow SCI subjects to walk again.

METHODS

To further validate the NCM, we simulated force perturbations of various magnitudes and directions, applied at the waist of the walking model. We compared the simulation data with recently collected kinematic and kinetic data of perturbed human gait [3].

To investigate the applicability of the NMC in exoskeleton control we implemented it in the control framework of the haptic gait trainer LOPES2 [4] of the University of Twente. Six SCI subjects (4 complete, 2 incomplete) were included in a walking experiment to evaluate the NCM

RESULTS AND DISCUSSION

In response to perturbations during walking, humans adjust the location and timing of foot placement after medio-lateral perturbations and the timing of foot-placement after anterior-posterior perturbations [3]. After perturbations modulations in muscle activity and joint torques are observed, which are dependent on the direction of the perturbations and scale with perturbations amplitude. However, responses of the NMC model to similar perturbations do not correspond well with human data. For medio-lateral perturbations no adjustment of timing was observed in the model. For anterior-posterior perturbations no counteracting torque in the ankle was observed, instead the model adjusts step-length after perturbation.

Without any major modifications, the NMC was successfully implemented in the LOPES 2 [5]. With only tuning controller gains (e.g. scaling torque assistance) All SCI subjects were able to walk in the LOPES with NMC at different speeds, although considerable body weight support was given. Knee and hip kinematics were close to normal (Fig. 1).

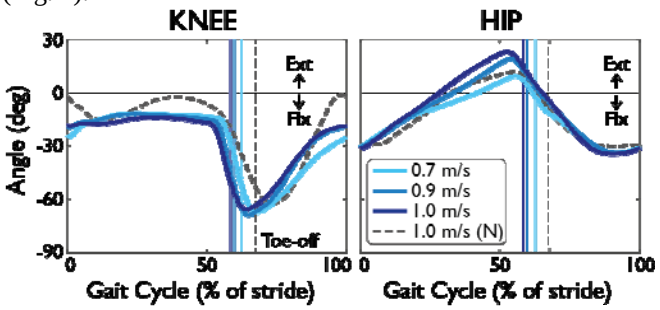

Figure 1: Knee and hip joint angles from a complete SCI subject walking in Lopes with NMC at various speeds. For comparison, the dashed grey is a healthy subject (not in Lopes) from slow walking data.

CONCLUSIONS

The NMC model is robust to mechanical perturbations, but reactive responses are different from those observed in humans. Although the movements are not pre-programmed a NMC controlled haptic gait trainer result in natural leg movements of SCI subjects walking in the gait trainer.

GAIT AND MUSCLE ACTIVITY DURING CLINICAL INTERVENTION USING ROBOT SUIT HAL (HYBRID ASSISTIVE LIMB) IN A PATIENT WITH SEVERE SPINAL CORD DISORDER

[1] **Hideki Kadone**, [1]Shigeki Kubota, [2]Yukiyo Shimizu, [1]Tetsuya Abe, [1]Aiki Marsushima, [2]Tomoyuki Ueno, [1]Yasushi Hada and [1]Masashi Yamazaki

INTRODUCTION

There are several recent reports on functional improvement after clinical intervention for gait improvement using a wearable exoskeleton type robot suit HAL (Hybrid Assistive Limb, Cyberdyne, Japan.) in patients with gait impairment after spinal cord disorders [1,2,3,4]. HAL assists motion of the bilateral hip and knee joints during walking in accordance with voluntary joint motion intension of the user. It actuates the electric motors embedded in the hips and knees of its exoskeleton in real-time amplifying bio-electric activation of the relevant muscles which are detected using surface electrodes attached on the thighs. In these studies, it is discussed that the voluntary motion assist of the robot is effective in enhancing the improvement of lower limbs motor function, contributing to improvement of walking ability.

However, the movement-physiological or biomechanical detail behind the functional improvement by the intervention using the robot has not been discussed enough as far as we know. In the cited studies, the improvements are evaluated by clinical measures comparing the state of before starting and after finishing the entire robot assisted intervention. As well in cases without controls, patients may receive conventional physical therapy in parallel with the robot assisted treatment, making it difficult to differentiate the effect of the treatment itself from the other treatments. In this study, gait and muscle activity during walking in intervention using the robot are recorded and analyzed in a patient with gait impairment after severe spinal cord disorder.

METHODS

The participant was a 64 years old man who showed severe sensorimotor dysfunction in the lower limbs, diagnosed as compressive myelopathy after cervico-thoracic ossification of posterior longitudinal ligament (OPLL).

HAL intervention was started in acute phase, 43 days after a decompressive surgery. The intervention included 2 sessions per week, lasting for 5 weeks, therefore 10 sessions in total. In all sessions, gait and lower limbs muscle activity during walking were recorded using a motion capture system (VICON MX, UK.) and a wireless EMG measurement system (Delsys Trigno Lab, USA.), during walking without HAL just before wearing HAL, during walking with HAL, and during walking without HAL just after taking it off. Joint kinematics during walking without HAL was recorded at the first and the last sessions.

Figure 1: A patient with gait impairment after severe spinal cord disorder went through 10 sessions of HAL intervention to improve lower limbs motor function and walking ability. Gait and muscle activity during walking in the intervention were recorded for analysis.

RESULTS AND DISCUSSION

Comparing gait without HAL between the first and the last session, the walking speed, the step length, extension of the hip and knee joints during stance, and dorsi and plantar angle of the ankle increased. Comparing gait with HAL and without HAL through the sessions, the walking speed, the step length and the ratio of swing duration to stance duration were greater in gait with HAL than without HAL. For the EMGs, activation of quadriceps muscles during stance was smaller and that of gluteus maximus was greater in gait with HAL than that without HAL. HAL enabled larger swing motion while reducing the chance of backknee.

CONCLUSIONS

In order to evaluate the effect of gait improvement after intervention using robot suit HAL, gait and lower limbs muscle activity were recorded through the intervention and analyzed in a patient with severe spinal cord disorder. Walking using the robot provided chances to walk in larger and smoother gait, which might lead to the gait improvement after the intervention.

INTRODUCTION

Spinal cord injury (SCI) causes paralysis and perception deficit below the site of injury, leading to disability in daily living with tremendous impact on the patient's quality of life. Wearable lower-limb robotic exoskeleton (WRE) presents a great hope to individuals with SCI to stand up from the seated position again. However, even with the assistance of a WRE, performing sit-to-stand (STS) would still be difficult if the trunk and upper limb muscles are not of sufficient strength to enable necessary whole body balance control. Failure during STS would lead to falls and thus injuries. The trunk movement prior to seat-off has great influence on balance and success of STS [1], and for individuals with SCI, the use of crutches also plays an important role in controlling the necessary forward momentum of the center of mass (COM) for successful STS. The purpose of this study was to determine key factors affecting the success in WRE-assisted STS in patients with SCI, by comparing the joint and COM kinematics and kinetics between successful and failed trials.

METHODS

Twelve patients with SCI below T4 (age: 37.7±6.5 years, body mass: 66.8±10.0 kg; height: 1.67±0.07 m) performed STS in a WRE in this study. The WRE (weight: 20.6kg) had actuators at both hips and knees and could be adjusted to fit individual users (Figure 1). Each subject performed STS with WRE 12 times while the kinematic and kinetic data were measured by a motion capture system (Vicon, OMG, UK), and 3 forceplates (AMTI, USA), and a pair of instrumented crutches (Figure 1). A trial was considered unsuccessful if falling backward occurred after seat-off. Both successful and failed trials were recorded. Angles and moments at the hips and knees were calculated, as well as the inclination angle (IA) of the body's COM to the center of pressure in the sagittal plane [2], crutch forces normalized to total body weight (%TW), total mechanical energy, and EMG of major upper limb muscles. Paired-t test was used to compare the calculated variables between Success vs. Failure conditions, with a significance level of 0.05.

RESULTS AND DISCUSSION

Compared to the failure condition, the successful condition showed significantly increased mean normalized crutch forces (0.09±0.03%TW), horizontal COM momentum (mean: 48.7±20.9kg*m/s; peak: 107.1±32.5kg*m/s), mean IA (2.45±4.38°), and mean triceps activities (0.08±0.05mV) prior to seat-off ($p<0.05$), but showed no significant differences in knee and hip angles, joint moments, total mechanical energy, and activities of the other upper limb muscles.

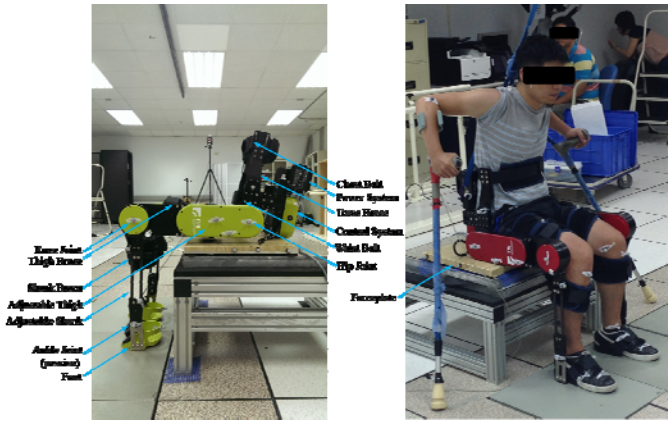

Figure 1: The lower-limb WRE (left) and a subject performing WRE-assisted STS.

The key factors affecting successful STS were identified in the current study by comparing the differences in the joint biomechanics and balance control between the success and failure conditions during WRE-assisted STS in patients with SCI. Compared to the orientation of the crutches, the triceps muscle activity and thus the pushing forces through the crutches significantly affected the performance of STS. Insufficient pushing forces prior to seat-off were found to be accompanied with reduced COM anterior momentum, leading to failure in STS. In fact, in most failed trials the subjects fell backward, indicating that anterior momentum is a critical factor for successful STS. On the other hand, compared to failure conditions, the success condition showed significantly increased mean IA, indicating that moving the trunk forward produced necessary forward momentum of the COM for dynamic balance. These results suggest that patients wearing WRE should be trained to improve their ability for pushing the body forward with crutches.

CONCLUSIONS

The crutch pushing forces, IA, COM forward momentum and triceps activity prior to seat-off were the key factors affecting the success of STS with a lower-limb WRE. The current results will be helpful for the training of individuals with SCI in using a lower-limb WRE.

ACKNOWLEDGEMENTS

The authors are grateful for the financial support and providing the WRE by Industrial Technology Research Institute of Taiwan, R.O.C. (Grant No. B353CX1100A2).

MEASURING UPPER LIMB LOADS DURING ROBOTIC ASSISTED GAIT: CASE STUDY OF AN EXPERT REWALK USER

INTRODUCTION

Patients suffering from Spinal Cord Injury (SCI) resulting in paraplegia suffer a reduced quality life due to the mobility impairment [1]. A partial restoration of their walking function over ground and a reduction of the secondary pathologies related to reduced mobility could be provided by the frequent use of powered exoskeletons for robot-assisted gait. However, many of these devices, require crutches to stabilize the body and initiate the step [2]. Since the usage of walking aids such as crutches is known to induce high loads on the shoulder joints [3], and this could account for shoulder pain and pathologies in SCI patients [4], an investigation on the upper joints involvement during assisted gait was deemed necessary. This study proposed a methodology to evaluate shoulder joints loads during robotic assisted gait, and presents preliminary results of the method applied to study an SCI patient who is proficiently using a Rewalk™ exoskeleton to walk over ground in everyday life.

METHODS

The subject is asked to perform a 6 m walk in an instrumented corridor, after donning his own Rewalk™ exoskeleton. Kinematic of the body is acquired using a marker-based Smart-dx vision system by BTS following a modified Davis protocol with 24 markers of which 12 on the exoskeleton and 7 on the patient. Ground reaction forces at the feet are recorded by 8 force platforms (P-6000 by BTS) hidden inside the corridor pavement. A pair of instrumented Lofstrand crutches, produced as an improvement of the wireless system designed by the authors [5], is used to measure force acting along each crutch.

A mechanical model of the patient is then used to interpret kinematic and dynamic data. The model is made up by 13 rigid bodies, representing the upper and lower legs, the feet, arms and forearms, torso and pelvis and the head, with 4 cylindrical joints (ankles and knees), and 8 spherical joints (elbows, shoulders, neck, hips and back). Inertial parameters of this model are adapted to the subject starting from anthropometric data from the literature [6]. A simulation in OpenSim [7] is used to perform both inverse kinematic and inverse dynamic analysis.

RESULTS AND DISCUSSION

A 56-years-old male (1.78m, 68 kg) with a complete SCI resulting in paraplegia and more than 9-months practice in robotic assisted gait using a Rewalk™ T5 model, performed 20 walking tests. Figure 1 reports the joints reactions forces, computed using the inverse dynamic analysis of the simulated model, during a typical stride performed by the subject without any support from his caregiver. For reference, ground reaction forces on feet and crutches are displayed in the same figure.

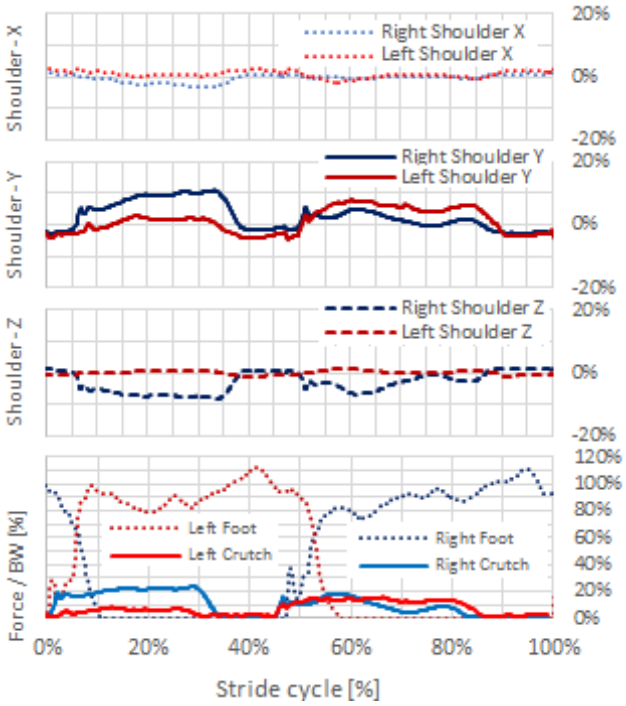

Figure 1: ***Shoulder joint reaction forces*** *acting on the torso and* ***Ground Reaction Forces*** *on feet and crutches during a stride. All forces are normalized on the patient's body weight (exoskeleton included). Shoulder joint reaction forces are expressed in the torso reference system (X pointing anterior, Y superior and Z pointing right). Stride starts and ends at each left-foot heel contact.*

CONCLUSIONS

Ground reaction forces amount to peak values of 110% of the subject body weight for the feet and 24% for the crutches, but inertial terms computed using the proposed model reduce the actual load on the shoulder joints to a maximum of 15%. This suggests a reduced involvement of those joints during robotic assisted gait of expert users.

HUMAN-EXOSUIT INTERFACES ABSORB AND RETURN ENERGY, RESHAPING EXOSUIT TO HUMAN POWER FLOW

[1]**Matthew B. Yandell**, [2]Brendan T. Quinlivan, [2]Dmitry Popov, [2]Conor Walsh, and [1]Karl E. Zelik

INTRODUCTION

Soft exosuits and rigid exoskeletons, two types of wearable assistive devices, have demonstrated the potential to improve mobility outcomes for individuals with disabilities, and to augment healthy human performance [1]. However, transmitting power from an assistive device to the human body is challenging because biological tissues and interface materials deform and displace when forces are applied, absorbing power. Inefficient device-to-human power transmission undermines the performance benefits of wearable assistive devices. Experiments on a recent running exoskeleton found that about 50% of the mechanical power provided by the device was lost in transmission to the body [2]. Although the practical difficulties of physically coupling wearable devices to the human body are well-known, only a few studies have published objective data characterizing interface dynamics [3], due partly to the lack of methods to quickly estimate these quantities. The objective of this work is two-fold: first to present a novel methodology for quickly estimating interface power during dynamic tasks using common motion capture and force measurements, and second to apply this method to quantify how a soft robotic exosuit interacts with and transfers power to the human body during locomotion.

METHODS

We performed a motion analysis study on one healthy male subject wearing a soft robotic ankle exosuit (Figure 1), similar to [4], while collecting synchronous motion capture, motor encoder, load cell, and ground reaction force data. The subject walked on an instrumented treadmill at 1.5 m/s for 5 minutes while the exosuit generated plantarflexion assistance about the ankle using a walking controller to apply peak cable force of up to 500 N. We then performed a new biomechanical analysis to quantify exosuit-to-human power transmission using force and motion data, which enabled us to parse augmentation power (powering ankle plantarflexion) vs. interface power (due to deformation and motion of interface materials and underlying soft tissues).

RESULTS AND DISCUSSION

We found that interface dynamics complicate the transmission of power from wearable assistive devices to the human body, resulting in three key consequences: (i) Augmentation power (and work) was reduced in magnitude during exosuit loading (as applied forces increased). During this phase, about 60% of exosuit end-effector power (i.e., power output from the device) was absorbed into the interfaces. (ii) However, during subsequent exosuit unloading (as applied forces decreased) most of the absorbed interface power was returned elastically. As a result, the majority (~80%) of exosuit end-effector work over each stride augmented ankle plantarflexion. (iii) Ankle augmentation power (and work) was delayed relative to exosuit power output, due to interface energy absorption and return dynamics. Here, we found that peak augmentation power was delayed by ~25 ms (Figure 1).

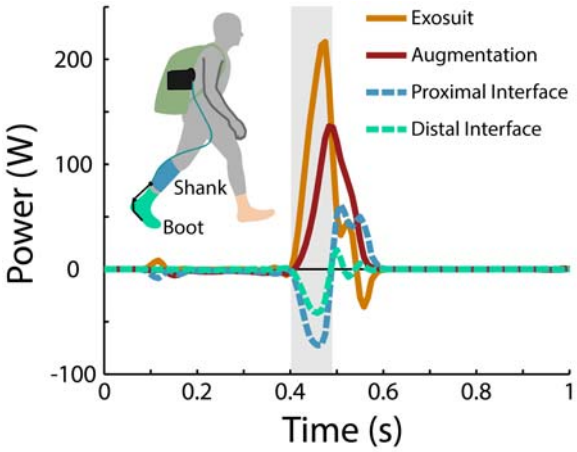

Figure 1: Human-exosuit interfaces absorb and return energy, reshaping exosuit to human power flow. Exosuit end-effector power (device output, orange) contributes to motion/deformation of the proximal (shank, dashed blue) and distal (boot, dashed green) interfaces, and augments ankle plantarflexion (red). Power is absorbed into interfaces during exosuit loading (increasing force application, gray box), then returned during unloading, contributing to ankle augmentation. Results are shown for a representative stride.

CONCLUSIONS

Physical human-device interfaces can absorb and return substantial energy, complicating power transmission. In order to optimize the performance of wearable assistive devices and fully realize their human augmentation benefits, it is important to account for these human-device interface dynamics. Here we present a new method to quantify power transmission and isolate power contributions from human-device interfaces using common force and motion measurements, which provides insight into how to improve the design and control of wearable assistive devices.

VOLUNTARY AMBULATION IS POSSIBLE IN PATIENTS WITH COMPLETE QUADRIPLEGIA OR PARAPLEGIA BY USING UPPER ARM MUSCLE ACTIVITIES AND HYBRID ASSISTIVE LIMB (HAL®) TECHNOLOGY

INTRODUCTION

Standing exercise for patients with complete quadriplegia or paraplegia due to spinal cord injury (SCI) has been reported to be effective in decreasing decubitus ulcers, osteoporosis, hip joint flexion, and adduction deformities, as well as in improving the performance of the cardiovascular and digestive systems [1].

Hybrid Assistive Limb (HAL®; Cyberdyne Inc., Japan) is a wearable robot suit that can assist voluntary hip and knee joint motion during walking. It estimates voluntary joint motion according to bioelectric activation of the relevant muscles detected by surface electrodes attached on the thigh of the wearer [2]. Therefore, it has been considered that HAL is not applicable to patients with complete paralysis without detectable bioelectric signals in the lower extremities.

We hypothesized that voluntary ambulation is possible in patients with chronic SCI with complete quadriplegia or paraplegia by using the activities of the upper arm muscles as the trigger for voluntary motion in HAL

METHODS

Participants

Four patients (3 men, 1 woman) were enrolled in this study. The mean patient age ± standard deviation was 36.8 ± 19.6 (range, 20–65) years. Clinical evaluation before intervention showed the following findings: case 1-neurological level C6, grade B on the American Spinal Injury Association impairment scale (AIS); case 2-T6, AIS A; case 3-T10 AIS A; and case 4-T10 in the right leg, L1 in the left leg, AIS B.

HAL Intervention

The intervention included 10 sessions. Each HAL session lasted 60–80 min, including rest, attachment and detachment of the device, and evaluation before and after intervention. For safety reasons, a walking device (All-in-One Walking Trainer; Ropox A/S, Denmark) with a harness was used to prevent falls. The electrodes of HAL for hip and knee flexion-extension were placed on the anterior and posterior side of the upper arms contralaterally corresponding to each of the lower limbs.

Clinical Assessment

Clinical assessments were performed before and after HAL intervention. A Trigno™ Lab Wireless EMG System (Delsys, USA) was used to evaluate the muscle activity of both quadriceps femoris, both gluteus maximus, and the tensor muscle of fascia lata. Motion capture (VICON MX with 16 T20S cameras; VICON, UK) was used to evaluate limb motion in synchronization with electromyography.

RESULTS AND DISCUSSION

In all cases, voluntary ambulation with HAL by using muscle activities of the upper arms was safe and feasible (Figure 1).

Figure 1: HAL session busing upper arm activities in case 3.

In all cases, there was no activation of the quadriceps femoris before HAL intervention. However, during the HAL session, periodic activation of the quadriceps femoris was observed in stance phase.

It is considered that the central pattern generator might be activated through voluntary gait in HAL intervention by using muscle activation of the opposite upper arms.

CONCLUSIONS

This study reported the safety and feasibility of upper-arm-driven robot-assisted locomotion in patients with SCI. In all cases, the quadriceps femoris contracted periodically in stance phase. HAL enables walking of patients with complete paraplegia or quadriplegia, who are not eligible for existing walking exercises.

LIFE IS MECHANOBIOLOGICAL - UNLOCKING AND EMULATING NATURE'S SECRETS WITH PAIRED IMAGING AND COMPUTATIONAL TECH

Melissa L Knothe Tate
University of New South Wales
Email: m.knothetate@unsw.edu.au

Starting from a single fertilised egg, the emergent complexity of the biosystem comprising the over 30 trillion cells of the adult human body is nothing short of miraculous. In recent years, the indisputable role of mechanical cues in this process has spawned the field of multiscale mechanobiology. Unraveling connections, between subcellular events and emergent tissue and organ architectures that pattern the whole organism, provides an unprecedented means to understand engineering paradigms underpinning our own bodies' multiscale structure and function. It also enables the engineering of advanced functional materials that mimic the body's own, as well as next generation medical devices and therapies that harness physiological activities to deliver drugs and biologics. This talk outlines the power of paired multiscale imaging and computational technologies to unlock and emulate nature's mechanobiological secrets to understand, prevent and treat musculoskeletal disease and to develop advanced materials.

FASCICLE-TENDON INTERACTIONS OF PLANTAR FLEXORS AND KNEE EXTENSORS DURING MAXIMAL SQUAT JUMP IN HUMAN: EFFECT OF THE EXTERNAL LOADING

INTRODUCTION

In human squat jump, a catapult-like effect was evidenced by direct ultrasound measurements [1], showing that tendinous structures importantly contribute to muscle-tendon unit (MTU) shortening at the lower limbs extremity during this task (i.e. ankle). Interestingly, Farris et al. [2] recently proposed two main mechanisms that could enable this catapult-like effect during this concentric task in the absence of a 'physical' catch. First, the resistance of supporting and accelerating body weight (gravitational and inertial loading) acts as a 'dynamic catch mechanism'. Therefore, an alteration of the external loading would modify the amount of the catapult effect. Second, the proximo–distal sequence of joints movement observed during jumping can facilitate the elastic energy storage-release at the distal joint [2], inducing lower loading of the tendinous tissues at the proximal knee joint compared to the ankle. To better understand the catapult effect in a concentric task as squat jump, the aims of this study were i) to analyze the effect of external loads on the fascicle-tendon interactions during squat jumping and ii) to compare fascicle-tendon interaction between knee extensor (VL) and plantar flexor muscles (GM). .

METHODS

Fifteen healthy males (22.8 ± 3.2 years, 179.0 ± 5.5 cm, 75.4 ± 6.2 kg) performed series of maximal squat jumps in five loading conditions: 0 (body weight condition, BW) 20, 40 and 60% of the 1-RM and an unloaded condition (EB) using elastic bands to lighten the body weight. The ground reaction force was measured by a 3D platform. , 3D motion analysis was performed to measure 2D knee and ankle angles. Moment at the ankle and knee were calculated by 2D inverse dynamics. The muscle-tendon unit (MTU) length was obtained using anthropometric models and kinematics data. The muscle-fascicles behaviors of GM and VL were simultaneously tracked using two identical ultrafast ultrasound scanners. Muscle fascicles length was obtained using automatic tracking method [3] and the length of tendinous tissues was calculated as the difference between MTU and the horizontal projection of fascicle length. .

RESULTS AND DISCUSSION

A first phase was characterized by an isometric behavior of MTU, while muscle fascicles shortened and tendinous tissues lengthened for GM and, despite shorter, also for VL (Figure 1). Preceding the take-off, muscle fascicles shortening velocity became very small and the release of tendinous tissues elastic energy allowed MTU to reach extremely high shortening velocity. It demonstrates for the first time a catapult-like effect for knee extensors. The cross-correlation coefficient between patterns of MTU and muscle fascicles shortening velocities was higher for VL (mean r=0.45±0.25) compared to GM (mean r=0.10±0.38) whatever the condition. It showed that VL fascicles contributed more directly to the vertical velocity/power of the center of mass than for GM.

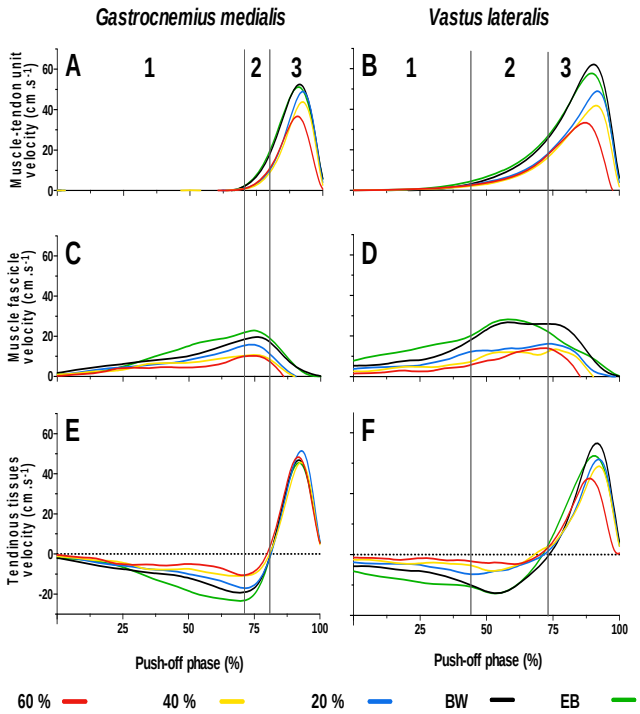

Figure 1: Mean patterns of shortening velocity of each components for GM and VL during squat jump in different load conditions: 0 (body weight condition, BW) 20, 40 and 60% of the 1-RM and the unloaded condition using additional elastic bands (EB). Vertical bars represent the three key phases of the push-off for both muscles. .

The index of muscle-tendon interactions (ratio between peak shortening velocities of MTU and fascicles) showed that tendinous structures amplified more MTU shortening velocity when the external loading was higher ($p<0.001$) confirming that the external load optimizes the 'catapult' mechanism. This mechanical advantage was more pronounced for GM.

CONCLUSIONS

Both the external loading and the proximo-distal sequence largely affect fascicle-tendon interactions supporting the hypothesis they play a major role to enable a catch mechanism and the catapult effect during maximal squat jump. The ability of tendinous structures to amplify the MTU shortening velocity is reduced at low external load. Despite also present, this phenomenon is of minor significance at the knee joint where MTU behavior is more directly related to the muscle fascicles behavior and thus more influenced by its maximal contractile properties. These findings have important consequences for the understanding of human performance and its optimization.

FASCICLE MECHANICS AND NEUROMUSCULAR ACTIVATION DO NOT CONTRIBUTE TO THE REPEATED BOUT EFFECT IN THE HUMAN GASTROCNEMIUS MUSCLE

INTRODUCTION

The repeated bout effect (RBE) is the protective adaptation following a single bout of lengthening contractions that initially cause delayed, localised soreness and reduced force-generating capacity (i.e. muscle damage). While muscle damage and the RBE have implications on strength development, recovery and performance in sports, identifying the mechanism responsible has remained elusive.

Mechanically, it has been hypothesized that a change in the muscle's operating length during the exercise task, away from long "unstable" lengths, can explain the adaptation underpinning the RBE [1]. Alternatively, a neural adaptation is proposed, where slow-twitch motor units are preferentially recruited in the repeated bout over fast-twitch motor units that are thought to be more susceptible to damage during lengthening contractions [2].

Previously, the RBE has been conferred in the medial gastrocnemius (MG) without changes in fascicle mechanics [3]. However, force production and strain magnitude were not controlled in this study while neural activation was not assessed. The aim of the present study was to examine fascicle mechanics and neural activation changes during a highly-controlled MG lengthening task that confers the RBE.

METHODS

Twenty subjects performed two bouts of 500 voluntary lengthening contractions of triceps surae, separated by one week. Subjects laid prone with the knee extended (~175°) while attached to an isokinetic dynamometer that controlled stretch velocity (50°/s), pre-contraction torque level (70% MVC), and range of motion (15° plantar flexion to maximum dorsiflexion). MG fascicle length (ultrasonography), plantar flexor torque and EMG activity of MG, lateral gastrocnemius (LG) and soleus (SOL) were measured in each bout.

Pre-, 2-hr post- and 2-d post-each bout, fascicle length-torque (L-T) curves, triceps surae MVC EMG and soreness measurements were made. L-T curves were constructed using ultrasonography of MG and supramaximal electrically-stimulated torque twitches to derive maximum torque (T_{max}) and optimum fascicle length (L_o). Soreness was measured via palpation and during brief walking.

RESULTS AND DISCUSSION

The presence of a RBE was indicated by T_{max} being significantly lower (~8%) and soreness scores being significantly higher post-initial bout vs. the repeated bout.

Between the two bouts, there were no differences in fascicle strain (17.9 vs. 17.2 % L_o), mean torque produced during stretch (2.53 ± 1.1 vs. 3.07 ± 1.3 /Twitch; Fig. 1) and EMG activity during stretch (Table 1). Also, no shift in the L-T curve or change in operating length range relative to the curve occurred suggesting that the fascicle was already operating at an optimal and "stable" length in the initial bout. Furthermore, there were no differences between bouts in triceps surae MVC EMG following exercise. This indicates that changes in fascicle mechanics or neural activation did not explain the RBE observed here.

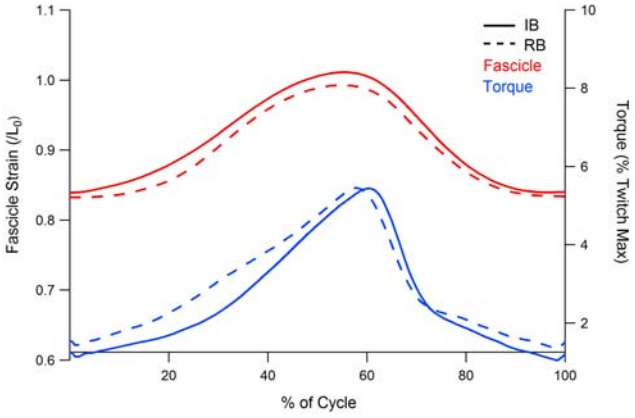

Fig. 1: Fascicle strain and torque (normalized to the resting twitch) averaged over the initial (IB) and repeated bouts (RB), presented as percentage of the ankle extension-flexion cycle during the eccentric contractions.

Table 1: Triceps surae EMG RMS (/M-wave) averaged over the stretch phase of each exercise bout.

	MG	LG	SOL
Initial Bout	2.10 ± 0.45	2.58 ± 0.48	1.76 ± 0.18
Repeated Bout	2.34 ± 0.65	2.28 ± 0.53	1.61 ± 0.17

CONCLUSIONS

Mechanical adaptations were not responsible for conferring the RBE in the MG for this task. This is likely due to the high compliance of the Achilles tendon, minimizing contractile tissue strain. Furthermore, no neuromuscular adaptations were present. We suggest that non-contractile adaptations, such as extracellular matrix remodeling, better explain the RBE conferred for the human MG muscle.

CHANGES IN MULTI-SCALE ARCHITECTURE OF THE HUMAN MEDIAL GASTROCNEMIUS MUSCLE DURING PASSIVE LENGTHENING

Bart Bolsterlee, Arkiev D'Souza, Simon Gandevia and Rob Herbert
Neuroscience Research Australia
University of New South Wales
Corresponding author email: b.bolsterlee@neura.edu.au

INTRODUCTION

During active or passive changes in muscle length, muscle architecture changes in three dimensions (3D) [1]. This has been difficult to study with conventional techniques such as measurements on cadavers or ultrasound imaging in vivo. Using diffusion tensor imaging (DTI, an MRI technique) it is now possible to quantify the multi-scale 3D architecture of whole human muscles in vivo [2]. We used MRI and DTI to measure changes in 3D architecture of the whole muscle belly and muscle fascicles of the human medial gastrocnemius during passive lengthening.

METHODS

DTI and MRI scans were obtained from the left legs of eight healthy subjects at three ankle joint angles ranging from the angle corresponding to the slack length of the muscle-tendon unit to the longest in vivo muscle-tendon length. The knee was flexed ~18°. Muscle volume, length, cross-sectional area (CSA), width and depth were calculated from 3D MRI-based surface models of the medial gastrocnemius. Muscle CSA and width were calculated as the area and maximum width of cross-sections of the surface model at 5% intervals along the muscle's long axis. Muscle depth was defined as the ratio of the CSA and width. The mean value for a muscle is the mean of the values measured at cross-sections between 20% and 80% of the total muscle length.

For each joint position in each subject, DTI tractography was used to reconstruct 5,000 fibre tracts in the medial gastrocnemius. Third-order polynomial curves were fitted to the tracts and extended until their endpoints were located on the muscle surface (i.e. on the muscle's deep and superficial aponeurosis). Tracts that were extrapolated by less than 30% of their total length were assumed to represent muscle fascicles, and were included in further analyses. The 3D pennation, length and curvature were calculated for these fascicles.

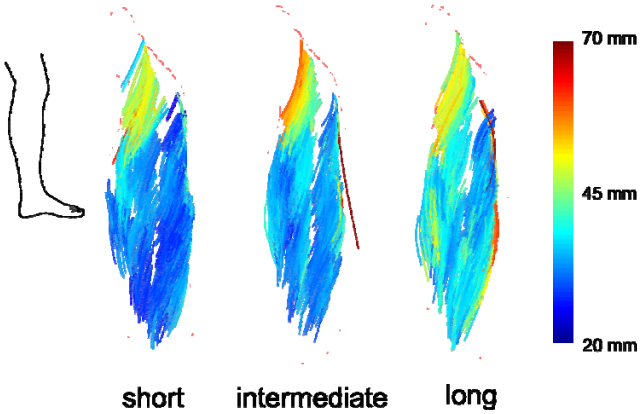

Figure 1: Surface models and fascicle reconstructions of the medial gastrocnemius at three muscle-tendon lengths.

RESULTS AND DISCUSSION

Over the range of muscle lengthening from a mean of 222 to 233 mm, muscle depth decreased more than muscle width in relative terms (-4.8% and -2.5%, respectively), although the absolute reduction in width (-1.6 mm) was larger than the reduction in depth (-1.1 mm). Muscle volume decreased with muscle lengthening (mean -1.6%), but this decrease was small compared to the difference between repeated measurements (on average, 3.9% difference).

For all muscles, fascicles were successfully reconstructed in regions spanning almost the whole muscle (on average, 3,000 fascicles per muscle). As fascicles lengthened from a mean of 39 mm at the slack length to 53 mm at the longest measured length, pennation decreased from 30° to 22°, and curvature from 14 /m to 9 /m. Most of the change in pennation occurred at the deep part of the muscle (-11° in the deep part, -5° in the superficial part). There was no systematic variation in architecture along the muscle's long axis at any muscle length. Further analysis of the DTI data show that axial and transverse diffusion of water molecules changes in the same direction as fascicle strains (data not shown).

CONCLUSIONS

Novel MRI and DTI techniques revealed changes in three-dimensional architecture of the human medial gastrocnemius during passive lengthening. Width and depth of the whole-muscle belly decreased as the muscle was lengthened. The reduction in width implies a violation of the assumption, frequently used in 2D planimetric muscle models, that the area occupied by muscle fibres remains constant. Muscle architecture changed uniformly along the muscle during passive lengthening.

SHIFTING GEARS: DYNAMIC MUSCLE SHAPE CHANGES AND FORCE-VELOCITY BEHAVIOUR IN THE MEDIAL GASTROCNEMIUS

INTRODUCTION

When muscles contract, they bulge in thickness or in width to maintain a (nearly) constant volume [1]. These dynamic shape changes are tightly linked to the internal constraints placed on individual muscle fibres and are thought to play an important functional role in modulating the mechanical performance of skeletal muscle by enhancing the range of velocities over which it operates [2]. When pennate muscles shorten, fascicles rotate and their velocity is decoupled from the velocity of the whole muscle in a process known as gearing (v_{MTU}/v_{f}; [2]). Studies have shown that gearing varies depending on the mechanical demands of the task [2]. During contractions, compressive forces develop due to cross-bridge forces compressing the myofilament lattice [3], and in pennate muscles a substantial component of the fibre contractile force draws the aponeuroses together. But to maintain a (near) isovolumetric state, fibres develop additional forces that oppose this compression and instead act to expand the fibres in their transverse direction [4]. Thus, the ability of fascicles to rotate and operate at high gearing should be limited in situations where fascicle compressive forces and connective tissue stiffness constrain increases in muscle thickness. Yet to date, the association between force, dynamic muscle shape change, and gearing remains unexplored *in vivo* under submaximal conditions. The purpose of this study was to (i) determine the *in vivo* changes in muscle behaviour as a function of force and velocity and (ii) determine how muscle shape changes are linked to gearing under varied levels of force and velocity. We hypothesized that (i) higher force contractions would be associated with smaller changes in muscle thickness, decreased fascicle rotations, and increased fascicle shortening velocity; and (ii) increases in force would be accompanied by decreases in muscle gearing.

METHODS

Ten competitive cyclists (6M, 4F) pedalled at 9 conditions ranging from 80-140 r.p.m. and 14-44 N m while we recorded B-mode ultrasound images of the MG muscle belly and muscle-tendon junction (MTJ), 3D trajectories of 32 LED markers, and surface EMG patterns. Ultrasound images were digitized to estimate time-varying fascicle lengths, pennation angles, muscle thickness, and tendon lengths. MG tendon force was estimated based on the measured Achilles tendon (AT) length changes, and tendon stiffnesses from ramped isometric tests. Muscle-tendon unit (MTU) lengths were determined using scaled musculoskeletal models and the LED marker data; muscle belly lengths were calculated as the difference between MTU and AT length. Instantaneous muscle belly, fascicle, and MTU velocity (v_b, $v_{f,}$ v_{MTU}) were calculated as the first time-derivative of the l_b, $l_{f,}$ and $l_{MTU,}$ respectively. Muscle belly gearing v_b/v_f was determined at the time when v_b was maximum. We used an ANOVA to test for differences in the v_b, $v_{f,}$ v_{MTU}, rate of pennation angle change, change in muscle thickness, activation, gearing, tendon strain, and tendon force between the different conditions.

RESULTS AND DISCUSSION

The shortening behaviour of muscle fascicles was uncoupled from the shortening behaviour of the muscle belly. v_b decreased with force whereas v_f increased with force (p<0.05) (Fig. 1A). In support of our first hypothesis, the increase in v_f was accompanied by a decrease in the extent and rate at which the fascicles rotated (p<0.05) and a decrease in the change in muscle thickness (p<0.05) (Fig. 1B/C).We propose that these variable muscle shape changes are in part due to the stress asymmetries that result from the interplay between the compressive forces and connective tissue resistance [4,5]. Specifically, we found a reduction in the increases in muscle thickness and a decrease in fascicle rotation with increasing force— consistent with [2,4]. Muscle belly gearing was linked to the measured shape changes; in support of our second hypothesis, gearing decreased with increasing force (p<0.05) (Fig 1D), but did not vary significantly with v_{MTU}. The range of conditions, varied levels of activation and detailed experimental techniques in this current study have allowed us to identify muscle force, and not velocity or activation, as the mechanistic driving factor to allow for the gearing to vary between *in vivo* contractile conditions.

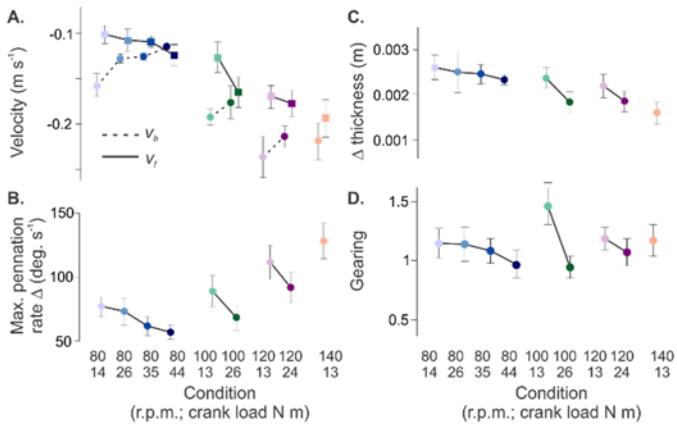

Figure 1: Changes in muscle belly (v_b) and fascicle shortening velocity (v_f) (A), rate of pennation angle change (B), change in muscle thickness (C), and belly gearing (D) are presented as mean ± SE for 10 subjects.

CONCLUSIONS

Here we provide the first comprehensive set of *in vivo* data that supports the myriad of theorized mechanisms of dynamic muscle shape change from both animal studies and human muscle modelling.

MUSCLES' ACTIVATION STATE AFFECTS MEDIAL GASTROCNEMIUS FIBER STRAIN HETEROGENEITY: ASSESSMENT USING MRI AND DTI METHODS

INTRODUCTION

Our previous work [e.g., 1] on muscles of human subjects in vivo yielded novel methods for quantifying deformation along muscle fibers using magnetic resonance imaging (MRI) and diffusion tensor imaging (DTI) tractography analyses combined. One particularly important outcome of that is the quantified heterogeneity of strains along different muscle fibers within a muscle. Such heterogeneity determines the force production capacity and excursion of a muscle and is caused by epimuscular myofascial loads acting on it [2]. We hypothesized that the effects of those loads originating from stretching of connective tissue structures linking muscle belly to the surroundings depend on the muscles' activation state. The aim was to test that via fiber strain heterogeneity across tracked muscle fibers.

METHODS

Healthy female subjects (n=5) participated. Each subject was positioned prone within the MRI scanner with the ankle fixed at 90°. DTI and high-resolution 3D MRI anatomic image sets were acquired in each of the following states: (1) *Stretch* the knee was brought from flexion (140.8±3.0°) to extension (177.0±1.0°) (2) *Activation* maintaining this position, the subjects were asked to sustain isometric plantarflexion at 15% MVC with the help of visual feedback. (3) *Relaxation* Following 5 minutes rest, the subjects were asked to sustain a reduced activity at 5% MVC. Analyses performed (strain calculations using Demons' algorithm, tractography using 4th order Runge-Kutte integration and rotation of strain tensors to local fiber unit tangents) for each successive state yielded strain distributions along gastrocnemius muscle fiber tracts. Reference images for each state were also transformed by a synthetic rigid body motion imposed. Resulting fiber direction strains were used as estimates of error strains and were compared to fiber strains using Wilcoxon rank sum test.

Fiber strain heterogeneity across tracked muscle fibers was calculated as the ratio of the number of fiber pairs with statistically different mean strains to the total number of fiber pair combinations (σ_p). Comparisons of mean of that for the subjects were done based on Kruskal–Wallis with Dunn's post hoc test. This was used as a metric to test the hypothesis objectively.

RESULTS AND DISCUSSION

Pooled over all subjects, relaxation state strain errors were small and significantly different ($p<0.05$) from fiber strains (for lengthening (0.44% vs. 3.11%). Similarly, stretch and activation state strain errors were significantly smaller than fiber strains.

The fiber strain heterogeneity within each subject changed drastically in each state. The figure exemplifies the effects of stretch, activation and relaxation states on fiber strains for one subject. Stretch state caused around %25 fiber strain heterogeneity across different muscle fibers. Activation state nearly doubled that heterogeneity. However, relaxation state caused fiber strain heterogeneity to diminish, dropping it down to <1%. This confirms our hypothesis. This is explained by the relaxation state releasing the connective tissue structures at the muscle belly, which eliminated the complexity of the fiber strains including both lengthening and shortening in the activation state.

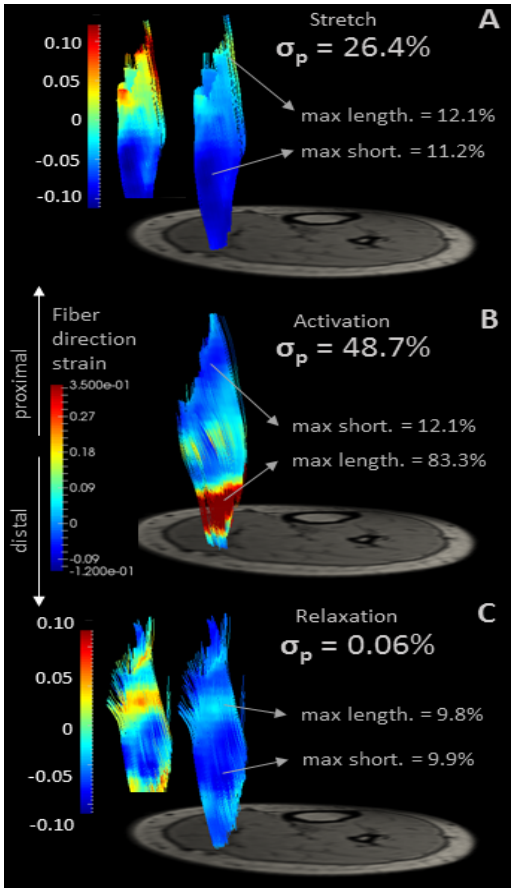

Figure 1: Panels A, B and C demonstrating the results of the analyses for one exemplary subject. Top and bottom color bars with white text applies to the respective insets on their side.

CONCLUSIONS

We conclude that have used a metric to quantify changes in the strain heterogeneity along the fibers of a muscle and demonstrated how epimuscular loads acting on a muscle are state dependent *in vivo* in human subjects.

CUP-TO-NECK CONTACT AND MOTION RANGE IN TOTAL HIP ARTHROPLASTY WITH LARGE HEAD DIAMETERS: 3D GAIT AND VIDEO-FLUOROSCOPIC ANALYSES

INTRODUCTION

In case of severe coxarthrosis, pain and reduced joint function are the most common symptoms. Hence, pain relief and restoration of normal range of motion (ROM) are the objectives of Total Hip Arthroplasty (THA) [1]. Unfortunately, limited hip ROM and lower limb disability are observed in THA patients. Several factors such as implant design and the head-neck ratio seem to affect hip joint ROM. So far, these factors have been extensively investigated in-vitro and also in in-silico evaluations, the latter suffering of unrealistic overall conditions of hip function and soft tissues arrangement. Accordingly, the real capability of THA patients to perform correct hip movements is still unknown. It is expected that the recently introduced THA designs with larger head diameters may result in larger ROM. These designs claim to imply reduced risk of dislocation and of cup-to-neck contact at the motion extremes [1]. Current radiological and stereo-photogrammetric methodologies have the potential for in-vivo accurate investigations on THA ROMs and contacts.

The objective of this study was to assess in-vivo via originally 3-dimensional (3D) video-fluoroscopy (VA) and gait (GA) analysis whether the hip joint ROM is limited by the cup-to-neck contact, i.e. impingement, in patients implanted with THA designs with larger head diameters

METHODS

45 patients undergoing THA are planned to be recruited in this study, randomly allocated to 3 different groups related to as many head diameters, i.e. the 28, 36, and 40 mm, with the Pinnacle Acetabular System in the former, the Delta Motion System in the latter two (both by DePuy Synthes, Warsaw, IN-USA). So far, 22 patients were implanted and 11 patients were assessed at 12 months. At follow-up, a 3D GA (8-cameas Vicon, Oxford-UK; 2 Kistler force platforms, Einterthur-CH; 8-ch electromyography ZeroWire, Aurion, Milan-IT) was performed during standard activities of daily living [2], and also during the execution of extreme hip ROM arcs, those most possibly able to provoke cup-to-neck contact: squat, tailor-sitting, chair, stair climbing and descending, lunge-forward, high-step (i.e. hyperflexion), lunge-backward (i.e. hyperextension), full-squat. All GA acquisitions were executed using the IORgait protocol for appropriate marker-set and joint motion reconstructions [3].

Afterwards, accurate 3D VA evaluations [2] were executed in the aforementioned extreme positions and with patients wearing the same marker-set as in GA. A 2D-to-3D shape-matching technique was used to reconstruct 3D position and orientation of the cup and of the femoral prosthesis components, and also of the marker-set, the latter being used to reconstruct relevant cup and stem implantation parameters with respect to related anatomical reference frames (Figure 1). 3D component poses were used to calculate the cup-to-neck distance. Correlations between ROMs and these distances were also calculated. Pre- and post-THA clinical assessments were performed using the Harris Hip, UCLA, Oxford Hip and Womac scores.

Figure 1: VA software screenshot (Kneetrack®, University of Florida, USA): cup, femur and pelvis marker-set matched on 2D contours on X-ray images for 3D pose reconstruction.

RESULTS AND DISCUSSION

After THA, excellent clinical scores were obtained. From GA, an overall good recover of normal walking was observed. In the extreme ROM exercises, the maximum flexion over all patients, were 97°, 92°, 84°, 68°, 54°, 94°, 106°, 23°, 101°, respectively in squat, tailor-sitting, chair, stair climbing and descending, lunge-forward, high-step, lunge-backward, full-squat. Maximum adduction and external rotation were achieved in lunge-forward (23°) and squat (49°). As a sum of the three planar rotations, the maximum combined hip motion was achieved in squat (90° flexion, 4° abduction, 49° internal rotation) and in high-step (106°, 29° and 24°, respectively). Very small hip extension was observed, also in lunge-backward (range 0÷23°). 3D VA confirmed the achievement of pre-operative implant planning. Minimum cup-to-neck distances were 24, 29, 12, 14, 15, 10 mm respectively in squat, tailor-sitting, lunge-forward, high-step, lunge-backward, full-squat. Correlation analysis revealed that larger head diameters are associated with larger distances and larger ROM (see also the other paper at this Congress from these authors).

CONCLUSIONS

3D GA and VA provided accurate and original findings. Successful THA with large femur heads were observed, GA revealing very large hip ROM in all anatomical planes. Despite these, the cup-to-neck distances from VA were found large enough to exclude definitely any contact. This multi-instrumental analysis is essential for thorough evaluations in THA patients and on the specific motor performances allowed by the implanted prosthesis designs.

INTRODUCTION

Total knee arthroplasty (TKA) is the primary treatment for end stage knee osteoarthritis (OA). While it is suggested that obesity is related to poorer outcome from TKA using self-report measures, the literature is conflicted [1]. TKA in general has been shown to improve knee joint biomechanics, but with large person-to-person variability in response and evidence that functional outcome is influenced by demographic factors such as sex [2,3]. Furthermore, there is evidence to suggest altered gait patterns before TKA in conjunction with higher BMI may increase risk of early implant loosening [4]. Obesity in the presence of earlier stages of knee OA has been associated with altered knee joint mechanics and muscle activity patterns [5,6], but it is unclear if these relationships persist with end stage knee OA or influence functional response to TKA. The purpose of this study was to examine differences in knee joint level biomechanics and muscle activity during walking gait before and after TKA surgery between those with class II obesity and overweight or healthy-weight individuals.

METHODS

Seventy-one participants receiving primary standard-of-care TKA surgery for end stage knee OA underwent 3D gait analysis approximately one week before and one year after surgery. Optoelectronic motion capture (NDI, 100Hz) and synchronized floor-embedded force platform (AMTI, 2000Hz) collected motion and forces during walking at self-selected speed. Knee moments calculated using inverse dynamics, expressed in ISB coordinate axes, were normalized to body mass. Synchronized surface electromyography (sEMG) data of medial (MG) and lateral gastrocnemius, medial (VM) and lateral vasti, rectus femoris (RF), and medial and lateral hamstrings (Bortec Biomedical, 2000 Hz) were collected using standardized protocols [7]. Maximum voluntary isometric contraction exercises were used for EMG normalization and strength testing [7].

Principal component analysis extracted key features of variability (PCs) in gait biomechanics [7]. Participants were grouped into i) healthy/overweight: BMI <= 30 (N = 35) and ii) class II obesity: BMI >=35 (N = 36). Two-way mixed model ANOVAs examined group and time interactions of all gait biomechanics, and main effects ($\alpha = 0.05$).

RESULTS AND DISCUSSION

The class II obesity group (25 females) was significantly younger (mean diff.: 6 yrs.) than the healthy and overweight group (17 females) ($p<0.05$). Gait speed and strength were not different between groups at either time point ($p>0.05$).

There were no statistically significant interactions or group effects on 3D knee angles or moments during gait, but significant time effects, as previously reported [2]. While differences have been reported with obesity in individuals with moderate OA [5], the lack of differences in TKA patients may reflect the level of severity in gait compensations in the group as a whole, regardless of BMI.

There were no statistically significant interaction effects on sEMG patterns, but group differences for overall activation magnitudes (PC1) of VM and RF, with class II obesity associated with higher activation magnitudes of both throughout stance ($p=0.012$, $p=0.016$). In addition, the class II obesity group walked with a phase shift in MG resulting in later peak activity in late stance (PC2) ($p=0.028$). Only two muscle differences were found, this was not surprising given no biomechanical or strength differences. The shift in MG activity supports increased synergetic gastrocnemii activity during late stance propulsion in the class II group. The potential for crosstalk and phase shifts are associated with greater adiposity but likely do not explain the differences found, as they were muscle specific, not uniform

CONCLUSIONS

Despite a few muscle activation differences, our current results suggest those with class II obesity do not have significantly different knee joint biomechanics during gait before or after surgery compared to those of lower body mass, and do not support a hypothesis that those of class II obesity can expect a poorer functional outcome to TKA surgery than those of lower body masses. Biomechanics in end stage knee OA, and the functional response to TKA surgery are highly variable, and the current results suggest that more than BMI alone is needed to understand knee joint function variability among those presenting for TKA.

INTRODUCTION

Hip replacement is a routine surgery for orthopaedic patients. The gait analysis is important in clinical practice. Although many studies focused on detecting the gait changes at the hip but little research was focused on the biomechanical changes that occurs postoperatively at the ankle joint. Therefore, the aim of this study was to investigate the postoperative 3D gait changes at the ankle joint in patients with hip surgery.

METHODS

The 126 patients with hip replacement surgery (aged 30-87 and weighted 58-120 kg), and 45 healthy subjects (aged 20-62 and weighted 50-116) participated in the study. Hip surgeries had two types, total hip replacement (THR) and hip resurfacing (HR). Their gait was collected using Vicon motion capture system and force platforms. Of the 126 operated subjects 53.2% had unilateral Hip Resurfacing (HR) operation while 46.8% had unilateral Total Hip Replacement (THR). The gait data from patients were collected in following up between 1 to 6 years.

The Vicon® nexus motion capturing system with 8 MX cameras were used to capture data at 100Hz. Two Kistler® force plates were used to collect the ground reaction force (GRF) while the subject was walking along the 20 m walk way. A group of 14 mm retroreflective markers were placed on the appropriately anatomical landmarks for the subjects according to Vicon management system, and the gait data was analysed using the Plug-in-Gait® model. For each subject, 5 good trials were selected for further statistical analysis.

The biomechanical parameters from the data analysis were space-temporal variables, joint kinematic and kinetic variables, e.g. angle, force and moment.[1, 2]

SPSS (v16) was used to carry out statistical analysis. Significant level is set at 0.05. Data normality was checked using K-S test, and statistical methods used were independent t-test, general linear model, non-parametric test or ANOVA, depending data characteristics and requirements in analyiss.

RESULTS AND DISCUSSION

The reported gait speed in the current research project for the HR 1 to 3 year postoperative group was 1.22 m/s, and for THR 1 to 3 year postoperative group was 1.15 m/s. All groups displayed significantly reduced gait speed when compared to the healthy normal group. In the current study patients with hip surgeries also showed significantly reduced stride length when compared to the healthy normal group. Table 1 reports the part of results in ankle joint angles. The results shows that HR and THR significantly reduced the dorsiflexion but increased plantarflexion, and as a result the range of motion in THR was reduced but not changed too much in HR (Table 1).

Table 1: Comparison of the healthy people dominated side and patient operated side in ankle angles (* $p<0.05$).

Similar results can be found in the ankle forces and moments, i.e. that HR and THR have reduced joint forces and moments in the ankle in compared with the healthy. These reduced walking speed, stride lengths, range of motion, and forces and moments all are due to the surgeries in the hip. It should be noted that the ankle range of motion in HR has not been reduced too much in compared with the healthy. In other words, HR has better effect than THR in terms of ankle movement.

CONCLUSIONS

The gait in post-operative THR and HR patients are different from the healthy people. The patients usually have reduced functions in walking speed, stride length, joint force and moments. The range of motion in the ankle is not changed too much in HR in compared with the healthy.

INTRODUCTION

Biomechanical analysis of function during demanding activities in the weeks following surgery can give an indication of joint performance and the success of a TKA. Compared to stair ascent and uphill walking, TKA patients find stair descent and downhill walking more difficult as the effects of gravity increase joint loading to 3.5x body weight [1]. Further, higher knee flexion (~85º) is also required to carry out these activities which may be painful for those with mobility difficulties [2]. This study looked at short-term outcomes to give information regarding initial recovery after TKA surgery.

METHODS

Three-dimensional motion analysis was conducted on seven healthy control participants and seven TKA patients (Columbus®, B. Braun Aesculap, Tuttlingen, Germany) performing five stair descents at their own self-selected pace, choosing whether or not to use handrails. Participants also walked on a self-paced treadmill inclined to -7.5º (Motek CAREN, Motekforcelink, Amsterdam, Netherlands). Patient data were collected pre-operatively and between 9 and 16 weeks (mean 12 weeks) postoperatively. Control group data were collected once. Ground reaction force data were collected from an instrumented step in the staircase, but were not collected in downhill walking.

RESULTS AND DISCUSSION

Table 1 details gait parameters for each participant group for each activity. Control data were averaged from both limbs as there were no significant differences between the sides.

Paired t-tests showed no significant differences in any of the parameters for the downhill walk between the pre- and post-operative limb. Non-operated limbs had a significantly higher maximum knee extension (p=0.003) compared to the operated side post-operatively, indicating a larger range of motion. Compared to controls, the post-operative maximum knee flexion was significantly lower for the operated (p=0.003) and non-operated sides (p=0.03). Post-operative walking speed was significantly slower than controls (p=0.01).

Other than minimum knee adduction angle, the pre-operative affected side was not significantly different from the control group in both tasks. In the stair descent, the post-operative operated limb had significantly lower maximum knee flexion (p=0.03), flexion at toe off (p=0.02) and knee adduction moment (p=0.02) compared to pre-operative which may be a result of joint swelling and pain following TKA.

CONCLUSIONS

The short-term (9 to 16 week) outcomes of TKA during demanding activities suggests function has still not recovered the pre-operative state. This study is continuing to determine if there is an improvement over time.

ACKNOWLEDGEMENTS

The authors would like to acknowledge B. Braun Aesculap for funding this study.

INFLUENCE OF FRICTION ON AXIAL KNEE ROTATION IN PATIENTS WITH KNEE ARTHROPLASTIES DURING ACTIVITIES OF DAILY LIVING

[1] **Igor Komnik**, [1]Sina David, [1]Wolfgang Potthast
[1]German Sport University Cologne – Institute of Biomechanics and Orthopaedics

INTRODUCTION

In recent decades, knee arthroplasty (KA) succeeded to improve patients' clinical scores and gait patterns [1]. However, to date, studies primary focused on biomechanical analysis of level walking with total knee arthroplasty (TKA) patients. The investigation of neuromuscular more challenging activities of daily living (ADL) like stair climbing and especially ramp negotiation was partly neglected [2]. Furthermore, non-sagittal plane parameters have mostly not been considered, whereby the evaluation of e.g. transverse plane kinematics and kinetics may reveal potential differences between various endoprosthetic designs. Additionally, frictional forces transmit appreciable shear between the femoral component and the tibial polyethylene insert, potentially contributing to axial knee rotational constraints [3].

The aim of this study was to investigate transverse plane kinematics and kinetics in connection with the force of friction (FOF) during ADL in patients after TKA and unicondylar knee arthroplasty (UKA) surgery.

METHODS

Motion analysis was performed using a ten-camera motion capture system (100 Hz, Vicon). Two force plates (1000 Hz, Kistler) were embedded in the floor, one under a ramp (gradient: 21%) and each in the second and third step of a five-step-stair case. According to the author's own created marker-set, fifty retro-reflective markers were attached to subject's feet, shank, thighs, pelvis, thorax, upper arm, lower arm and head to create a 17-segment rigid model. Kinematics and inverse dynamics were calculated with AnyBody Modeling System™ (AnyBody Technology). A Butterworth low pass filter (recursive, 6 Hz) was applied for kinematic and kinetic data. FOF was estimated of the two articulating artificial surfaces (μ=0.12) compared with the cartilage on cartilage friction (μ=0.01). The Coulomb model of friction was applied to calculate FOF ($F_f=F_n*\mu$). Data post-processing was conducted with Matlab 2013b (The MathWorks, Inc., Natick, US). Completed ADL: level and decline walking, stair descent. Eleven subjects formed the TKA group and 13 subjects the UKA group (medial compartment replaced). Thirteen healthy subjects served as a control group (CG). Statistical analysis was performed by means of Statistical non-Parametric Mapping (SnPM) (http://www.spm1d.org/) ensuring a statistical evaluation of the entire time normalized time series.

RESULTS AND DISCUSSION

No statistically significant differences were detected between the TKA and UKA group, regardless of the locomotion task. Each motor task revealed impaired knee internal rotation angles in the TKA group compared with the CG, indicated by the supra-threshold clusters (Figure 1, a-c).
Figure 1 (d) clarifies the determining role of the coefficient of friction regarding FOF which showed the highest values during stair ascent and decline walking in all groups. Interestingly, the mentioned tasks exposed lower knee internal moment time series compared with level walking. Lower internal rotation moments might contribute in connection with high friction to the constraint knee internal rotation motion, particularly during ADL including greater normal force values, such as stair climbing and ramp negotiation.

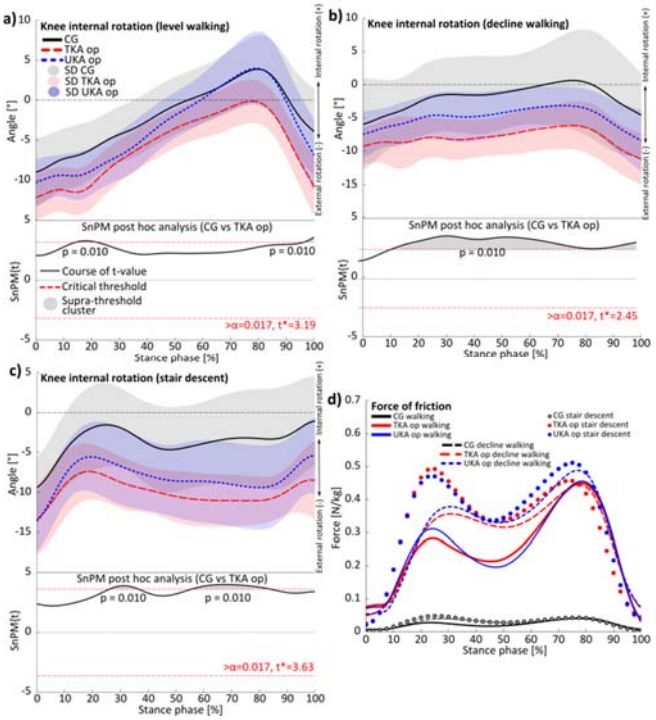

Figure 1: a-c) Mean trajectories and standard deviation (shaded area) for the knee internal rotation angles and SnPM{t} post hoc results during ADL. d) Depiction of the FOF during ADL.

CONCLUSIONS

Both KA-groups presented similar curve progressions compared to the CG. However, the abnormal kinematics were more obvious in the TKA group particularly during decline walking and stair descent, showing considerable impaired knee internal rotation almost throughout the entire stance phase. In this regard, FOF could represent a mechanical resistance, which, among other aspects, inhibits knee motion in the transverse plane.

ACOUSTIC LOCALISATION OF CORONARY ARTERY STENOSIS: PHANTOM MEASUREMENTS

[1] Malcolm Birch,[2] Paresh Date [1] **Stephen Greenwald,** [2] Ashraf Khir, [1] Jonathan Reeves, [2] Simon Shaw, [2] John Whiteman

INTRODUCTION

Plaque developing in a coronary artery produces disturbed flow downstream and time varying wall stresses. These give rise to low amplitude acoustic waves which propagate through the chest and can be measured by skin sensors.

The objectives of this project are to simulate the propagation of acoustic waves induced by an arterial stenosis both experimentally in chest phantoms composed of tissue mimicking materials (TMM), and computationally by software approximations to the underlying partial differential equations. The overall aim is to produce a stand-alone system consisting of an acoustic/accelerometric sensor array to be placed on the patient's chest suitable for the non-invasive screening of coronary artery disease. We report here measurements of shearing oscillations and flow-induced turbulence in TMM gels which provide input to the numerical model of soft tissue behaviour described in a companion presentation by S Shaw ('Computational Aspects'). In preliminary experiments we characterised the quasi static and dynamic elastic properties of the TMM and we now report measurements of waves generated in gels of various geometries either by a vibrating bead or a piezo-electric device. The displacement field at the gel surface is detected optically or with accelerometers and, in planned experiments, acoustically. As a more realistic representation of the clinical problem we also report detection of surface displacement waves generated downstream of a stenosed tube embedded in gel of the same composition and detected accelerometrically.

METHODS

Cylindrical specimens of 3% agarose or polyvinyl alcohol (PVA) gel were cast around a freely mobile axial rod and bead connected to an electromechanical vibrator to generate shear-waves of known characteristics and location (frequency 250-750 Hz, amplitude 10-70 μm). Displacement of the bead, monitored with a laser transducer (AR700, Schmitt Industries, Oregon, USA) were sampled at 10kHz (Powerlab 16/35, AD Instruments, Oxford, UK) and displayed in real time with associated *Labchart* software. Circumferential and axial displacements at the gel surface were mapped by tracking the movement of carborundum micro-particles on the surface with a video camera (MotionBLITZ EoSens Mini, Mikrotron GmbH, Unterschleissheim, Germany) running at a frame rate of 10 kHz. Particles were tracked by custom written software. For the steady flow experiments the model consisted of a cuboidal gel, length 400, width 150, height 100 mm), with an embedded tube (i.d. 4.5mm, wall thickness 0.15 mm) representing a major coronary artery (20 mm below the surface). The flow system was filled with water or 40% glycerol/water mixture. Pressure in the tube was measured with 2 catheter-tip manometers (6f gauge, Gaeltec, Dunvegan, Scotland), flow with a cannulating ultrasonic transducer (Transonic Systems, Maastricht, The Netherlands) and surface movement, with up to 6 miniature 3-axis MEMS accelerometers (ADXL 337, Analog Devices, Norwood MA).

RESULTS AND DISCUSSION

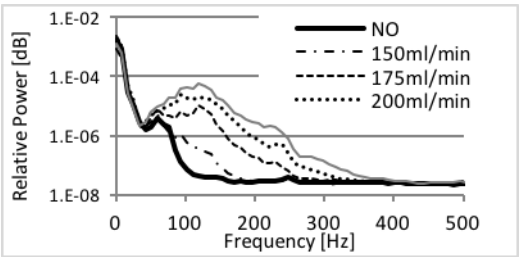

Figure. Typical set of power spectra for various mean flow rates, derived from the steady flow experiment in which, in this instance, the tube, fitted with an axisymmetric stenosis occluding 70% of the lumen area, was embedded 20 mm below the gel surface.

The accelerometer was placed on the gel surface 10 mm downstream from the centre of the stenosis. The peak power for this combination of stenosis, tube and accelerometer position was seen at a frequency of between 100 and 150 Hz (in keeping with previous observations in man), increased monotonically with flow rate, although at flow rates below 150 ml/min no significant signal was seen in this frequency range (data not shown). Some variation in the magnitude and frequency of the peak power was seen with different degrees of stenosis and different accelerometer positions. These data are currently being processed to map in detail the acceleration field on the gel surface.

At a frequency of 256Hz, the mechanical vibrating source measurements in the cuboidal gels gave wave speed values of 7.33 ms^{-1} ± 1.17 (SD) for agar and 13.0 ms^{-1} ± 1.42 (SD) for PVA. Measurements using piezo-electric vibrators to provide data over a wider frequency range are imminent.

CONCLUSIONS

The methods described above have yielded repeatable data, forming a reliable experimental basis for the computational arm of the project. Future measurements on more realistic chest phantoms with waves generated by pulsatile flow in stenosed tubes will simulate real arteries in a real chest.

INTRODUCTION

The skin aging process, e.g. wrinkles and saggings, caused by not only aging but also ultraviolet irradiation, could be related to the depression of metabolic function. The microcirculation system should be an important guideline of skin care for the anti/smart-aging. Rheological behavior of interstitial in epidermal and dermal tissue, including blood micro-circulation, can vary skin mechanics in micro scale, i.e. visco-elasticity. Therefore, an *in vivo* quantitative measurement of capillary blood flow velocity is crucial to clarify their properties. The purpose of this study is to visualize the tomographic flow velocity of red blood cell in capillaries below human epidermal skin using Optical Coherence Doppler Velocigraphy, i.e. OCDV. This is constructed on a low coherence interferometer, which is based on Hilbert transform and adjacent auto-correlation. The paper presents the result of applying OCDV to human forearm skin inside, it was possible to provide blood flow velocity of capillary vessels non-invasively as an *in vivo* micro-tomographic imaging.

METHODS

Figure 1 shows the schematic of experimental setup based on Michelson interferometer with the rapid scanning optical delay (RSOD) line. In reference arm, RSOD based on a grating-curved mirror with a resonant scanner is instrumented to achieve high-speed axial scan, e.g. 4 kHz and enable the compensation of group-delay dispersion. This is constructed around an optical fiber interferometer based on Time-domain OCT [1]. A super luminescent diode (SLD) with a center wavelength of 1340 nm and bandwidth of 102 nm is used as a light source. The light passes through a fiber coupler from SLD, split by a fiber coupler to the reference arm and the object arm, and coming back from each arms, can be interfered there to be the interference signal. This is received by a photodetector, and then is recorded through an analog filter by a high speed AD converter. The interference signal can be frequency-modulated, i.e. Doppler frequency, by moving red blood cells through capillary vessels. Hilbert transformation is applied in frequency domain to the depth-scanning signal so as to maintain higher frequency resolution. The depth-profile of a phase change between some adjacent

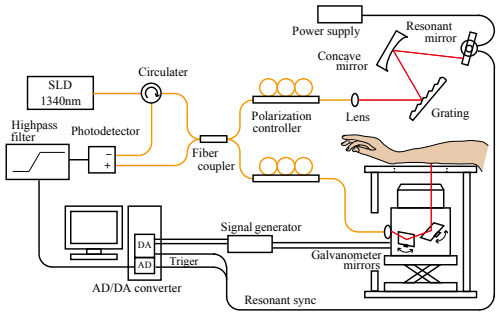

Fig. 1 OCDV system with RSOD scanning system

axial scanning signals is calculated locally by an adjacent auto-correlation technique, which can be converted to Doppler velocity. The optical specification, e.g. the depth and horizontal resolution, frame rate, are Δz = 7.5 μm, Δx = 5.0 μm and 13.1 fps, respectively. In order to validate OCDV system, this was *in vivo* applied to human forearm skin under the conditions of control and avascularization using a tourniquet.

RESULTS AND DISCUSSION

Figure 2 shows a morphologic OCT images of forearm skin tissue. From 40 tomographic images of Doppler velocity obtained by OCDV, the maximum velocity is projected pixel by pixel to a *xz* cross-section. These maximum intensity projection images (MIP) are overlapped to OCT images, respectively. A cross-sectional imaging of MIP is found to display networks of capillary blood vessels inside dermal tissue, where low intensities are distributed correspondingly in a morphological OCT image. Additionally, it was confirmed that blood velocity further decreased in upper dermis under avascularization shown by Fig. 2 (b) than control condition shown by Fig. 2 (a). It is, therefore, considered that OCDV system could non-invasively and tomographically diagnose Doppler frequency modulated by red blood cells moving through capillary vessels, i.e. microcirculation. In the future, it is highly expected that OCDV system can lead to the elucidation of skin mechanism, metabolic function, neo-vascularization and drug efficacy.

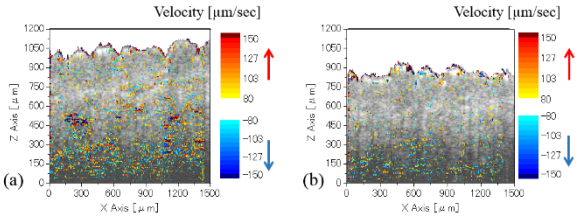

Fig. 2 Maximum intensity projection images of Doppler velocity overlapped to OCT images of human forearm skin under the conditions of control (a) and avascularization (b)

CONCLUSIONS

This paper presents the OCDV system, which was *in vivo* applied to human forearm skin under the conditions of control and avascularization. In summary, OCDV system is quite useful for a micro-tomographic imaging of blood flow velocity of capillary vessels inside skin.

EFFECT OF LEAFLET ORIENTATION ON VORTEX DYNAMICS IN FLOW THROUGH AORTA WITH PROSTHETIC BI-LEAFLET MECHANICAL HEART VALVE

Satheesh Kumar and S.D. Sharma
Cardio Vascular Flow Dynamics Laboratory,
Aerospace Engineering Department, IIT Bombay

INTRODUCTION

The present numerical investigation is carried out to understand influence of orientation of prosthetic Bi-leaflet Mechanical Heart Valve on flow pattern through human aorta during different phases of cardiac cycle. The focus is on swirling flow evolving due to curvature and twist affecting distribution of blood to various branches.

METHODS

A 3D model of adult aorta was constructed based on averaged dimensions obtained from various clinical data. Systematic numerical simulation was performed for three orientations of the valve (0°, 45°, 90° between the valve hinge line and cardiac long axis plane) using ANSYS Fluent - a finite volume code. Transient flow simulation used a fluid with density and viscosity same as that of blood. Duration of systolic phase of the entire cardiac cycle, when the blood flows through aorta, was considered. A total of ten such cycles were simulated to obtain the time independency as well as the repeatability in results.

RESULTS AND DISCUSSION

Plots of velocity vectors and iso-vorticity contours in four planes (P1, P2, P3, P4) from Sino-Tubular junction to the aortic isthmus shown in (i) & (ii) of Fig.1 elucidate the complex swirl pattern with contra-rotating stream-wise vortices for peak flow at 90° orientation as shown in the figure. From P1 to P2, the vortex filaments appear to twist about aortic axis by 90° and despite outflow from O1, O2 and O3, the flow possesses significant vorticity at P4.

Iso-vorticity surfaces obtained at various time steps of the aortic cycle shows the complex nature of swirling flow through the aortic arch. Flow appears to be symmetric having contra rotating-vortex filaments about the central plane of aorta with the 90° orientation where as the 45° orientation has the maximum effects of secondary flows adding disturbance to the flow. During the deceleration phase the flow appears to be highly disturbed in aortic arch having its maximum effect in 45° orientation with similar amount of reverse flow in branches for all the orientations.

Mass flow rates from outlets of aorta (Brachiocephalic trunk-O1, Left common carotid artery -O2, Left subclavian artery - O3, Descending aorta-O4) at three instants during acceleration, peak and deceleration stages of systolic phase are tabulated. Outflow from O1 shares about 19%, 22% and 9% of the total mass inflow during acceleration, peak and deceleration respectively whereas from each of O2 and O3 the share is between 4-5% with marginal effect of BMHV orientation. Interesting to note that while during acceleration and peak, about 30% of the blood supply goes to upper body, it reduces to about 20% during deceleration.

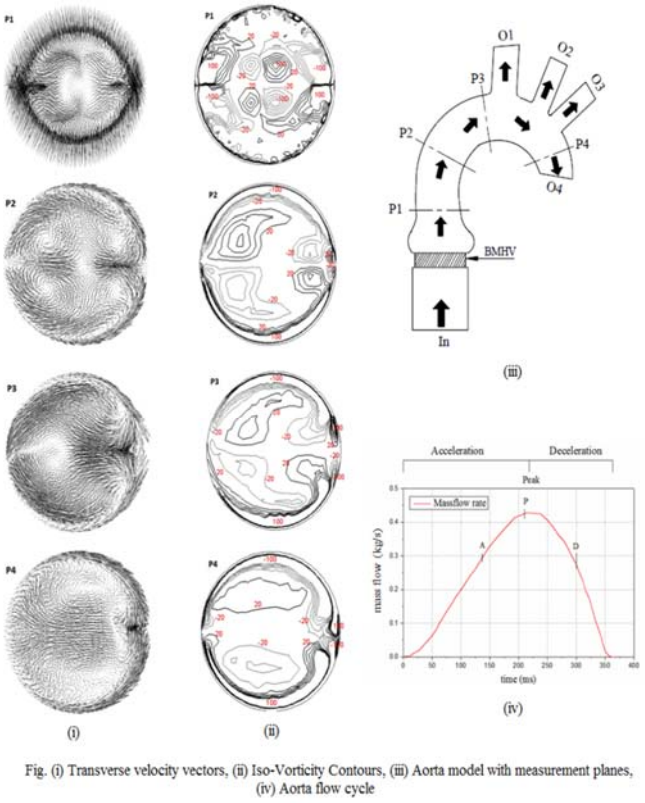

Fig. (i) Transverse velocity vectors, (ii) Iso-Vorticity Contours, (iii) Aorta model with measurement planes, (iv) Aorta flow cycle

Figure 1: Transverse Velocity and Iso-Vorticity contours at various cross sectional planes of aorta during peak flow (i) Transverse velocity vectors, (ii) Iso-Vorticity contours, (iii) Schematic aortic flow with measurement planes, (iv) Aortic flow profile

CONCLUSIONS

Complexity of swirling flow and influence of the BMHV orientation on the pattern including the distribution of mass flow rate through different branches of aorta are seen in the present study. There is need to assess ensuing effects on haemodynamic and blood cells.

ACOUSTIC LOCALISATION OF CORONARY ARTERY STENOSIS: COMPUTATIONAL ASPECTS

INTRODUCTION

Disturbed blood flow in the wake of an atherosclerotic coronary stenosis will, for a range of percentage lumen occlusions, impart oscillatory tractions to the artery wall which then travel to the chest surface. The resulting acoustic signal (or *bruit*) is very weak but nevertheless detectable through sensing devices and, in rare cases, through cardiac auscultation. The signal is generated in diastole, typically confined to within 50-500 Hz and, therefore, separated in frequency or time from most 'normal' heart sounds.

The detection and localization of the source of this surface signal has the potential to provide a relatively low-cost, non-invasive routinely deployable screening or diagnostic device for coronary artery disease. We envisage that a patient, in breath hold, has chest surface readings collected for around 10 secs, and that these signals are then analysed off-line with the results reported back within hours.

We will describe a proof-of-concept investigation into using computational mathematics, underpinned by experimental verification, to prototype such a device. An accompanying presentation by SE Greenwald ('Phantom Measurements') will describe: (i) experimental characterisation of an agar gel TMM (tissue-mimicking material); and, (ii) generation of benchmark acoustic signals from a mechanical oscillator and from disturbed flow in a stenosed artery phantom – each embedded in the TMM.

METHODS

The bruit is weak and so with the patient assumed to be in breath hold we assume that the signal's waves are a small disturbance that can be modelled with the linear theory of continuum viscoelasticity. In a region $\Omega \subset \mathbb{R}^d$, and for times $t \in (0,T)$, the mathematical problem is to find the displacement vector $(u_i)_{i=1}^d$ such that $\rho\ddot{u}_i = \sigma_{ij,j}$ with initial data and boundary conditions and with implied summation over repeated indices. Here $(\sigma_{ij})_{i,j=1}^d$ is the symmetric stress tensor given in terms of damping and stress relaxation tensors, C and D, and the (linear) strain tensor $\varepsilon_{ij}(\mathbf{u})$ by

$$\sigma_{ij}(\mathbf{u};t) = C_{ijkl}\varepsilon_{kl}(\dot{\mathbf{u}}(t)) + D_{ijkl}(t)\varepsilon_{kl}(\mathbf{u}(0)) + \int_0^t D_{ijkl}(t-s)\varepsilon_{kl}(\dot{\mathbf{u}}(s))\,ds.$$

This system is implemented in software using both space-time Galerkin finite element approximations as well as the more traditional 'method of lines'. It is a 'forward problem' in that if the surface traction (the stenotic disturbance for example) is given, then the surface displacement is determined by the unique solution of the system. We couple this forward problem to an inverse solver which, given the surface signal, attempts to localise its source.

RESULTS AND DISCUSSION

We will report on three aspects of this *proof-of-concept* investigation.

1. Novel computational methods and results for approximating the forward problem given above.
2. Initial results for the inverse solver's performance for an *in silico* rig of cylindrical TMM through which a simulated stenosis signal is transmitted from its central bore to its surface. The vertical position of the source of the signal is sought. See Figure 1.
3. A new approach to signal source identification based on sequential Monte Carlo (or particle) filtering. In this approach a patient's current (at time t_i) unobservable thoracic state, x_i, is related to the previous, x_{i-1}, through the physics, f, of the thorax via $x_i=f(x_{i-1})+v$ where v is unavoidable system noise. The thoracic state is related to measurement via a model g, such that $y_i=g(x_i)+w$, for which y_i (with noise w) is observable; x_i is then extracted. The model is constructed from training data.

The companion presentation will describe the *in vitro* realisation of the configuration described in item 2. The material in item 3 is under current development – we will give an up to date resume of it.

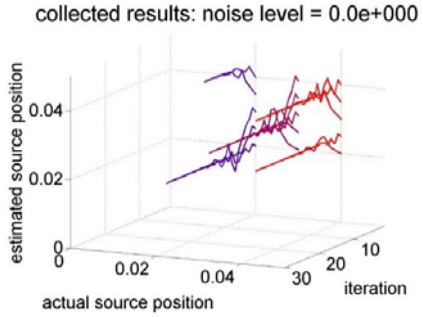

Figure 1: Sample inverse solver output. The estimated source location at each iteration is on the vertical axis and the true position on the main horizontal axis. The procedure seems well-posed unless the initial guess is very poor.

CONCLUSIONS

Our long term aim is an inexpensive technique that, given the chest surface signal, can non-invasively diagnose the presence of coronary artery disease. These initial results are encouraging but there is much yet to be done.

BLOOD FLOW MODELLING THROUGH AN ELASTIC STENOSIS

[1] César Alegre Martínez, **Donal McNally**, Kwing-So Choi and Outi Tammisola
[1]University of Nottingham
Corresponding author email: donal.mcnally@nottingham.ac.uk

INTRODUCTION

Arterial stenosis is a medical condition that can lead to myocardial or renal infarction, or stroke. It consists of a local narrowing of the artery diameter due to the thickening of the artery wall as a result of an accumulation of fatty substances (known as plaque) in the inner layer [1].

The plaque may rupture at some point, inducing the formation of a blood clot, and move into the circulation. This can block the supply of blood to the organs and become a life-threatening condition. Typical locations where plaque may appear are the carotid artery (near the bifurcation), coronary arteries in the heart, and renal arteries. By using numerical simulations of the blood flow as well as the solid deformation, we aim to shed some light on the process of plaque rupture.

METHODS

The problem is modelled taking into account fluid-structure interaction effects: The Navier-Stokes equations are applied to the incompressible blood flow, and a linear elastic model is used for the artery wall. The systems are coupled by imposing appropriate boundary conditions to the fluid, the solid, and the interface.

Different inflow velocity profiles are presented: on the one hand, a simple steady case and, on the other hand, two time-dependent pulsatile velocities (blood flow is naturally unsteady, due to its dependency of the heart rate). In both cases, the velocity profiles are parabolic at the inlet cross-section of the artery. For the plaque modelling, two different situations have been implemented: a linear elastic solid is used to simulate a hard plaque; while a liquid plaque model is applied to simulate a soft plaque case.

Simulations have been performed using COMSOL Multiphysics®. The software is based on the finite element method and uses a second order discretisation for the flow velocity field and first order for the fluid pressure field.

RESULTS AND DISCUSSION

Results are shown for an axisymmetric configuration, representing blood flow through an idealised stenosed carotid artery.

The stenosis follows a sinusoidal shape that has been adapted from former studies [2, 3]. The minimum diameter is 0.5D, where D denotes the inlet diameter. This 50 % reduction in diameter leads to a 75 % area constriction.

To analyse the influence of the fluid viscosity and velocity, three different Reynolds numbers have been tested as well.

Different variables are presented in this work. Focusing on the flow field, recirculation zones as well as vorticity and streamlines are also plotted for several cases. On the solid side, one important magnitude is the von Mises stress in the plaque membrane. For example, the difference of the stress distribution between the liquid and solid plaque cases for the same inflow condition (Figure 1).

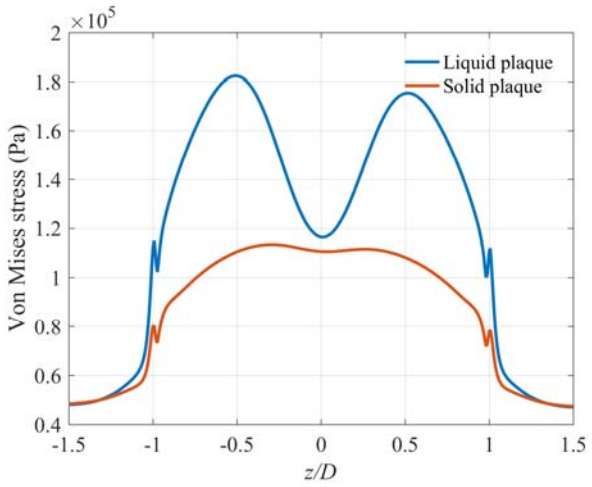

Figure 1: Von Mises stress in the plaque membrane along the stenosis region for the steady inflow condition. Both liquid and solid plaque cases are shown (z/D denotes the non-dimensional axial coordinate).

Results show the effects of the elastic wall and plaque modelling on the flow field. The difference in the stress distribution between the liquid and the solid plaque could give a way to detect if a plaque is either soft or hard.

CONCLUSIONS

Simulations of incompressible flow through an idealised axisymmetric stenosed geometry have been performed in order to model the blood flow through a partially blocked artery. Three different inflow conditions have been tested. Wall displacements are found to be mainly driven by stream-wise pressure variation and not by wall shear stress. In addition, the axial distribution of the von Mises stress along the plaque membrane depends greatly on the plaque composition, and to a lesser extent, on the inflow conditions.

BIOMECHANICAL PERFORMANCE OF RUGBY HEADGEAR IN LINEAR IMPACTOR TESTS

[1,2]Andrew S McIntosh and [1]**Declan A Patton**
[1]Australian Collaboration for Research into Injury in Sport and its Prevention (ACRISP), Federation University Australia
[2]McIntosh Consultancy and Research

INTRODUCTION

In 1993, the International Rugby Football Board, currently known as World Rugby, allowed the use of soft-shell padded helmets in rugby union to protect the scalp and ears from lacerations and abrasions, which will hereinafter be referred to as 'headgear'. Laboratory and epidemiological research has demonstrated that commercially available headgear is currently ineffective in reducing the risk of concussion [1]. World Rugby mandates specific headgear design regulations and performance requirements, the latter of which states that 'the peak acceleration of impacts delivered to test locations shall not be less than 200 g' for drop tests from a height of 0.3 m [2], which is in contrast to all performance-based standards for helmets. Injury criteria based on linear acceleration are currently used in sports helmet performance standards with tolerance limits that relate to observable focal injuries, e.g. skull fracture. However, concussion is a diffuse head injury, which is thought to be associated with stresses and strains of brain tissue caused by rotational motion of the head [3]. From a study of head impacts in unhelmeted collisions sports, McIntosh et al. [4] reported linear and angular tolerance limits of 65.1 g and 3958 rad/s^2, respectively, for a 50% likelihood of concussion and 88.5 g and 6633 rad/s^2, respectively, for a 75% likelihood of concussion.

METHODS

The impact performance of six headgear models was evaluated: two prototype models and four commercially available models. Impacts were delivered by a spring-driven linear impactor, which was previously used to investigate the impact performance of boxing headgear [5]. The impactor comprises a steel shaft, uniaxial force link, steel disc and standard rubber pad. The impactor was used to impact a Hybrid III head-neck system, which was mounted on an adjustable stand. The Hybrid III headform is instrumented with a tri-axial accelerometer array, which allows the measurement of linear and angular kinematics in the sagittal, coronal and transverse planes. Each model was impacted to the temporal region of the head at 4.0 m/s, which is within the range of closing speeds for head impacts in rugby union [6]. Peak linear acceleration (PLA) and peak angular acceleration (PAA) were used to assess impact performance.

RESULTS AND DISCUSSION

Compared to the bare headform condition, prototype headgear models reduced PLA by over 30% (Table 1). Prototype A had the best linear impact performance with a PLA below the tolerance limit of 65.1 g for a 50% likelihood of concussion. In contrast, PLA results for commercially available models were all above the tolerance limit of 88.5 g for a 75% likelihood of concussion. Commercially available models reduced PLA by less than 15% compared to the bare headform condition.

Table 1: Headform accelerations for 4.0 m/s impacts.

Headgear model	Peak acceleration	
	Linear [g]	Angular [rad/s^2]
Bare headform	107.2	7067
Prototype A	64.9	4825
Prototype B	75.3	5550
Steeden	90.7	6823
Canterbury	91.0	5796
Kooga	92.7	6478
Madison	99.8	6823

Prototype models had the best angular impact performance; however, improvements over commercially available models were less pronounced. Compared to the bare headform condition, prototype models reduced PAA by over 20%, whereas most commercially available models had PAA reductions of less than 8%. Prototype models and two commercially available models were able to reduce PAA below the tolerance limit of 6633 rad/s^2 for a 75% likelihood of concussion. However, no model was able to reduce PAA to below the tolerance for a 50% likelihood of concussion.

CONCLUSIONS

Performance tests using a linear impactor to impact a Hybrid III head-neck system allowed the measurement of angular headform kinematics, which are associated with concussion.

Prototype headgear models were found to out-perform commercially available models in linear impactor tests. Therefore, the current study supports the conclusions of McIntosh et al. [7]: small modifications to current headgear designs can achieve large improvements in impact attenuation performance.

Commercially available headgear design regulations and performance requirements mandated by World Rugby should be revised to encourage, and not inhibit, headgear designs, which have the potential to reduce the risk of concussion.

A "HEAD-DOWN" POSITION INCREASES CERVICAL SPINE LOADING IN HEAD FIRST IMPACTS: A COMBINED IN-*VITRO* AND IN-*SILICO* APPROACH

[1]Elena Seminati, [1]Ezio Preatoni, [1]Grant Trewartha, [1]Andreas Wallbaum and [1]**Dario Cazzola**,
[1]University of Bath
Corresponding author email: d.cazzola@bath.ac.uk

INTRODUCTION

High energy sport collisions, such as tackles occurring in Rugby Union, have been associated with chronic degeneration of cervical spine structures, impaired cervical function and acute cervical spine injuries [1]. Hyperflexion and buckling have been indicated as the primary injury mechanisms. Spinal injuries has been investigated using different methodologies, but none of them alone can fully elucidate the link between the external loads applied to the head and the internal stresses experienced at vertebral level. In this study, we propose a combined in-*vitro* and in-*silico* approach to analyse the mechanism of cervical spine injuries during head-first impacts in rugby. The application in this study is to investigate the effect of head and neck posture on cervical spine loading in a misdirected rugby tackle, where contact unintentionally happens through the head (i.e. "head first" collision).

METHODS

An anthropometric test device (ATD) (Hybrid III, Humanetics, Germany) was used to simulate the head and neck of the tackling player. The dummy head was instrumented with a six-axis upper neck load cell (at C1 joint level) and was attached to a rigid frame so that it could replicate three different neck positions (Figure 1): neutral (0°), head-down (-22°), and head-up (+22°). Repeated simulated tackles were generated using a 40-kg punch bag making contact against the ATD at 2 different speed ranges (low: 2.0-2.5 m/s) and (high: 3.1-3.6 m/s). Ten repetitions were recorded for each speed condition and ATD orientation, 60 trials in total. Kinematics of the head/neck system was captured through a 16-camera motion capture system (Oqus, Qualisys, Sweden) at 250 Hz, whilst force and torque data were sampled at 500 Hz. Kinematics and external load data were used as input for inverse simulations in OpenSim 3.3. The OpenSim Rugby Model (https://simtk.org/projects/csibath) was scaled, and a pipeline including inverse kinematics, inverse dynamics, and joint reaction analysis was run for estimating the joint reaction forces at intervertebral joint level. Mean values of forces and moments variables were calculated from ten trials for each condition. ANCOVA (covariate = bag speed) and effect sizes were used to assess the effect of the different tackle conditions on the loads applied to the neck.

RESULTS AND DISCUSSION

Dummy head measurements showed that low speed tackles generated 37% lower peak impact forces (1.61 ± 0.29 kN) than high-speed tackles (2.61 ± 0.09 kN). Peak flexion/extension external moments measured during high-speed impacts trials were 54.5 ± 5.7 and 45.3 ± 4.4 Nm respectively for head-down and head-up positions, with values close to the pain thresholds reported in the literature (60 and 45 Nm for flexion and extension) [2]. Of the total external force applied on the neck (2.37 ± 0.18 kN) 75% was compressive, and compression was substantially higher in head-down than in neutral (by 13%) and head-up orientations (by 17%).

Musculoskeletal simulations showed that the cervical spine vertebrae underwent high compressive forces at all levels (> 300 N). However, anterior shear forces and flex/extension moments at C2/C3 level reached the maximal absolute values in the head-down condition (Figure 1). The combination of high compressive forces and extension flexion moments at C2/C3 seems coherent with the hypothesis of buckling as the potential injury mechanism during head-first impacts in tackles. High repetitive stresses at this cervical spine level can cause the development of chronic degeneration pathologies as observed in asymptomatic Rugby Union players [1].

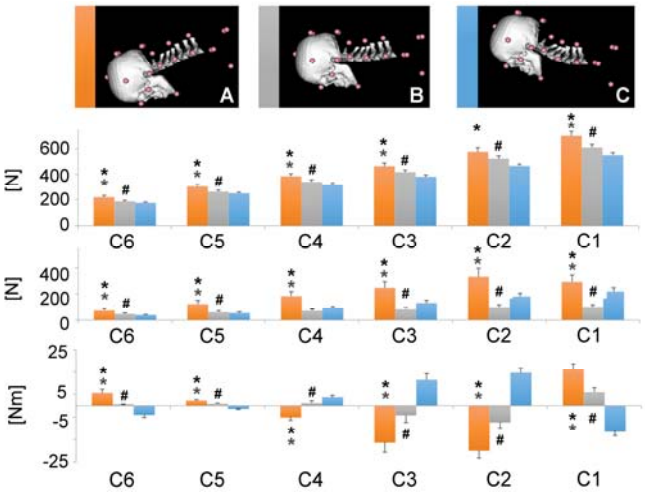

Figure 1: Intervertebral joint reaction forces, top to bottom: compression force, anteroposterior force and flexion/extension moments (mean and SD) for 6 vertebral joints (C1-C6) and for three different ATD positions showed in panel A, B and C, during high speed impacts.

CONCLUSIONS

Our findings support the idea that: 1) an integrated in-*vivo* and in-*silico* analysis of simulated head-first impacts provides insight into how misdirected loads applied to head/neck structures distribute at the level of the individual vertebrae; 2) a neutral or head-up position may be preferred in the scenario of unintentional head-first impacts in rugby tackles, which may occur in this open environment. 'Head-up' technique aligns with current Rugby Union coaching recommendations.

BIAXIAL MECHANICAL RESPONSE OF PORCINE SPINAL DURA MATER

[1] **Atsutaka Tamura**, [1] Yuki Kawaguchi, [1] Yuta Sone and [1] Takao Koide
[1] Tottori University
Corresponding author email: a-tamura@mech.tottori-u.ac.jp

INTRODUCTION

Accurate mechanical characterization of the spinal dura mater is of importance to predict neck injury due to traffic accidents and contact sports, because these data is crucial for formulating the constitutive model with a set of robust parameters. Mechanical response of soft biological tissues is generally dependent on the direction of the applied load. In specific, as for an incompressible biological material such as membrane, the analysis of planar mechanical behavior can be substantially complicated by its inherent tissue anisotropy, structural heterogeneity and artificial inelastic change in the specimen geometry resulting from slight misplacements of the grippers that commonly occur during testing. In the present study, we newly developed an equi-biaxial tensile tester for soft biological materials, which will be useful for characterizing mechanical data of membranous sample, e.g. spinal dura mater, subjected to relatively large deformation under moderate-to-subimpulsive loading conditions.

METHODS

Porcine spinal cords (N = 4) were harvested immediately after sacrifice at a local abattoir and carried back to the laboratory with an ice-packed box. Twenty-eight square samples of 15 x 15 mm with a mean thickness of 0.27 ± 0.12 mm were carefully cut out from the spinal dura mater located at the thoracic portion using surgical scalpel with a distinction of longitudinal and circumferential directions. Samples were then mounted in our custom-made biaxial tensile tester (Fig. 1) so that the longitudinal and circumferential directions were in line with each of the biaxial stretching displacements. To avoid edge effects and shear effects, a preliminary study was performed, i.e., a finite element (FE) model was built in RADIOSS ver. 13 (Altair, MI, USA). We simulated a displacement-controlled biaxial test of a square sample composed of membrane elements, in which orthogonal material anisotropy was assumed, and confirmed that the forces were almost equally distributed between each suture line, while uniformity of the strain fields was obtained around the sample center. In a series of actual experiments, LabVIEW-controlled biaxial displacements were imposed on the sutured sites at four adjacent sides of the specimen as given in a preliminary FE analysis. The applied traction forces were evenly distributed per side by the three attached tethers, and each of the tethers was loaded along its length axis. Nine markers were placed on the specimen surface such that they define four squares around sample center, spaced 1.5 mm apart. After four cycles of preconditioning was conducted, an equi-biaxial stretch was applied at the rate of 1 mm/s. When a specimen failed at the grips, mechanical test was stopped. The specimen cross-sectional area was assumed to be rectangular, i.e., the experimental stress was calculated as force divided by an undeformed section surface which was defined by the initial specimen thickness and the grip-to-grip initial section width. All the experiments were completed within 24 h after sacrifice.

RESULTS AND DISCUSSION

Based upon the nominal stresses in the longitudinal and its perpendicular directions, Young's modulus was calculated for small as well as large strain regions (n = 14 for each direction). For small strain region (0–0.05 strain), Young's modulus resulted in 0.74 ± 0.63 and 1.23 ± 1.10 (mean ± SD) MPa for the longitudinal and circumferential directions, respectively. For large strain region (0.05 strain to failure), Young's modulus resulted in 4.37 ± 1.62 and 6.04 ± 3.39 (mean ± SD) MPa for the longitudinal and circumferential directions. On the other hand, specimens failed at 0.20 ± 0.03 and 0.12 ± 0.03 (mean ± SD) strains in the longitudinal and circumferential directions, respectively. Although the used animal species are different, these failure strain values were smaller than those reported by Persson et al. [1], while they were larger than the ones obtained by Shetye et al. [2]. In the current study, only normal (longitudinal and circumferential) forces were measured. In most biaxial testing, however, it is likely that the resultant lateral forces will not be zero and a shear stress will be induced, which will complicate the handling of such a planar biological specimen. This shear effect is beyond the scope of this pilot study at this moment. Nevertheless, we need to take into account of it in the future work. In conclusion, an equi-biaxial tensile tester was newly developed and biaxial displacement was applied to investigate mechanical properties of the spinal dura mater. Although the sample size is still limited, our results implicate that mechanical strength of the dura mater is more compliant and tough in longitudinal direction than that in circumferential direction.

SLED TESTS FOR THE ANALYSIS OF HEAD AND NECK INJURIES DUE TO HEAD-ROOF IMPACTS IN MILITARY VEHICLES

[1] **Sheridan Laing,** [1]Mark Jaffrey and [1]Melanie Franklyn
[1]Defence Science and Technology (DST) Group
Corresponding author email: sheridan.laing@dsto.defence.gov.au

INTRODUCTION

When a military vehicle is subjected to underbelly (UB) blast loading, occupants can sustain traumatic head and neck injuries due to head impacts with the vehicle roof [1]. The severity of head and neck trauma can be influenced by a number of factors including the impacting velocity and mass of the occupant, the use of a helmet and the roof impacting surface. In previous research, impacts were performed with a free motion headform (FMH) [2]. When a military helmet was worn, the FMH head injury criteria, HIC(d), threshold of 1000 was found to be exceeded at an impact velocity between 6 and 7 m/s. Furthermore, the injury risk was similar between the tests with and without roof foam, suggesting that wearing a helmet is more important for head injury mitigation than the use of roof foam. The previous study was limited in that neck injury potential was not factored. Additionally, although the HIC(d) is intended to correct for the inertia of the body of the anthropomorphic test device (ATD), full-body ATD tests are required to confirm these findings. The aim of this preliminary study was to quantify the risk of head and neck injury to combatants due to head-roof impacts using a full-body ATD under various velocity and body-borne mass conditions.

METHODS

Sled tests were used to replicate the vertical loading of a vehicle occupant during a head-roof impact. Although there are a number of scenarios during which head-roof impacts may occur during an UB blast event, the focus of this study was head impacts due to the relative motion of the occupant and the vehicle hull due to looseness of the harness. An FAA 50th percentile ATD was positioned horizontally (i.e. lying supine, with knees bent) on two layers of Teflon sheeting on a flatbed sled. To mimic vertical loading, the sled was accelerated until travelling at the desired velocity, at which point the crown of the ATD impacted a rigid barrier, and the sled continued to slide beneath the barrier. The ATD was free to move during the impact as the Teflon sheeting minimised any friction between the ATD and the flatbed sled. For each test the ATD was wearing a combat uniform, military helmet and body armour (BA).

Tests were performed at three impact velocities: 1, 3 and 5 m/s, chosen based on analysis of live-fire blast events and the previous FMH study results [2]. In order to quantify any influence of greater body-borne mass on the potential for head and neck injury, two BA configurations were used: $BA_{Baseline}$ (7.2 kg) and BA_{Heavy} (20.4 kg). The BA_{Heavy} condition was only tested at 1 m/s due to the anticipated greater injury risk and included an instrumented BA pouch mass to compare the relative acceleration of the ATD chest and the BA mass. All tests were performed three times. The ATD head and neck outputs were assessed against injury assessment reference values (IARVs). The HIC, peak neck axial compression (-Fz) and peak neck extension moment at the occipital condyles (-MOCy) results are shown herein with thresholds of 1000, -4 kN and -97 Nm respectively.

RESULTS AND DISCUSSION

Twelve sled tests were performed during this preliminary test series. The HIC was well below the threshold value for each all conditions tested, however the neck IARVs were exceeded for impacts at 3 and 5 m/s (Figure 1). The peak -Fz values occurred 7 to 15 ms before the peak -MOCy values for all impacts. Linear regression analysis of the $BA_{Baseline}$ results indicated that the -Fz threshold of -4 kN would be exceeded at an impact velocity of 1.7 m/s ($R^2 = 0.98$) when $BA_{Baseline}$ is worn.

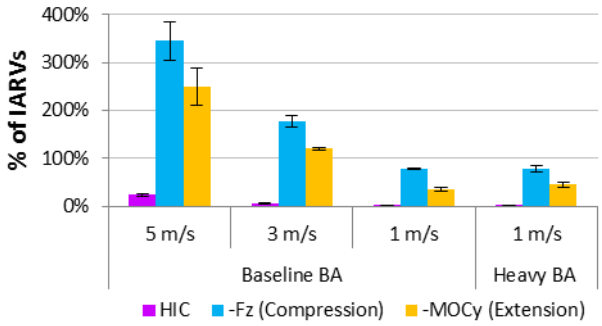

Figure 1: Mean HIC and peak neck compression and extension values for all tests with SD shown as error bars.

The addition of the BA_{Heavy} had little effect on the HIC or peak -Fz values at 1 m/s; however the mean peak -MOCy was ~15 Nm greater with the heavy BA, yet still below the IARV. The mean peak acceleration of the BA_{Heavy} mass was 3.4 g lower and occurred 30 ms later, than the mean ATD chest acceleration, indicating decoupling of the body-borne mass and the ATD.

The mass of the FAA 50th percentile ATD is equivalent to only the 25th percentile Australian Army male combatant [3], thus further tests will be used to examine the effect of varying occupant mass to quantify the risk to heavier occupants. The calculated HIC values were much lower than the HIC(d) values predicted in the previous FMH study [2]. This difference also requires further investigation.

CONCLUSIONS

The current preliminary study of head impacts replicating UB blasts events shows that neck IARVs are exceeded at lower velocities than the HIC. Initial results indicate that for impacts at 1 m/s, a higher BA mass does not result in a considerably greater injury risk. Further research is required to explore the risks associated with increased occupant mass.

CHARACTERISTICS OF HELMET IMPACTS IN YOUTH ICE HOCKEY

[1,2,3]**Declan A Patton**, [1]Maciek P Krolikowski and [1,4]Carolyn A Emery

INTRODUCTION

Helmets used in youth ice hockey are required to meet the same performance standards as adult ice hockey helmets, which are based on adult impact data [1,2]. The CSA and ASTM ice performance standards require an ice hockey helmet to be drop tested onto a rigid steel anvil from a height of 1.0 m at several sites: front, front boss, side, rear, rear boss and crown.

Few studies have investigated helmet impacts in youth ice hockey [3-5]. Mihalik et al. [3] reported that impacts to the crown of the helmet were more likely to be greater than 80 g in magnitude. More recently, Teel et al. [5] reported that impacts greater than 45 g were more likely for impacts to the rear and crown of the helmet; however, impacts greater than 4 krad/s^2 were more likely for rear and side helmet impacts. Hutchison et al. [6] analysed footage of 197 National Hockey League (NHL) concussion cases, of which almost all involved contact with an opposing player (88%) with contact to the head initiated by the shoulder, elbow and gloves in 42%, 15% and 5% of all cases, respectively. Of the 158 cases involving contact with an opposing player, the lateral aspects of the head or torso were the most common body part of initial contact (58%).

METHODS

A previously compiled video database of 7260 player-to-player contact cases from 22 bantam ice hockey games was searched for all cases involving helmet contact. Identified helmet contacts were initially analysed to establish the circumstances of contact: location of contact event within rink; whether the contacted player was playing offence or defence; whether a penalty was awarded; whether the contacted player was in possession of the puck. In addition, the characteristics of contact were identified: helmet contact site and impact surface. No injury data were available.

RESULTS AND DISCUSSION

A total of 260 helmet contact cases were identified, which represented 3.6% of all player-to-player contacts at a rate of 11.8 helmet contacts per game. One third of all helmet contacts occurred to defensive players (33%), whereas 62% and 6% of helmet contacts were sustained by offensive and neutral players, respectively. Over half of all helmet contacts were sustained by players in possession of the puck (57%). Only 12% of all cases resulted in a penalty. Most cases occurred in close proximity to the boards (61%), whereas 39% occurred on open ice. Similarly, Mihalik et al. [4] reported 37% of youth ice hockey collisions occurred on the open ice, which were associated with significantly higher linear and angular head accelerations compared to collisions along the boards.

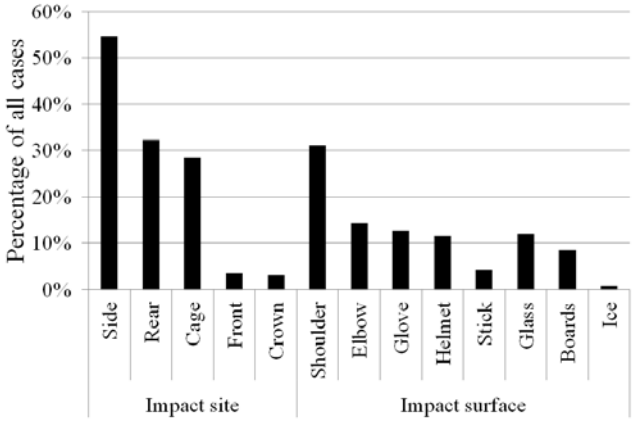

Figure 1: Characteristics of primary helmet contacts.

All 260 cases were analysed to identify helmet contact site and impact surface (Figure 1). Over half of all contacts were to the side of the helmet (55%), followed by the rear (32%), cage (28%), front (3%) and crown (3%). The body part of an opposing player was the primary impact surface in 74% of all cases with the most common being shoulder (31%), elbow (14%), glove (13%) and helmet (12%), which are similar impact surfaces to concussion cases in the NHL [6]. The impact surface was the glass and boards for 17% and 11% of all cases, respectively. A secondary contact occurred in 13% of all cases, of which 57% were to the side of the helmet followed by the rear (20%), cage (17%) and front (6%). In contrast to primary helmet contacts, the most common secondary impact surface was glass (49%) followed by body parts of opposing player (29%), boards (11%) and ice (11%).

CONCLUSIONS

Helmet contacts in youth ice hockey are typically to the side, rear and cage from padded body parts of opposing players. Further investigation with accompanying injury data is required to determine if helmet performance standards should include impacts to the cage and representative impacts by compliant surfaces to simulate impacts to padded body parts of opposing players.

THE DART THROWING MOTION

Frederick W. Werner
SUNY Upstate Medical University, Syracuse, New York, USA
Corresponding author email: wernerf@upstate.edu

INTRODUCTION

Frequently wrist motion is studied and described in the planes of flexion-extension and radioulnar deviation. However, many activities of daily living occur in a motion termed a dart throwing motion. For example hammering a nail, combing hair, wringing a washcloth, tying a shoe and pouring from a pitcher are all performed with the wrist moving from radial extension to ulnar flexion. The purpose of this review is to summarize how carpal motion is affected by the dart throwing motion, to discuss the benefit of a dart throw motion in wrist rehabilitation and to support the inclusion of this motion in research studies.

SUMMARY OF LITERATURE

Having a better understanding of the dart throwing motion and how the carpal bones move during this motion is important during surgical reconstruction of the wrist and physical rehabilitation. We and others [1-4] have shown that during both planar wrist flexion-extension and radioulnar deviation the scaphoid and lunate flex and extend. Interesting, in the intact wrist, the amount of scaphoid and lunate motion is reduced during a dart throw style of motion to be as little as 25% of the global wrist motion [1]. If there is less intercarpal and carpal/radial motion during a dart throwing motion, there may be less force between the scaphoid and lunate and between these bones and the radius. Moritomo et al therefore suggested that wrist motion during rehabilitation following distal radius fracture or scapholunate injury and reconstruction might be best performed in a dart throwing orientation of motion [4]. The actual dart throw orientation that minimizes scaphoid and lunate motion varies among wrists but can be determined by palpation of the scaphoid tuberosity during various wrist motions [5]. The orientation with the least tuberosity motion may be preferable for a physical therapist to use during rehabilitation.

The above suggested use of a dart throw motion during rehabilitation has also been based on several studies [5-6] which looked at the elongation of the dorsal and palmar portions of the scapholunate interosseous ligament (SLIL). The dart throw motion minimized SLIL elongation and therefore the force between the bones [6].

Dimitris et al [7] quantified the SLIL force during normal wrist motion. During wrist flexion-extension or a dart throw motion, the maximum SLIL force was as little as 20 N in wrists after the SLIL had been sectioned. However, these measurements were in wrists that initially had an intact SLIL. Thus, the secondary stabilizing structures could have continued to stabilize the scaphoid and lunate.

Garcia-Elias et al [8] found, in vivo, during a dart throw motion in normal wrists, minimal scaphoid or lunate flexion-extension occurred. But in patients with SLIL damage, a gap between the two bones was observed. This led them to not recommend dart throw exercises unless the joint is stabilized with wires or screws. More recently, we [9] compared the scapholunate gap magnitude during a dart throwing motion to planar flexion-extension or radioulnar deviation in wrists after the SLIL and other secondary stabilizers were sectioned. The smallest gap was during the dart throw motion, suggesting that the forces causing separation of the bones are less during this motion. Although a dart throw motion alone may not reduce the scapholunate gap, if some motion is required during rehabilitation, it should be preferably done during a dart throw style of motion.

Another potential benefit of the dart throw motion during rehabilitation is when a portion of the flexor carpi radialis (FCR) is used as an interposition graft in CMC surgery. A dart throw motion requires less FCR tendon force than other motions, thus reducing its potential to tear[10].

The importance of a dart throw motion is even seen with pisotriquetral arthritis. During a dart throwing motion greater FCU forces are required after removal of the pisiform [11].

CONCLUSIONS

The dart throw motion occurs commonly during our activities of daily living and appears to be an optimal motion following surgery and rehabilitation. This motion should be included in biomechanical assessments of various wrist injuries and treatments.

THE ROLE OF THE MUSCLE BRACHIORADIALIS IN ELBOW FLEXION - AN ELECTROMYOGRAPHIC STUDY

[1]Benoît Caufriez, [2]Pierre-Michel Dugailly, [2]Eric Brassinne and [1]**Frédéric Schuind**
[1]Department of Orthopaedics and Traumatology

INTRODUCTION

In the classical conception, the brachioradialis is a forearm supinator. The hypothesis of this study was that, at least in certain positions of elbow flexion and forearm rotation, the brachioradialis is, along with the biceps and brachialis, one of the main elbow flexors.

METHODS

Fifteen healthy male subjects accepted to participate in this monocentric interventional study. The mean age of the volunteers was 23.8 years (SD 1.8 years ; range : 19 to 26).

The electromyographic recordings were performed using the system Noraxon Myosystem 2000® (Noraxon, Scottsdale, USA) equipped with bipolar surface electrodes. The frequency of acquisition of the electromyographic signal was 1000Hz.

The elbow flexion-extension isokinetic measurements were performed using a Cybex Norm® dynamometer (Computer Sports Medicine, Stoughton MA, USA), at a speed of 60°/sec using an amplitude of 120°, starting from the anatomic zero position.

RESULTS AND DISCUSSION

The biceps, brachialis and brachioradialis muscles were electromyographically very active throughout resisted elbow flexion, in all three investigated positions of forearm rotation. At certain positions, the electromyographic activities were much higher than the maximal voluntary contraction signal. For what concerns specifically the brachioradialis, in all three forearm rotation investigated positions, the activity curves demonstrated a slow increase during the first part of elbow flexion, reaching in 73.3% of subjects its peak at the end of flexion ; in the remaining 26.7%, the brachioradialis had a flat activity without significant peak. The activity was slightly higher in supination.

This study therefore indirectly supports the idea that the brachioradialis is one of the main elbow flexors, especially when the elbow flexion is done with the forearm in supination. This observation could be important in clinical elbow and wrist surgical practice.

PREDYNAMIC SCAPHOLUNATE INSTABILITY – DORSAL CAPSULO SCAPHOLUNATE SEPTUM (DCSS): ANATOMY, BIOMECHANICAL ASPECT, LESIONAL CLASSIFICATION AND THERAPEUTIC RELEVANCE.

(1) L. Van Overstraeten, (2) E.J. Camus
(1) Erasme Hospital University Brussels Belgium
(2) Val de Sambre Maubeuge France

INTRODUCTION

There is not only one scapholunate instability but a lot of instabilities that depend on the lesional spectrum. Scapholunate instability can be acute or chronic depending on the period since onset of trauma. It may be pre-dynamic, dynamic, static depending on whether there are radiological changes or not. It may be dissociative or non-dissociative according to the presence or not of a scapholunar gap. The scapholunate stability is ensured by a set of ligamentary structures which organize anatomically and biomechanically a scapholunate (SL) complex. The scapholunate interosseous ligament (SLIOL) is the main stabilizer. However, there are capsular, extrinsic, interosseous secondary stabilizers located on the volar, dorsal or distal levels of the carpus. Their isolated or combined lesions will construct the lesional spectrum.

ANATOMY AND BIOMECHANICS

The Dorsal Capsulo-Scapholunate Septume (DCSS) is is a frenulum, linking the dorsal capsule, the dorsal radiocarpal crest and the dorsal part of the SLIOL. It probably participates to the stability of the SL space. A cadaveric study shows that the section of DCSS produces a arthroscopic SL predynamic instability ($p<.001$).

EXAMINATIONS

The treatment of the scapholunate instability will be conditioned by the repair of the various injured elements of the scapholunate complex. The diagnosis of these various and varied lesions is the first step. The arthroscanner seems to be the examination of choice to document a lesion of SLIOL (complete, partial, transfixing). The arthro-MRI gives information about the integrity (or non-integrity) of the capsular and / or extrinsic elements. Arthroscopy makes it possible to evaluate the scapholunate stability according to the shape and the enlargement of the midcarpal scapholunate space. Recently, Messina et al. specified the arthroscopic classification of Geissler and particularly its 3th stage.

LESIONAL CLASSIFICATION

It seemed important for us to assess arthroscopically the extrinsic ligament status in order to determine the level of instability in the lesional spectrum. Using a four-stage extrinsic ligament lesion classification based on the tension state and fibers continuity, we proposed arthroscopic testing of all capsular and / or extrinsic ligaments accessible by this procedure: the radiocarpal part of the radio-scapho-capitate (RSC), the long radio-lunate, the short radio-lunate, the ulno-lunate, the ulno-triquetral, and the dorsal radio-carpal. Midcarpal arthroscopy enables assessment of the mid part of the RSC, the triquetro-capitate (TC), the scapho-trapezial (ST), and the dorsal inter-carpal (DIC), and finally (with an adaptation of this classification) the DCSS.

The status of DCSS is graded in four stages according to the trampoline aspect and to the fiber attachment. (Stage S0: The DCSS presents an intact aspect. It's normally tensed when palpated with a probe. All the fibers are continuous, with a typical aspect of cathedral arches; Stage S1: The DCSS is loosened when palpated with a probe. It presents partial detachments on the distal insertion with more than 50% continuous fibers; Stage S2: The DCSS is loosened when palpated with a probe. It presents partial detachments on distal insertion with less than 50% continuous fibers; Stage S3: The DCSS is totally torn. The scope introduced through MCR can pass directly from midcarpal to radiocarpal spaces.
The lesional stage of the DCSS is correlated with the arthroscopic pre-dynamic scapholunate instability stage ($p < .01$)

THERAPEUTICAL RELEVANCE

For the chronic predynamic SL instability, a (dorsal/volar/combined) arthroscopic reinforcement can be indicated in the same time and according to this arthroscopic extrinsic testing.

PATIENT-SPECIFIC SCAPHOID REPLACEMENT OUT OF THE 3D-PRINTER. IDEA AND FIRST PRE-CLINICAL RESULTS

INTRODUCTION

In cases of non-preservable or –reconstructable scaphoid bone as after multifragmentary fracture, avascular necrosis or failed reconstruction after pseudoarthrosis, the treatment options are limited to partial wrist fusion, proximal row carpectomy (PRC) or implantation of a spacer made of metal or pyrocarbon. However, all these options alter wrist biomechanics significantly and lead to reduced grip strength and mobility. Whereas arthrodesis exhibits the risk of non-union, PRC does so for radio-capitate degeneration over time. On the other side, spacers do not prevent carpal collapse and are at risk to dislocate.

Up to now no prosthetic replacement for the scaphoid exists which includes a close-to-anatomic ligament suspension. We hypothesize that a combination of a near anatomic scaphoid replacement with ligament suspension might overcome some of the abovementioned disadvantages of current treatment options. We present a possible solution using a patient-specific scaphoid replacement with FCR-suspension to reconstruct the scapho-trapezial (STT) and scapho-lunate (SL) ligaments.

METHODS

Based on the mirrored healthy opposite wrist a prosthesis of the scaphoid was 3D-printed. The original scaphoid was removed and replaced by the prosthesis. One distally based half of the FCR was harvested and pulled through a tunnel along the longitudinal axis of the prosthesis from distal-palmar to proximal-dorsal. It was then brought back to the palmar side through a sagittal drill hole in the lunate before it was sutured back to its origin. This techniqe suspends the prosthesis and reconstructs the dorsal and palmar aspects of the SL-ligament as well as the palmar scapho-trapezial ligaments [1].

In a first series with two cadaver wrists one prosthesis made of titanium and one made of ceramics were implanted this way.

We qualitatively evaluated scaphoid-mobility under fluoroscopy to get an idea of the movements. We then took CT-scans of the wrist mounted on thermoplastic splints in five predefined positions (neutral, max. flexion, extension, radial- and ulnarduction) to evaluate scaphoid-excursions. Pre- and postinterventional CT-scans were compared with each other by evaluating the excursions of the longitudinal axes of the 3D-models of the 3rd metacarpal, scaphoid, lunate and capitate in relation to the radius. Pre- and postinterventional radio-scaphoid, radio-lunate, scapho-lunate and luno-capitate angles were compared.

RESULTS AND DISCUSSION

The qualitative evaluation under fluoroscopy showed a harmonic motion pattern of the scaphoid with flexion during wrist flexion and radialduction and extension in the opposite directions. The scapho-lunate interval remained stable in all positions.

Evaluation of the reproducibility of the mounting in thermoplast splints measured by the angle between the long axes of the radius and 3rd metacarpal showed differences between 0.25° and 5.5°. Differences of the measured angles ranged from 4.3° (neutral wrist position) to 12.5° (in extension). The extended wrist with the prosthesis showed 5.5° more ulnarduction in the splint than the one with the original scaphoid which most probably contributed to the 12.5° higher radio-scaphoid angle.

CONCLUSIONS

We found that the scaphoid prosthesis moved quite similar to the original scaphoid indicating that the anatomic shape and the suspension might help the prosthesis to move in a natural way and possibly prevent carpal collapse. Multi-cyclic testing with more specimens and different materials will be necessary to draw more reliable conclusions about these encouraging first results.

ACKNOWLEDGEMENTS

We thank the „Deutsche Arthrosehilfe e.V.“ for their support in the early phase of the project and Dr. Johannes Homa as well as Manfred Spitzbart from Lithoz GmbH, Vienna, Austria for the 3D-manufacturing of the ceramic prosthesis.

INTRODUCTION

Distal radius fractures account for around 15-20% of all fractures in extremities. Treatment options are wide, including close reduction and casting, open reduction and internal fixation, percutaneous pinning, and external fixation. Many studies have evaluated the biomechanical strength is different implants, including locking or non-locking plates, dorsal or volar plates, one plate or two plates, distal locking screws or pegs, intra-medullary nail or K-pins, internal fixation or external fixations in various fracture types. However, the results and conclusions differs between studies. Thus, in currently, there is no clear consensus as to which treatment modality is superior.

This studies is conducted to evaluate the implications that can be drawn for the clinical daily routine in operative treatment of distal radius fractures, regarding the published biomechanical studies concerning implant systems within the literature.

METHODS

A literature search was conducted. The electronic databases of PubMed, Medline and Embase were explored [1]. During the process, several characteristics such as study subject, intervention, and publish type were identified. Key words including key words and variations using wildcard: radius, wrist injury, fracture, biomechanical, mechanical and fracture fixation are retrieved [2].

After identification of 95 articles about biomechanical studies of implant systems for the treatment of distal radius fractures from a literature search, these articles were analysed concerning the specimens, the fracture model as well as the implants used. Among the 21 articles, Stiffness and load-to-failure data were extracted from the manuscripts. The quintessence was reviewed with regard to their clinical relevance.

RESULTS AND DISCUSSION

Long distal screws vs. short distal screws: Baumbach 2015, Liu 2014 and Wall 2012
Distal screws vs. distal pegs Wall 2012, Mehling 2012, Weninger and Koh 2006
One row vs. two rows distal locking screws Mair 2013, Drobetz 2013, Weninger 2011, Mehling 2010 and Koh 2006
Volar locking plates vs. intra-medullary nails Alluri 2015, Konstantinidis 2011, Capo 2009 and McCall 2007
Volar locking plates vs. dorsal locking plates Rausch 2013, Gondusky 2011, Krukhaung 2009, Trease 2005
Volar locking plates vs. dorsal non-locking plates Gondusky 2011, Kandemir 2008, Trease 2005 and Liporace 2005
Volar locking plates vs. volar non-locking plates Gondusky 2011, Müller 2006, Blythe 2006, Trease 2005 and Osada 2004
Dorsal locking plates vs. dorsal non-locking plates Boswell 2007 and Trease 2005

Table 1: Studies included for meta-analysis.

Table 1 showed the studies eligible for meta-analysis in the 21 studies. There were no difference between 75% vs. 100% of the distal locking screw length. Load to failure is significantly higher when using distal locking screws when compared to distal pegs. There was no significant difference when using two rows or one row distal locking screws. Intra-medullary devices had lower load to failure when comparing to volar fixed angle plates. There are also no significant difference when comparing volar locking plats to dorsal locking plates or dorsal non-locking plates regarding the stiffness and load to failure. However, volar locking plates have higher load to failure when compared to volar non-locking plates.

CONCLUSIONS

Biomechanically, regarding load to failure, distal locking screws are better than distal pegs, volar locking plates are better than intra-medullary nails, and volar locking plates are better than volar non-locking plates. There are no obvious advantage either when using distal screws of more than 75% of full length or when using locking plate volarly or dorsally.

THE INFLUENCE OF UPPER BODY INERTIAL PROPERTIES ON JUMP PERFORMANCE

[1]**Zachary Domire**, and [2]John H. Challis
[1]East Carolina University
[2]The Pennsylvania State University
Corresponding author email: DOMIREZ@ECU.EDU

INTRODUCTION

If vertical jumping is modeled as a mass-spring-mass system the distribution of the body mass between the upper and lower masses strongly influences jump height. Indeed the highest jumps occur with the upper mass being the heaviest, due to greater impulse being generated with a heavier upper mass compared with a lighter upper mass. Clearly human jumping is more complex than a simple mass-spring-mass system but analysis of that simple system raises questions about the influence of upper body mass on vertical jump performance. Therefore the purpose of this study was to use a simulation model of maximal human vertical jumping to examine the influence of upper body inertial properties on jump performance.

METHODS

A previously validated model of jumping was used in this study [1]. The model consisted of four rigid links (foot, shank, thigh, and a combined head, arms, and trunk), with the simulated jumps assumed to be bi-laterally symmetrical and therefore simulations of motion were for the sagittal plane only. The segments of the model are connected by frictionless hinge joints, with the foot connected to the ground at the metatarsal-phalangeal joint *via* a rotational spring-damper. The model was actuated by eight models of the muscles of the lower limb. The muscles were modeled using a Hill-type model, and had a series elastic component representing the tendon, and a contractile component representing the function of the muscle fibers.

The model was an optimal control model where the sequence of muscle activations was determined so that the model jump height was maximized. The objective function was,

$$J(\theta_0, \dot{\theta}_0, u, q_0) = Y_{CM}(t_f) + \frac{\dot{Y}_{CM}^2(t_f)}{2.g}$$

Where,

$\theta_0, \dot{\theta}_0$ - initial segment angles and angular velocities, u – sequence of neural excitations to muscle models, q_0 - initial active state of muscle models, Y_{CM} - vertical location of the center of mass at the time of take-off (t_f), and $\dot{Y}_{CM}$ is the vertical velocity of the center of mass at the time of take-off.

The inertial properties of the segments in the model were based on the data collected on 10 male experimental subjects (age 23.9 ± 2.7 years; height 1.83 ± 0.06 m; body mass 85.5 ± 17.4 kg). For each subject their segmental inertial properties were determined by modelling the segments as series of geometric solids [3].

The model simulated jump performance with constant lower limb inertial properties, but with varying properties of the model component representing the head, arms, and trunk (HAT). The original HAT inertial properties was the mean value from the experimental subjects, for the other simulations, for the other conditions heavy, light and negligible HAT length and center of mass position were maintained but segment mass and moment of inertia changed to reflect the variability inherent in human body segments [2].

RESULTS AND DISCUSSION

The changes in body segment inertial properties, Table 1, produced changes in jump height. Jump kinematics for three of the conditions (Original, Heavy, and Light) were similar to those of the experimental subjects; for example they had the same proximal to distal sequencing of joint extensions. The model with negligible HAT inertial properties produced a jump whose kinematics were not the same as seen in maximum jumps, and a jump height that was only 9.3% greater than the jump height compared with the original model. Jump height was reduced for the Heavy condition (-9.8%), and increased for the Light condition (3.1%). These changes indicate that athletes seeking to jump as high as possible may not need to pay too much attention to their upper body mass, although it is appreciated that in regular jumping arm swing can contribute to jump height [4]

Table 1: Trunk inertial properties for the four conditions.

	Mass (kg)	***Moment of Inertia ($kg.m^2$)***
HAT - Original	46.8	2.01
HAT - Heavy	59.8	3.16
HAT – Light	39.5	1.91
HAT – Negligible	3.00	0.60

N.B. - moment of inertia is relative to trunk center of mass.

CONCLUSIONS

Human jumping is more complex than the motion of a simple mass-spring-mass system, however these results were similar to mass-spring-mass findings. Increases in HAT inertial properties do not decrease jump height to such a large extent, as this additional load can lead to a longer propulsive phase and therefore greater impulse, and therefore jump height. In contrast a reduction in HAT inertial properties does not result in great increases in jump height, indicating that with the lower inertia to accelerate the impulse is somewhat reduced.

MUSCLE FORCES BASED ON EXPERIMENTAL KINETIC AND KINEMATIC DATA: TOWARDS EVIDENCE BASED STRENGTH TRAINING

Silvio Lorenzetti, Florian Schellenberg and William R. Taylor
Institute for Biomechanics, ETH Zurich
Corresponding author email: sl@ethz.ch

INTRODUCTION

Strength training is used for injury prevention and rehabilitation to enhance general fitness and increase the level of performance in competitive sport [1]. For adaptation of the soft tissues, a certain level of functional loading is required to allow for biological adaptation. As a result, it is important to understand the internal loading conditions, as well as their modulators, in order to ensure for positive adaptation and avoid overload of the tissue. Therefore, the aim of this study was to determine the level of muscle forces that are active during deadlifts (DLs), goodmornings (GMs) and split squats (SQs).

METHODS

In total, 24 subjects (25 ± 4 years, 73 ± 11kg, 1.78 ± 0.07m) experienced in strength training were analysed while performing either DLs and GMs or SQs. DLs were performed with an extra load on the barbell of 25% and 50% of subject's bodyweight, while GMs and SQ were executed using 25% extra load only. The stride length of the SQs was equal to 70% of subject's leg length and the tibial angle maximal 90° to the ground floor. Body motion was captured using 12 Vicon cameras (OMG, UK) at 100Hz, while the ground reaction forces were measured under each foot using two 400x600mm force plates (Kistler, CH) at 2kHz. All subjects performed standardized basic motion tasks to functionally determine the centres (hips and ankle joints) and axes (knee joint) of rotation [2]. In OpenSim, an adapted standard and widely used musculoskeletal model ("Gait2392_simbody" [3]) including 14 body segments, 29 degrees of freedom (including 3 DoFs in each knee and ankle joint) was scaled to each subject's individual segment length, based on the hip, knee and ankle joints, as well as the skin markers and pre-calculated joint angles.
Muscle forces in the Quadriceps and Hamstrings muscles were evaluated during DLs, GMs, and SQs (in both the front and rear limbs) and plotted as a function of the knee angle. Maximal muscle forces were compared between the exercises.

RESULTS AND DISCUSSION

All trials in all subjects could be successfully simulated. GMs, DLs and SQs resulted in different Quadriceps muscle forces (Figure 1). During GM almost no forces in the quadriceps were observed.
During all the examined exercises, the force of Semitendinosus muscle remained low (< 5 N/kg) compared to other muscles, with the highest muscle force observed when performing DLs with 50% additional weight. During GMs, the RoM of the Hamstrings remained rather low. Furthermore, the long and short head of biceps femoris, and m. semimembranosus muscles were all loaded, but only the short head of biceps femoris produced a force that was significantly higher in SQs and GMs than during DLs

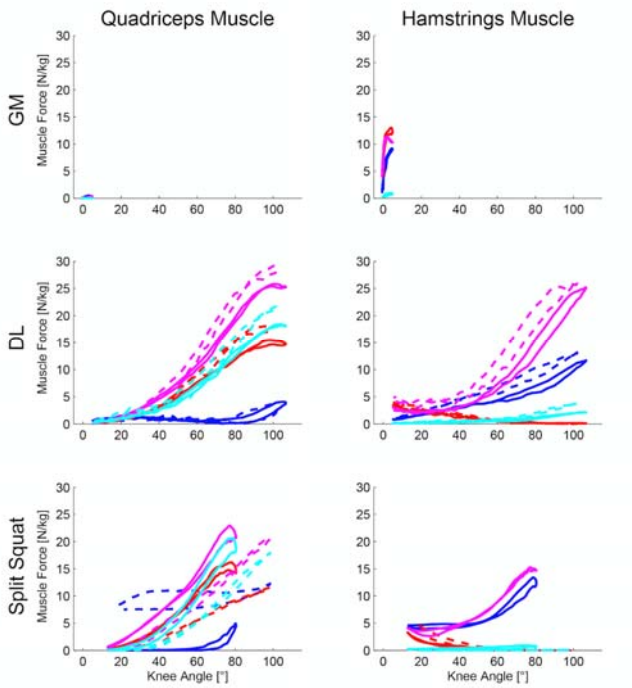

Figure 1: Muscle forces normalised to each subject's bodyweight as a function of knee flexion angles for the exercises goodmornings (GMs), deadlifts (DLs) and split squats (SQs). The four parts of the Quadriceps muscles are shown: *m rectus femoris* in blue; *m. vastus intermedius* in red; *m vasuts lateralis* in purple; *m. vastus medialis* in green, together with the four parts of the Hamstring muscles: *m. biceps femoris long head* in blue; *m. biceps femoris short* head in red; *m. semimembranosus* in purple; *m. semitendinosus* in green.

CONCLUSIONS

Until now, muscle forces acting during strength exercises were almost unknown. The results of this study provide coaches and physiotherapists the ability to choose a performance targeted strength-training design for athletes training or patients during rehabilitation with a minimal risk of injury.

INTRODUCTION

Central to athlete power development is strength training. Velocity based training provides an alternative means to develop power within athletes. Optimizing exercise selection throughout training cycles is needed to safely and efficiently train athletes. The purpose of this study was to determine which lift and velocity range provide the highest levels of power and force production. The question posed whether one lift is better than another for average power, peak power, partial peak power, and force outputs and how the lift velocity impacts the lift outputs.

METHODS

Participants included 7 highly trained strength professionals. The study paired 3 sets of power lifting exercises: deadlift (DL) and back squat (SQ), power clean (PC) and hang clean (HC), and power clean (PC) and clean pull (CP). Velocity ranges, 0.5-0.75 m/s, 0.75-1.0 m/s, and 1.0-1.3 m/s were used. A portable power analyzer was used to collect the data. Data were scaled for body mass and lift load [1,2]. A 2 x 3 ANOVA with post-hoc test investigated the data.

RESULTS AND DISCUSSION

A two-way ANOVA of lift type (DL, SQ) and velocity (0.5-0.75, 0.75-1.0, and 1.0-1.3) on the DV of average power, peak power, partial peak power, and force was conducted. A significant main effect of DL vs. SQ on average power ($F(1, 66) = 18.25$, $p < .0000$), peak power ($F(1, 66) =$, $p < .0000$), partial peak power ($F(1, 66) = 7.88$, $p=.0066$), and peak power ($F(1, 66) = 13.65$, $p < .0004$) was found. Significant main effect of lift velocity on average power ($F(2, 66) = 220.04$, $p < .000$), partial peak power ($F(2, 66) =178.43$), $p=<.0000$, peak power ($F(2, 66) = 159.46$, $p < .0000$), and force ($F(2, 66) = 155.34$, $p < .000$) was found. The main effect of lift type on average power was significant $F(1x2, 71) = 6.2989$ $p= .0031$. Tukey-Kramer HSD indicated that the slower velocity was better than the higher paired velocity in gernetating average power, partial peak power, peak power, and force when compainrg the DL and SQ. The interaction of velocity on lift type was significant for average power $F(1x2, 89) = 6.30$, $p < .0013$).

A two-way ANOVA of lift type (PC, CP) and velocity (0.5-0.75, 0.75-1.0, and 1.0-1.3) on the DV of average power, peak power, partial peak power, and force was conducted. A significant main effect for lift type of PC vs. CP on average power ($F(1, 84) = 30.32$, $p < .0000$), partial peak power ($F(1,84) =26.09$, $p <.0000$), peak power ($F(1,76) = 25.60$, $p < .0000$). and force ($F(1, 84) = 34.42$, $p <.0000$) was found. Significant main effect of lift velocity between PC and CP on average power ($F(2, 84) = 36.54$, $p < .0000$), peak power ($F(2, 84) = 36.54$, $p < .0000$), partial peak power ($F(2, 84) = 27.71$, $p <.0000$), and peak power ($F(2, 84) = 27.27$, $p < .000$), and force ($F(2, 84) = 30.16$, $p < .0000$) was found. Tukey-Kramer HSD indicated that .5-.75 m/s and 0.75-1.0 m/s were better compared to 1.0-1.3 m/s in gernetating average power, partial peak power, peak power, and force when compainrg the PC and CP. The interaction of velocity on lift type (PC vs. CP) was significant for partial peak power $F(1x2, 89) = 7.17$, $p < .0013$).

A two-way ANOVA of lift type (PC, HC) and velocity (0.5-0.75, 0.75-1.0, and 1.0-1.3) on the DV of average power, peak power, partial peak power, and force was conducted. No significant main effects for lift type between PC vs. HC for average power, peak power, partial peak power, and force were found. A significant main effect of lift velocity of PC vs. HC on average power ($F(2, 76) = 2.76$, $p < .0000$), $p < .000$), peak power ($F (2, 76) = 25.09$, $p <.0000$), and force ($F(2, 76) = 17.55$, $p < .000$) was found. Tukey-Kramer HSD indicated that the slower velocity was better than the higher paired velocity in generating average power and peak power when comparing the PC and HC. Partial peak power and force were better when using 0.5-0.75 m/s than 1.0-1.3 m/s when comparing the PC and HC according to Tukey-Kramer HSD.

CONCLUSIONS

Lift choice did matter for average power, partial peak power, peak power, and force when selecting lifts from the following combinations: DL and SQ, PC and HC, and PC and CP. DL was better than the SQ and, PC was better than CP for generating average power, partial peak power, peak power, and force. Velocity range mattered in average power, force, and partial peak power in some but not all. Slower velocities were better for generating average power, partial peak power, peak power, and force between the DL and SQ and the PC and the CP. Lift choice and velocity interaction were not significant for these paired combinations. Understanding which lift and velocity range are better in generating power and force outputs will optimize exercise selection for athletes throughout their training cycles.

INTRODUCTION

The time between successive foot-ground contacts during running (stride interval) displays long-range correlations that breakdown in the presence of fatigue [1,2]. The presence of these long-range correlations is considered a sign of a healthy functioning motor control system [3]. In contrast, breakdown of these long-range correlations is associated with fatigue and injury [1,2]. Monitoring stride interval long-range correlations may be a means for tracking performance deficits in athletes at risk of developing overtraining syndrome during periods of heaving training [1]. Therefore, the aim of this study was to investigate whether a state of temporary overtraining (termed functional overreaching) can be identified using stride interval long-range correlations measured at different running speeds.

METHODS

Ten trained male runners (age: 35.8±10.0 years; mass: 77.3±10.0 kg) completed three training blocks in a fixed order. The training consisted of one week of light training (baseline), two weeks of heavy training designed to induce functional overreaching, and ten days of light taper training designed to allow athletes to recover from the effects of heavy training. Running performance was assessed at the completion of each training phase using a 5-km treadmill time trial and deficits in trial performance were used to confirm the presence of functional overreaching [2].

Stride intervals were assessed after each training phase at slow (65% maximum heart rate) and fast (85% maximum heart rate) treadmill running speeds. Force-sensitive resistors positioned under the heel and forefoot recorded foot contacts wirelessly at 2000 Hz (Trigno™, DelSys Inc, Natick, USA). Foot-ground contacts were identified using the findpeaks function in MATLAB (R2013a, MathWorks, Natick, MA) and stride intervals were calculated as the time between successive peaks [2]. This process generated a series of 300 strides for analysis at each running speed.

The long-range correlation strength of each stride interval time series was determined using detrended fluctuation analysis [1-3]. First, the integrated times series was divided into bins of length *n*. In each bin, a least squares line was fit to the data to represent the local trend. The integrated times series was then detrended by subtracting the local trend in each bin. Finally, the root-mean-square fluctuation of this integrated and detrended time series was calculated across all bins lengths from n=4 to n=30 strides. The coefficient (α) relating fluctuations to bin length on a log-log plot was used to assess the degree of long-range correlations [5]. A running stride with long-range correlations across all times in a time-series has a scaling exponent α=1.0, while stride-to-stride fluctuations that occur in an entirely unpredictable sequence have a scaling exponent α=0.5.

RESULTS AND DISCUSSION

Heavy training induced a state of functional overreaching in the runners as evidenced by a decline in time trial performance (standardized mean difference [SMD]: -0.15; P<0.001; Table 1). Time trial performance recovered following taper training and was improved relative to baseline training status (SMD: 0.16; P=0.002; Table 1). Heavy training caused reductions in α coefficients (SMD: -0.56; P=0.011) that persisted following completion of taper training (SMD: -0.77; P=0.002). There was no main effect of speed (P=0.352) nor a session*speed interaction (P=0.243). There was a moderate within-subject correlation between changes in time trial performance and changes in stride interval α coefficient at the slow (r -0.46; P=0.047) but not fast running speed (P=0.711).

Table 1: Outcomes at baseline, post-heavy training (HT), and post-taper training (TP). HR_{max}, maximum heart rate.
[a] Increased from baseline (P<0.05).
[b] Decreased from baseline (P<0.05).

	Baseline	**Post-HT**	**Post-TP**
Time trial (s)	1165±144	1187±145[a]	1143±138[b]
α coefficient (slow speed)	0.75±0.11	0.64±0.11[b]	0.64±0.09[b]
α coefficient (fast speed)	0.68±0.13	0.66±0.22	0.60±0.14

CONCLUSIONS

Both time trial performance and stride interval long-range correlations were reduced due to functional overreaching. Changes in stride interval correlation strength at 65% but not 85% maximum heart rate were moderately effective at tracking deficits in time trial performance. However, reductions in stride interval correlation strength had not recovered ten days after cessation of heavy training. Thus, functional overreaching may have detrimental effects on motor control that persist even after measurements of athlete performance suggest complete recovery has occurred.

DOES AN IMMEDIATE REDUCTION IN HIP ABDUCTION STRENGTH CHANGE RUNNING KINEMATICS?

JJ Hannigan and Li-Shan Chou
University of Oregon
Corresponding author email: chou@uoregon.edu

INTRODUCTION

On average, female runners with patellofemoral pain have weaker hip abductors than healthy, matched controls [1], as well as compared to their unaffected limb [2]. Females with patellofemoral pain also appear to run with greater hip adduction compared to uninjured females [3]. This led to the hypothesis that hip abduction strength was significantly correlated to hip adduction during running. However, a 6-8 week hip strengthening program does not appear to significantly change running kinematics [4], calling into question the relationship between strength and kinematics.

To date, studies investigating this relationship have either been longitudinal or cross-sectional in nature. Investigating kinematic differences after an immediate change in hip strength would help better define this relationship. Therefore, the purpose of this study was to investigate the immediate effect of hip abductor fatigue on running kinematics in healthy runners.

METHODS

To date, 5 runners in this study have been analyzed, 3 females and 2 males (age: 31.0 ± 8.0 years). Thirty-nine reflective markers were placed on these runners who ran continuous overground laps in the laboratory while whole-body kinematic data were collected at 200 Hz using a 10-camera motion capture system (Motion Analysis Corp.).

Isometric hip abduction strength was measured sidelying in 0-degrees of abduction on a Biodex System 3 Dynamometer (Biodex Medical Systems) at 4 time points: before the first bout of running, immediately before the fatigue protocol, immediately after the fatigue protocol, and after the second bout of running. For each test, subjects pushed maximally for 5-seconds. Maximal torque was normalized by bodyweight for analysis.

For the fatigue protocol, subjects again laid sidelying on the Biodex Dynamometer. Subjects were instructed to maximally push in the direction of abduction while the dynamometer passively rotated up and down through a 30° range of motion at 30° per second for 2 minutes. A previous validation study in the Motion Analysis Laboratory demonstrated that this fatigue protocol decreased hip abduction strength by 27% immediately, and that hip abduction strength remained 10% lower than baseline 10 minutes after the fatigue protocol.

Immediately after fatigue, subjects again ran continuous laps in the laboratory while whole-body kinematics were collected.

Paired t-tests compared angular excursion and peak angles of the knee, hip, pelvis, and trunk before and after hip abductor fatigue. For all tests, the family-wise alpha-level was set to .05.

RESULTS AND DISCUSSION

Immediately after the hip abductor fatigue protocol, normalized hip abduction strength was 37% ± 13% lower than immediately before the test (pre-fatigue: 1.69 ± .29 Nm/kg; post-fatigue: 1.08 ± .22 Nm/kg), p = .02. After the second bout of running, hip abduction strength remained 8% ± 1% lower than baseline (post-run: 1.57 ± .11 Nm/kg).

Angular excursion of the knee, hip, pelvis, and trunk did not significantly change after fatigue. Peak ipsilateral trunk lean was significantly greater after the fatigue protocol (pre-fatigue: 3.1° ± 1.9°; post-fatigue: 3.6° ± 2.2°), p = .02. No differences were seen in any other kinematic variable.

Increased peak ipsilateral trunk lean may be a compensation to decrease the force needed from the hip abductors by decreasing the moment arm of the body's center of mass. Hip adduction and internal rotation were not changed after hip abductor fatigue, which may suggest that the body prefers to compensate superiorly at the trunk in order to not sacrifice the runner's ingrained motor pattern of the lower extremities. More data from this study is needed to support this hypothesis.

CONCLUSIONS

Despite a significant reduction in hip abduction strength that remained after the second bout of running, no changes were seen in hip adduction or hip internal rotation during running. Greater peak ipsilateral trunk lean during running was seen in runners after hip abductor fatigue, which may suggest a superiorly-directed compensation pattern.

SYNTHESIS OF SUBJECT-SPECIFIC, TASK-LEVEL STEPPING RESPONSE FOR PREDICTING BALANCE RECOVERY

Nicolas A Vivaldi and Jeffrey A Reinbolt
University of Tennessee, Knoxville

INTRODUCTION

Falls are the leading cause of both fatal and nonfatal injuries in elderly people [1], resulting in approximately $31 billion in medical costs annually in the U.S. [2]. These injuries motivate balance control studies focused on identifying prevention strategies for reducing the number of fall events. Experimental methods provide data about subjects' kinematic response to a loss of balance. However, simulations can offer additional insights, and may be used to make predictions about functional outcomes of various interventions. To make these predictions, simulations require accurate musculoskeletal modeling and robust control-system architecture. Several approaches already exist in biomechanics to generate accurate models on a subject-by-subject basis. Moreover, roboticists have developed control systems approaches for humanoid robots simultaneously accomplishing multiple complex tasks, including balance recovery [3]. Predictive subject-specific simulations of balance recovery can be generated by synthesizing approaches from both fields of study and creating surrogate models of task-level coordination from experimental data.

Related to fall prevention, roboticists use the Zero-Moment Point (ZMP) concept [4] to maintain dynamic stability during inherently unstable tasks, such as stepping and gait. In human balance recovery, stepping is one of the primary reflexes used when it becomes impossible to keep the center of mass (CoM) over the base of support (BoS) [5]. The step(s) redefine the area of the BoS in the horizontal plane to maintain control of the CoM, thereby preventing a fall.

In this study, we investigated the potential of using the ZMP approach for simulating human balance recovery during single-leg stance in response to perturbations at the BoS. Specifically, we examined support surface perturbations large enough to destabilize the subject (and model) to the point of making it impossible to recover balance without stepping. Our goal was to determine whether the ZMP approach could control the task-level motion of the model to generate a predictive, closed-loop simulation of stepping response that matches the subject's own balance recovery.

METHODS

Experimental motion data was collected (female 25 yrs | 1.72 m | 68.0 kg) during perturbation from single-leg stance. An OpenSim [6] 3D model with 17 degrees of freedom was scaled to match the subject. Trials in which a step was necessary to recover balance after perturbation (anterior | 6 cm | 40 cm/s) were identified and inverse kinematics determined model kinematics by matching the recorded marker trajectories. Body kinematics determined the body segment center of mass positions during the motion. The experimental positions of the CoM, swing foot, and torso were represented by surrogate second-order polynomial response surfaces in the anterior, vertical, and lateral directions, which defined these bodies' predicted motions. Proportional-integral-derivative (PID) controllers were used to calculate the task vectors needed to move the model by reducing errors between surrogate response surfaces and predicted body kinematics. The CoM horizontal plane position was controlled to be above the ZMP position, while vertical position followed its surrogate response surface. ZMP position was calculated from residual forces and moments acting on the pelvis [7]. Robotic control systems generated prioritized joint torques necessary for synthesizing the subject-specific stepping response [3].

RESULTS AND DISCUSSION

The simulations resulted in a predicted stepping response to perturbation at the BoS (Figure 1). CoM position was predicted well with the smallest RMS error (0.6 cm in the horizontal plane) among the 3 tasks. The ZMP control played a crucial role in the predicted CoM position. The largest RMS error (3.4 cm) was observed for the swing foot's vertical position, which undergoes the largest accelerations of the bodies during the stepping response.

a

b

Root Mean Square Error (cm)			
Task	*Anterior*	*Vertical*	*Lateral*
Center of mass	0.6	1.3	0.6
Swing foot	2.0	3.4	2.0
Torso	0.8	1.5	1.4

Figure 1: (*a*) Comparison of experimental motion (*green*) and predictive simulation (*red*); (*b*) root-mean-square (RMS) error between experiment and predictive simulation.

CONCLUSIONS

ZMP control with surrogate response surfaces is an effective approach for simulations predicting task-level stepping response during balance recovery. Future work will explore the role that ZMP trajectories play in decision making for stepping response during balance recovery and gait.

DETAILING THE START AND END OF COP TRAJECTORY OF OLDER ADULT GAIT

Albert K. Chong[1], Peter Milburn[2]
[1]University of Southern Queensland
[2]Griffith University
Corresponding author email: chonga@usq.edu.au

INTRODUCTION

Plantar coordinate system and center of pressure (COP) trajectory has been studied by a number of researchers recently (e.g. Pataky et al 2014). In Khoury et al. (2015), the authors demonstrated that placement of an orthotic allowed direct control of the COP trajectory and this feature could have implications for implant design and clinical practice. To fully benefit from this feature, it is necessary to develop an accurate method of mapping the COP trajectory. The purpose of this study was to investigate a method for the detailing the beginning and end of the COP trajectory.

METHODS

1. Reference system for mapping COP trajectory

Two anthropometric marks, the 2nd metatarsal head and the conjugate pternion, were marked by a set of custom-fabricated devices and targets placed on these locations before a gait trial. These targets defined the medial foot coordinate reference axis (MFCRA) and established two reference marks for the COP trajectory on the pedobarographic image. In mapping exercises, relative position of points could be recorded as vectors (magnitude and direction) based on a Cartesian Reference Frame. Utilizing the 2nd Metatarsal as the coordinate reference system origin and the line connecting the two marks as the x-axis, the beginning point (BP) and terminus point (TP) of the COP trajectory could be mapped precisely. Also, their location could be identified as medial positive (M+ve), medial negative (M–ve), lateral positive (L+ve) and lateral negative (L–ve). The direction is measured from the medial foot axis. Example, a BP of L-ve in Figure 1 has a value of 40 degrees while the TP of L-ve has a value of 70 degrees.

2. Protocol

Two fall-free and two occasional fall subjects (age: 68-73 yrs) were recruited for this investigation. After locating the 2nd metatarsal head (2ndMH) and the conjugate pternion (ConP) they were marked and targeted before the gait trial. The ConP position was determined by extending the pternion to the edge of the plantar surface and then transferring it onto the medial foot axis 2 cm from the edge. The medial foot axis (MFA) line was drawn connecting the two marks on the plantar surface pedobarograph. Plantar pressure data were collected for normal-speed gait at the 20th step of a 25 step gait trial using a TekScan pressure-sensing floor mat.

F-scan Research ver.6.70-03 and custom software were used to record the pedobarographic image and digitize the vector relating to the BP and TP of the COP trajectory.

RESULTS AND DISCUSSION

Figure 1 showed: the target imprints, the medial foot (MF) axis, lateral positive, lateral negative, medial positive, medial negative and the beginning and end position (TP) of the COP trajectory.

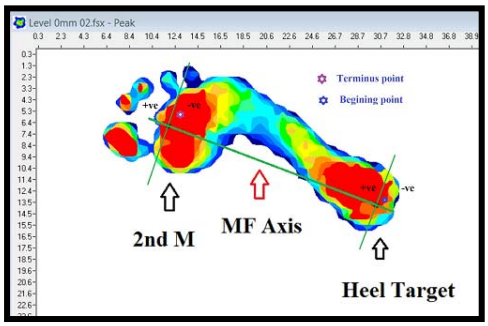

Figure 1: Sample of the pedobarographic image showing the BP and TP location of the COP trajectory.

Table 1: TP detail of COP trajectory of four test subjects.

COP Trajectory Terminus Point details				
ID	Location	Distance (cm)	Ailment	Fall (frequency in the past year)
1R	L-ve 7	3.1	Arthritis in large toe	Tripping on stairs (2)
2R	L-ve 6	2.2	Previously broken large toe	Unsteady for downslope
3R	L+ve 4	3.6	Arthritis in the large toe	Tripping on stairs (1).
4L	L+ve 3	2.0	Over-sized Bunion	Unstable gait

The direction of the BP and TP from the respective anthropometric marks was provided in 10 degree increments. In Table 1, subject 1 (right foot) and subject 3 (right foot) had one or more falls in the past year.

The ability to determine the 2ndMH and the ConP on the pedobarographic image enabled accurate mapping of the BP and TP of the COP trajectory. Accurate mapping and description of these features enabled evaluation of gait changes in older adults. The information also allowed the design of shoes and insole to change the position of these features, thus reducing the likelihood of unstable gait or falls.

CONCLUSIONS

The aim of the research was to determine a suitable method of collecting accurate details the BP and TP of COP trajectory. The result was a set of details necessary for the study of COP trajectory. The method will be used to collect data of 50 older adults in the near future.

INTRODUCTION

Falls are a leading cause of disability in older people. In the laboratory, slower and more variable gait patterns are associated with reduced quality of life, greater disability, increased fall-risk and mortality [1]. However, clinical gait assessments may represent "optimal" walking under standardized conditions rather than usual performances [2]. It is not known if daily-life gait provides a better indicator of fall-risk than clinical gait assessments. It is also not known which demographic, health, sensorimotor, psychological and cognitive factors underpin the daily-life gait of older people.

Here we investigate if the new remote daily-life gait assessments are better than clinical gait assessments at identifying older people with high fall-risk. We also examine the correlations between the new daily-life gait assessments, demographic and health factors.

METHODS

A total of 96 independent-living participants (age 75.5 ± 7.8 years) underwent sensorimotor, psychological and cognitive assessments, and the Timed Up and Go (TUG) and 10-meter walk tests. Daily-life gait was assessed using the senior mobility monitor (SMM, Philips Research Europe, The Netherlands). The SMM is a small (39.5x12.0x63.5mm) pendent sensor containing a 3D-accelerometer and a barometer. Accelerometer data were sampled at 50Hz with a range of ±8 times gravitational acceleration. The barometer measured pressure changes related to postural transitions, stair climbing and falls. The barometer resolution was 1Pa (1Pa~8.3cm @ 15ºC). Participants wore the SMM under their clothes at sternum height during waking hours.

One-week's daily-life gait data were processed in MATLAB (R2010a) using custom algorithms [3] to calculate: (1) Total Steps. (2) Gait intensity. (3) Between-walk adaptability. (4) Within-walk variability and (5) Gait endurance. In the clinic, 10-meter walk and TUG times were assessed with a stopwatch. Health, psychological, cognitive and sensorimotor factors were assessed at baseline using gold standard protocols. Fall-risk was assessed using a self-reported history of falls in the past 12-months (people reporting one or more falls were defined as "fallers").

RESULTS AND DISCUSSION

During daily-life, fallers had significantly ($p \leq 0.05$) lower gait endurance, higher within-walk variability and lower between-walk adaptability, but not reduced total steps or mean cadence. In the clinic, fallers had slower TUG, but not 10-meter walk test times. However, after adjusting for demographics using Analysis of Covariance (ANCOVA), only the daily-life assessments of gait endurance (Fig 1A & 1D) and within-walk variability (Fig 1B & 1E) remained significant. Reduction in daily-life gait quality was significantly ($p \leq 0.05$) correlated with older age, higher body mass index, multiple medications, disability, concern about falling, poor executive function and sensorimotor fall-risk. Furthermore, using their daily-life walking patterns it was possible to assign participants to one of four risk-groups: The Impaired (93% fallers), Restrained (8% fallers), Active (50% fallers) and Athletic (4% fallers).

These findings highlight how a combined approach that aims to advance healthy aging and improve daily-life walking patterns might provide a better mechanism to prevent falls. This also provides a new way to distinguish "Impaired" people at risk of falling because of frailty from "Active" people at risk of falling from greater exposure to situations where falls could occur.

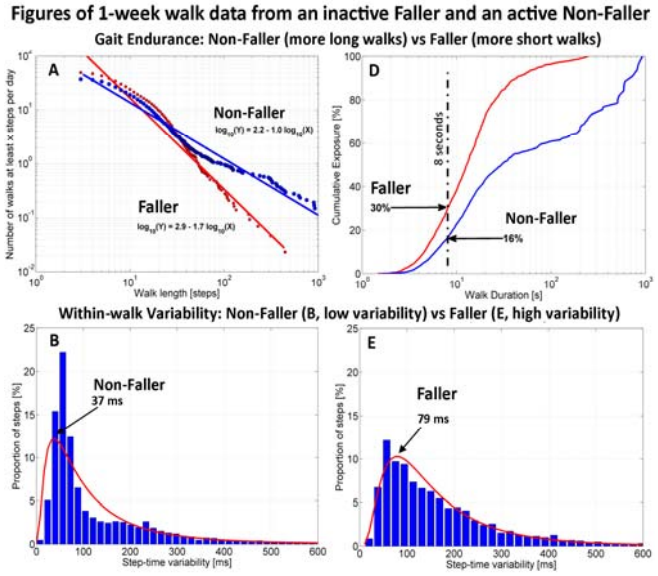

Figure 1: Daily-life assessments of gait endurance (panels A & D) and within-walk variability (B & E).

CONCLUSIONS

The daily-life assessments (gait endurance and within-walk variability) were better than the clinical gait assessments at identifying high fall-risk older people. Daily-life gait was not only affected by demographics and physiological capacity, but also general health, executive function and the ability to undertake a variety of activities without excessive concern about falling. Wearable device risk-profiling may therefore help better personalise future exercise programs.

HEALTHY OLDER ADULTS CAN EXPLOIT MOTOR ABUNDANCE DURING WALKING ACROSS AN UNEVEN SURFACE

[1]**Nils Eckardt**, [2]Noah J. Rosenblatt

[2]Rosalind Franklin University of Medicine and Science, North Chicago, USA
Corresponding author email: nilseckardt@uni-kassel.de

INTRODUCTION

Aging is associated with degenerative processes affecting postural control and thus poses an increasing risk of falling [1]. Mediolateral stability of lower extremities during gait may be particularly diminished with age [2]. While step-width variability can serve as a mean to describe mediolateral foot placement precision, no information regarding the actual stability of the foot trajectory can be derived. In recent years, the uncontrolled manifold (UCM) analysis has become an appealing tool to investigate the structure of joint configuration variance in greater detail [3]. According to the UCM approach, variance can be divided into two components (VC). The variance component that leads to a stable trajectory is termed as "good variance" (V_{UCM}), whereas the orthogonal variance component that results in a disturbed, more variable trajectory is termed as "bad variance" (V_{ORT}). If V_{UCM} statistically exceeds V_{ORT}, it indicates the existence of a synergy. The normalised difference between V_{UCM} and V_{ORT} determines the strength of the synergy, i.e., the synergy index (ΔV_Z), to stabilise the task variable.

Healthy older adults have shown to stabilise the trajectory of the swing foot by a kinematic synergy during walking across an even surface [4]. Since surface configuration (e.g., uneven surface) can alter lower limb kinematics [5], walking across an uneven surface may affect kinematic synergies too, particularly with age. Therefore, the purpose of the study was to quantify age and surface related changes in the synergy index and its variance components. In line with recent studies, we hypothesised first, that the swing-foot trajectory would be stabilised through a kinematic synergy during the even surface condition across both age groups. Second, we hypothesised, that when older adults would be facing more challenging demands like walking across an uneven surface, they are less able to exploit motor abundance i.e., the use of flexible joint configuration variance, resulting in a weaker synergy index. Following the weaker synergy, we expected larger values of VC for older adults.

METHODS

Thirteen healthy younger adults (23.15 ± 2.48 years old) and 11 healthy older adults (73.27 ± 4.61 years old) walked across a 10m path under two conditions: walking across the lab floor (i.e., an even surface) and across an uneven surface (terrasensa® classic, Sensa® by Huebner, Kassel, Germany). We used a six-camera motion capture system (Oqus 3+, Qualisys AB, Gothenburg, Sweden) operating at 120 Hz to track the motion of 32 super-spherical marker placed at prominent landmarks according to a modified IOR-model [6]. Data were processed using Visual3D (C-Motion, Germantown, MD, USA). Derived elemental variables (segmental angles) were entered into a UCM analysis using a custom-written R code (R Foundation for Statistical Computing, Vienna, Austria) to calculate VC and ΔV_Z.

To test our hypotheses, we conducted a 2x2 (ΔV_Z x group) and a 2x2x2 (surface x VC x group) repeated measures ANOVA and pre-planned t-tests (VC). Further, Bayesian statistics were used to support plausibility of the t-tests results (i.e., calculation of Bayes Factor [BF]; Cauchy prior width = 0.707).

RESULTS AND DISCUSSION

We found a significant main effect of variance component ($F(1,22) = 174.40$, $p < 0.01$, $d = 5.63$), indicating the existence of synergies (V_{UCM}>V_{ORT}). Further, synergy indices did not differ between conditions and age group supporting our first hypothesis and contradicting our second (Figure 1): ($F(1,22) = 3.61$, $p = 0.69$, $d = 0.17$). There is strong evidence (BF) that variance components meaningfully differ between groups during walking on uneven surfaces (Figure 1): V_{UCM} ($d_{unb} = 1.37$; 95%-CI [0.50 – 2.31]; BF = 31.37), V_{ORT} ($d_{unb} = 1.56$; 95%-CI [0.67 – 2.54]; BF = 81.30). Older adults appear to channel variance into V_{UCM} to compensate for the increase in V_{ORT} across the uneven surface and thus preserve the kinematic synergy.

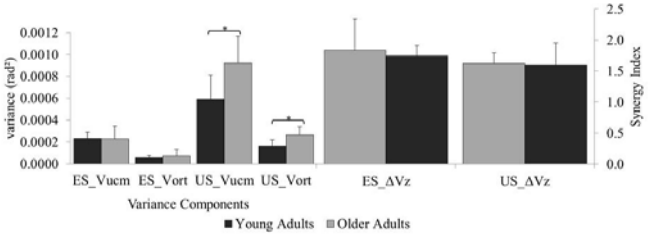

Figure 1: Average values of variance components (left) and synergy indices (right) across the entire swing phase on even (ES) and uneven (US) surfaces. Error bars are standard deviations.

CONCLUSIONS

We conclude that healthy older adults are still capable of exploiting motor abundance during walking across an uneven surface. The meaningful difference in V_{ORT} between age groups while walking across the uneven surface might indicate degenerative effects of aging. Thus, challenging conditions could serve as a magnifier to highlight even mild regressive effects, which wouldn't be obvious otherwise.

COMPARISONS OF SLIP FALLING KINEMATICS IN PELVIS OF THE YOUNG TO THE ELDERLY

[1]**Jeongwoo Lee**, [1]Youngho Lee[1], [1]Jaemin Kim, [1]Soonmoon Jung, [1]Dongwook Yang, [1]Beomgeun Jo and [1]Junghwa Hong[#]

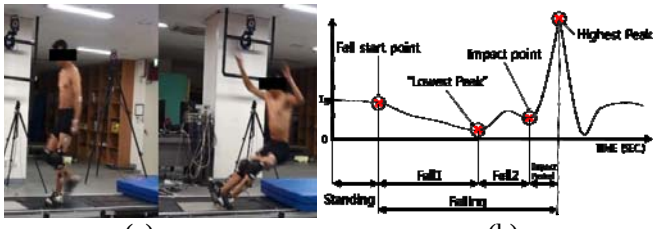
INTRODUCTION

Elderly peoples are most likely to lose a balance by slipping, tripping or stumbling. The imbalance causes falls of the elderly. More than 30 % of the elderly over the age of 65 years have experiences at least one fall per year, which significantly deteriorates quality of life. Furthermore, two in three fall experiencer over the age of 85 years directly leads to mortality [1]. Particularly, it was found that a slip was a main cause of falling injury. For the elderly, it was reported that more than 66 % of the slip fallers have the hip injuries in pelvis [2]. However, it is still unknown why the slip fallers in the old age have the high injury value at the pelvic region. The purpose of this study is investigate differences of falling kinematics of pelvis induced by a slip perturbation between the elderly and the young.

METHODS

7 of young (20s) and 7 elderly (> 60s) subjects were participated in this experiments. The 3D accelerometer (LIS3DSH, ± 16 g, 0.73 mg/digitl; STMicroelectronics, Switzerland), gyro-sensor (L3G4200D, ±2000 Deg/sec, 70 mdps/digit; STMicroelectronics, Switzerland), and compass (HMC5883L, ± 8 Gauss, 5 mm-gauss; Honeywell Solid State Electronics Center, USA) put on the sacrum of the subjects for the falling experiments. The data from the sensors were wirelessly transmitted by using RF (nRF2401+, 2.4GHz). Fig. 1 (a) shows the experimental setups and an example of the falling experiments, which was using a slider to induce a backward falling. The falling postures were determined based on the resultant pelvic acceleration and angular velocity, and pelvic tilt and obliquity angles. Based on the resultant acceleration as depicted in Fig. 1 (b), a falling event could be classified as the Fall 1; the period from the start of fall to the lowest peak, and the Fall 2 + Impact period; the period from the lowest peak to the highest peak. Using the measured results, the falling posture of the elderly and young people were analyzed.



(a) (b)

Fig. 1 Falling experiments (a) and definitions of fall (b)

RESULTS AND DISCUSSION

First, the measured mean values for the Fall 1 were analyzed. The duration of time was 0.431 ± 0.075 sec for the elderly and 0.457 ± 0.138 sec for the young, thus the elderly's was shorter as much as 0.026 sec. At the lowest peak, the other kinematics were analyzed. The resultant pelvic accelerations were similar for the elderly (0.429 ± 0.152 m/s^2) and the young (0.322 ± 0.18 m/s^2). The resultant pelvic angular velocity was 25.363 ± 19.262 °/sec for the elderly and 46.139 ± 28.212 °/sec for the young, thus the young's was higher as much as 20.83 °/sec. The tilt was 2.556 ± 9.582° for the elderly and 0.877 ± 11.714° for the young people, thus the elderly's was higher as much as 3.433°. The obliquities were 0.157° ± 9.546 for the elderly and 10.86° ± 14.95 for the young. The significantly short interval time of the Fall 1, high angular velocity, and large tilt for the elderly compare to those for the young could imply that the falling movements of the elderly is abruptly processed almost without reflective reactions to the balanced posture.

Second, the measured mean values for the Fall 2+Impact period were analyzed. The duration of time was 0.439 ± 0.075 sec for the elderly and 0.602 ± 0.506 sec for the young, thus the elderly's was shorter as much as 0.163 sec. At the highest peak, the other kinematics were analyzed. The resultant pelvic accelerations were similar for the elderly (6.151 ± 3.563 m/s^2) and the young (6.155 ± 1.478 m/s^2). The resultant pelvic angular velocity was 142.4 ± 64.78 °/sec for the elderly and 398.96 ± 83.03 °/sec for the young, thus the young's was higher as much as 256.53 °/sec. The tilt was 41.53 ± 19.45° for the elderly and 56.84 ± 22.73° for the young, thus the elderly's was lower as much as 15.31°. The significantly short interval time of the Fall 2 + Impact period, and high angular velocity for the elderly compare to those for the young could imply that the impulse and impact energy of the elderly is much greater than that of the young.

CONCLUSIONS

In this study, the difference in posture between elderly and young people is quantitatively analyzed in the falling event. The falling event is fast and unstable for the elderly compared to that for the young. In addition, the impact energy and impulse is large for the elderly compared to those for the young. These would be reasons that the slip elderly fallers are vulnerable for hip injuries in pelvis.

TIBIO-FEMORAL KINEMATICS OF THE NATURAL KNEE DURING COMPLETE GAIT CYCLES

[1]**Barbara Postolka**, [1]Pascal Schütz, [1]William R. Taylor, [2]Michael A.R. Freeman, [3]Guoyan Zheng and [1]Renate List

INTRODUCTION

Accurate knowledge of the three-dimensional kinematics of the natural knee is crucial for the evaluation and improvement of current total knee arthroplasty (TKA) designs, as well as for understanding joint pathology. Despite extensive investigations into the movement of the knee, tibio-femoral kinematics of the healthy joint remain controversially discussed [1,2]. While the majority of studies have assessed movement of the knee joint using optical systems, these approaches are subject to inaccuracies due to soft tissue artefact. Other approaches including magnetic resonance imaging (MRI), computed tomography (CT) and fluoroscopy systems are generally overly heavy and immobile for moving assessments, resulting in the common approach to examine knee joint kinematics during activities with a limited motion. As a result, knowledge regarding tibio-femoral kinematics of the healthy knee during complete cycles of daily activities is still missing.

To overcome these limitations of a static imaging modality, a moving fluoroscope that is capable of tracking the knee joint throughout complete cycles of level walking has been developed and successfully applied for analysing TKA kinematics [3]. With the vision to investigate the parameters that modulate tibio-femoral kinematics in the natural knee, the aim of this study was to demonstrate the efficacy of the moving fluoroscope for assessing healthy knees over complete cycles of level walking.

METHODS

After CT scanning, one male subject (26 years, 1.95m, 78.4kg, 7° varus, clinically assessed healthy knee joint) was assessed during six complete cycles of free level walking using the moving fluoroscope (25Hz, 1ms shutter time) [3]. Registration of the 3D joint kinematics was performed using a new intensity based 2D/3D registration program to fit the CT intensity data to the 2D fluoroscopic images [4]. For each frame, the location of the nearest point on each femoral condyle relative to the tibial articular surface was calculated as the mean of the 100 nearest points (mean point separation 0.4mm). A-P translations of the femoral condyles were calculated with respect to the mid-coronal plane of the tibial articular surface.

RESULTS AND DISCUSSION

The medial and lateral condyles showed a mean range of A-P translation of 13.2±1.9mm and 22.8±4.7mm respectively. During the loaded stance phase, both femoral condyles showed a similar range of A-P translation (medial 11.3±2.2mm; lateral 12.2±4.2mm; Figure 1). During the unloaded swing phase, the lateral condyle showed a larger range of A-P translation (21.4 ± 6.0 mm) than the medial condyle (12.7 ± 2.2 mm). These data suggest predominantly pure translation during stance phases, but a somewhat medial rotation in the transverse plane during the swing phase of gait. While these data are in agreement with previous reports [1,2], the subject tested exhibited varus limb alignment, and further studies must therefore elucidate the kinematic influence of anatomical variation.

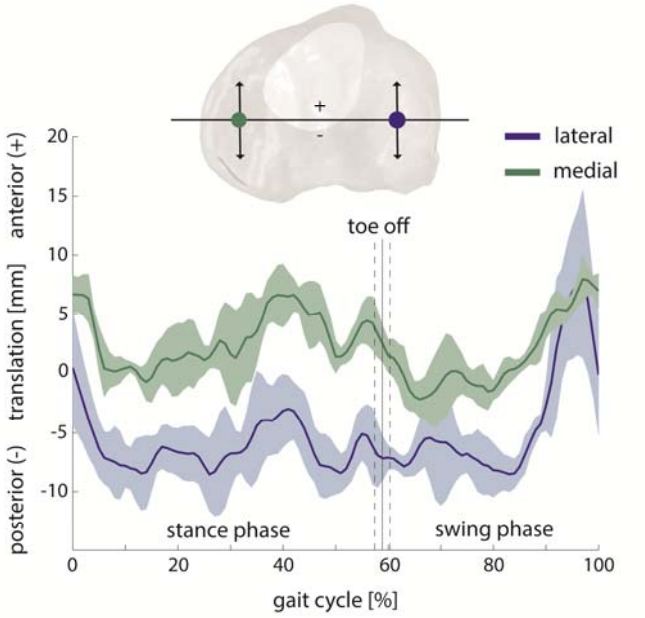

Figure 1: A-P translation of the nearest points of the medial and lateral femoral condyles over a full gait cycle. Mean (line) and standard deviation (coloured area) over all trials.

CONCLUSIONS

In combination with new intensity based registration, this preliminary data demonstrates the ability of the moving fluoroscope to assess complete gait cycles of healthy knee kinematics. The clear differences in range of A-P translation of the lateral condyle between the loaded stance and unloaded swing phases reinforce the need to analyse complete gait cycles, and now lay the foundations for investigating the factors (e.g. limb alignment, activity etc.) that play key roles in governing healthy tibio-femoral kinematics.

SYNCHROTRON-LIGHT TIME-LAPSED IMAGING OF HUMAN FEMORAL NECK FRACTURE

[1] **Saulo Martelli**, [1]Egon Perilli
[1] Medical Device Research Institute, Flinders University, School of Computer Science, Eng. and Mathematics, Australia

INTRODUCTION

The age-related microstructural deterioration of bone is an important co-factor to millions of fragility fractures occurring worldwide every year [1]. Time-lapsed micro-computed-tomography (micro-CT) with concomitant mechanical testing is increasingly used to study the bone deformation and fracture mechanism. However, technological limitations linked to the size of the human femoral epiphysis (up to 130 mm width, 150 mm length) and the need of a dedicated mechanical stage for loading such a big specimen inside the imaging chamber, have limited previous studies to either micro-CT imaging of the unloaded femoral epiphysis [1] or of small loaded femur cores [2]. We developed a protocol for time-elapsed micro-CT imaging of entire human femoral epiphyses under load at the Australian Synchrotron (AS).

METHODS

This study has received ethics approval from the Institutional Research Ethics Committees.

Femurs: Twelve human femurs from elderly female donors (age range 56-91 y) were obtained (Science Care, USA).

Finite element (FE) modelling of the fracture load: Clinical CT images were taken (isotropic voxel size 0.7 mm) including a 5-sample calibration phantom (Mindways Software Inc., USA). The osteoporosis level (T-score) was estimated from the clinical CT scans [3]. The femur geometry was extracted (ScanIP, Simpleware Ltd., UK) and meshed (unstructured ten-node tetrahedral mesh, average edge length 1 mm). CT-based locally isotropic material properties and a nominal 1000 N hip force resembling a single-leg-stance hip force orientation were assigned, producing a strain pattern consistent with clinically relevant femoral neck fractures [4]. Models were solved using an iterative linear solver (ANSYS Inc., USA) and the fracture loads estimated [4].

Compressive stage: A compression stage (weight 14.2 kg) was manufactured featuring a cylindrical aluminum compression chamber (245 mm diameter, 524 mm length), a 6-degree-of-freedom load cell (K6D68, ME-measurement sys. GmbH, Germany), a low-friction x-y table (THK Co., Japan), a vertical rail (SKF Inc., USA) and a screw-jack mechanism (Benzlers, Sweden). Femur samples, with the diaphysis potted in aluminum cups replicating the simulated loading conditions, were mounted inside the compressive stage and wrapped in wet tissue.

Time-elapsed synchrotron scans: Micro-CT scans were performed at the AS Imaging and Medical Beamline using a 2560 x 2160 pixels detector ("Ruby", in shift mode), 60 keV beam energy, 360° projections, 0.1° rotation step, isotropic voxel size 30 □m. One-fifth of the calculated fracture load was incrementally applied to the sample from the initial unloaded condition, with one micro-CT scan taken at each load step. At each step, the total volume scanned was 160 mm in diameter and 130 mm in height, scanning time 25 min. Four femurs were loaded to fracture, whereas 8 femurs were loaded to a single load step elastically. The 6 component force was recorded for the duration of the experiment. Cross-section images were reconstructed and examined.

RESULTS AND DISCUSSION

Time-elapsed synchrotron micro-CT imaging of the entire human femoral epiphysis with concomitant step-wise mechanical testing was successfully performed, at 30 μm pixel size. Clinically relevant fracture patterns were experimentally replicated and visible in the 2D and 3D micro-CT images, together with the bone microarchitecture. The specimens T-score ranged from +0.77 to -4.75 while range of the calculated fracture load was 1998-8636 N. Incomplete fractures were experimentally obtained in 4-5 load increments, according to the FE-predicted load step increment. The 2D and 3D images micro-CT images showed deformation and fracturing of the trabeculae and cortex. Sub-capital femoral neck fractures were obtained and were visible in the micro-CT images, consistent with observed patterns of clinical fractures (Figure 1). Morphometric and micro-finite-element analyses are being undertaken to investigate the contribution of the different microstructural compartments to withstand load.

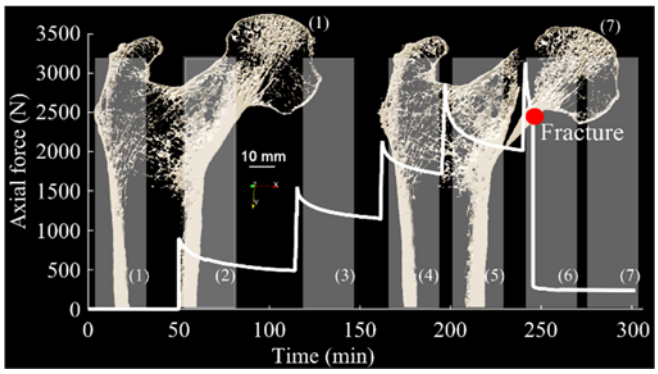

Figure 1: Load time history (white line), scanning time (shaded gray bars) and 2 mm-thick 3D micro-CT volumes (in yellow) of a femur unloaded (1) and once fractured (7).

CONCLUSIONS

This study is the first to perform high-resolution synchrotron light time-lapsed imaging of the entire proximal human femur microstructure while inducing clinically relevant neck fractures. The images can be used to study the femoral neck deformation and fracture mechanism at the micro-architectural level, of both cortical and trabecular bone at the same time, leading to clinically relevant fracture patterns of the femur at the whole-organ level. This will contribute to increase our understanding of femoral neck fracture mechanics, including the validation of FE models from micro-CT scale to clinical CT scale.

A TECHNIQUE FOR THE IN VITRO REGISTRATION OF CT, MR AND STEREOPHOTOGRAMMETRIC DATA

[1] **Michele Conconi**, [1]Nicola Sancisi and [1]Vincenzo Parenti-Castelli
[1]University of Bologna
Corresponding author email: michele.conconi@unibo.it

INTRODUCTION

To analyze the complex interaction among bone, cartilage and other tissues during the motion of a joint without opening the capsule and thus altering its behavior, data coming from different sources, for instance from medical images and stereophotogrammetry, have to be registered [1]. The registration process often relays on the optimal alignment of a set of points, anatomical reperi or artificial landmarks, observed in all the data set. With this approach, the measurement error may considerably affect the registration accuracy, in particular in terms of orientation. For instance, the definition of the tibia reference system according to the ISB standard [2] requires the identification of the two malleoli: assuming the two points are 60 mm apart, a measurement error of 1 mm on each point may result in 1.9° of error in the orientation of the line through the malleoli for each dataset, leading to a maximum registration error of 3.8°.

The purpose of this paper is to present an alternative approach based on axes rather than points. The axes are defined by drilling through holes in the bones, where cylindrical rods are inserted. The approach has several potential advantages. Axes can be easily identified and reconstructed both on medical images and on kinematic data. In fact, rods can be made of different materials that can be modified between measurement techniques to optimize the axis visibility and reconstruction. Rods can be removed and reinserted, also during the same experiment, without losing accuracy. Accuracy relies on the fitting of a very simple feature such as a line; moreover, accuracy does not depend on the rod axial position on the holes.

This approach is here presented to register CT and MR to stereophotogrammetry data. The registration accuracy is evaluated for a wooden object with known geometry and for a bovine femur.

METHODS

Three holes, 4.25 mm in diameter, were drilled in a bovine femur with generic position and orientation. Although two axes would be sufficient for the identification of a reference frame, the redundancy provided by the third axis increases the robustness of the method.

An aluminum rod with 4 mm as diameter with a reflective marker axially mounted at one end was manually moved within each hole while the marker motion was registered by an 8 camera VICON system. The three axes were defined by best fitting the resulting point envelopes. Three plastic hollow rods, 4 mm in diameter and filled with thickened water, were then inserted in the holes and CT (pixel spacing 0.48 mm, space between slices 0.625 mm) and MR (T1 3D fast gradient echo, pixel spacing 1.6 mm, 1.5 T) scans were acquired. Thanks to plastic and water properties, the rods and their axes could be automatically segmented by thresholding in both the CT and MR images.
Registration was performed by optimization in two steps. First, the three-dimensional rigid rotation that minimizes the sum of the angles between corresponding axes was determined via an optimization algorithm. Then, the minimum distance points between the axes in each data set were computed and the rigid translation that minimizes the sum of the distances between corresponding points was determined via an optimization algorithm.

The same procedure was repeated on a wooden model with axes controlled in position and orientation, in order to test the method with a known geometry.

RESULTS AND DISCUSSION

Orientation error was evaluated as the mean residual angle between corresponding axes, while position error was evaluated as the distance between the centroid of the minimum distance points.

Results show orientation errors smaller than 0.2° and position errors smaller than 0.1 mm when registering CT on VICON data. Registration of MR on VICON data shows a slightly lower accuracy. This can be ascribed to MR distortion [3], possibly caused by the low amount of resounding material during scans. Indeed, angles and distances among the axes of the wooden model reconstructed from MR differ from the known geometry.

Table 1: Registration errors

Error	CT vs VICON		MR vs VICON	
	bone	wood	bone	wood
Orientation (°)	0.16	0.17	0.45	2.19
Position (mm)	0.04	0.05	0.95	0.28

CONCLUSIONS

The proposed technique for the registration of stereophotogrammetry, CT and MR data proved to be accurate. The method is very simple and it does not rely on the operator experience for the axis identification. Also, it allows registration of data from different data set taken at different times and automatic segmentation of the axes. Future work will implement the presented technique within the in vitro analysis of knee joint motion.

A NOVEL TIBIOFEMORAL KINEMATICS TRACKING SYSTEM BASED ON A-MODE ULTRASOUND

[1]**Kenan Niu**, [1]Victor Sluiter, [2]André M.J. Sprengers, [1]Jasper Homminga and [1,2]Nico Verdonschot

INTRODUCTION

Improving the accuracy of measuring 6 DOF (degree of freedom) tibiofemoral kinematics is a crucial step in gait analysis. The use of skin-mounted markers is well established, in which the trajectories of skin markers represent the movements of the bony segments beneath the skin. However, the skin-marker estimated kinematics is subject to soft tissue artefacts (STA), with errors ranging from 2 mm to a maximum of 50 mm [1]. Alternatively, fluoroscopic systems have been reported to achieve accuracies of kinematics in the order of 1 mm and 2 degrees [2], but induced irradiation to the subject and a limited field of view hampers routine usage on large patient cohorts. The aim of this study is to assess the feasibility of measuring tibiofemoral kinematics using a 3D-tracked A-mode ultrasound (US) system in an in-vitro experiment and calculate the achievable accuracy of tibiofemoral kinematics relative to the ground truth.

METHODS

A cadaver was placed on the surgery table and legs were hanging in the air. Upper body was fixated by nylon straps on table and right leg was pulled by rope to produce a certain movement. To tracking the ground truth of the certain movement, two bone pins with optical markers were mounted to femur and tibia separately, which provided the ground truth of certain movement. Additionally, six custom A-mode ultrasound holders that contain 30 A-mode ultrasound transducers and 18 optical markers were mounted on six anatomical regions: ankle, middle tibia, tibia epicondyles, femur epicondyles, middle femur and greater trochanters. Then, 30 ultrasound reflection points on the bone surface of femur and tibia were calculated based on acquired raw ultrasound echoes and spatial information from optical markers on holders. The sample rate of acquiring ultrasound points is 20Hz. During measurement, the acquired points were fed to a registration algorithm that combined an iterative closest point [3] and perturbation method to register the acquired points to corresponding bony segments per frame. The tibiofemoral kinematics were determined from the positions of registered femur and tibia [4] per frame. The final estimated tibiofemoral kinematics were displayed in real-time fashion.

RESULTS AND DISCUSSION

The resulting kinematics showed an average error of 1.25 ± 0.94° for flexion-extension and 9.06 ± 3.94° for internal-external rotation and 2.62 ± 1.34° for adduction-abduction rotation, 3.05 ± 2.09 mm for anterior-posterior translation, 5.25 ± 2.90 mm for distal-proximal translation and 6.76 ± 2.73 mm for medial-lateral translation.

Compared to skin-mounted markers, 3D-tracker A-mode US system has the potential to provide more accurate reconstructed tibiofemoral kinematics, with relative high accurate in flexion-extension, adduction-abduction rotation angle and tibia anterior-posterior. However, internal-external rotation and distal-proximal and medial-lateral translations show higher error. This higher error is most probably caused by the lack of geometric constraints in distal and proximal direction and lack of enough transducers covering more anatomical regions.

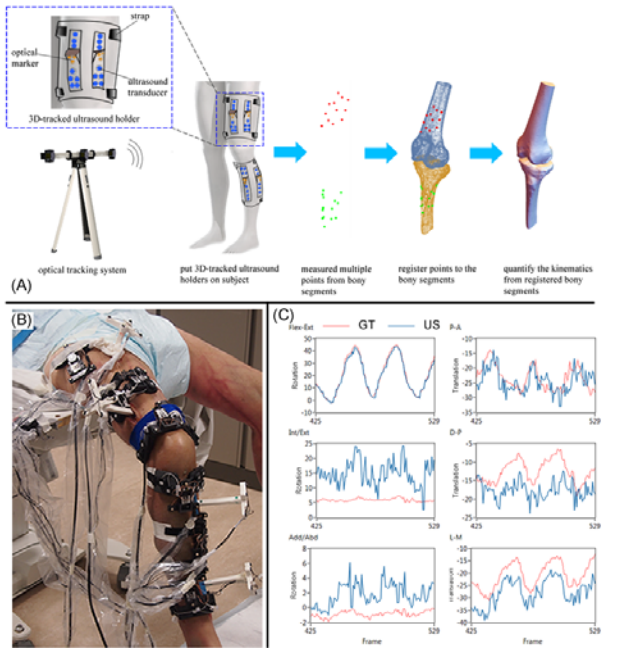

Figure 1: (A): The schematic of multiple US knee kinematics tracking system; (B): the setup of in-vitro experiment with mounting 6 ultrasound holders and 4 bone pins; (C): the estimated 6 DOF tibiofemoral kinematics (US) relative to ground truth (GT) within 104 frames.

CONCLUSIONS

This study has presented a 3D-tracked A-mode ultrasound system and proven its feasibility of the reconstructed knee joint kinematics in an in-vitro experiment. The accuracy measured in this in-vitro experiment outperforms the error of in-vivo experiments using skin-mounted markers and is comparable to the accuracy of Fluoroscopy based systems. Thus, this A-mode Ultrasound approach could provide a low invasive method for measuring knee joint kinematics with higher accuracy.

DO LOWER-LIMB TORSIONAL DEFORMITIES HAVE SIMILAR EFFECTS ON MUSCLE AND JOINT FUNCTION DURING GAIT IN TYPICALLY-DEVELOPING CHILDREN AND CHILDREN WITH CEREBRAL PALSY

INTRODUCTION

Torsional deformities of the femur and tibia have been associated with gait impairments, lower-limb pain and joint dysfunction [1,2]. Three-D gait analysis is used to inform clinical decision making reagarding surgical correction.

In children with cerebral palsy (CP), surgical correction may be indicated when gait impairments are identified from 3D gait data [3]. In contrast, when typically-developing (TD) children present with torsional deformtites, surgical correction is seldom performed because the effects of the deformities are often dismissed as cosmetic issues [4]. However, knowledge of muscle and joint contact forces during walking is warranted to fully inform surgical descion making. This may be obtained from musculoskeletal modelling if the models include patient-specific lower-limb joint definitions and bony anatomy.

We utilised a new medical imaging modality, EOS, to create patient-speciifc musculoskeletal models and investigated the effects of torsional deformities in TD children and children with CP.

METHODS

Twenty-two children and adolescents with lower-limb torsional deformities participated. Twelve were TD (2♂, 10♀) and ten had a diagnosis of spastic diplegic CP (7♂, 3♀). Written informed consent was obtained from their parent\guardian and approval granted by the local ethics committee.

Each patient underwent 3D gait analysis and EOS imaging. From EOS imaging the 3D shape of the pelvis, femur, and tibia, and 3D position of the external markers was obtained using the dedicated software, sterEOS.

Two models were created for each patient. Model 1 had patient-specific joint centres and axes and in addition Model 2 also included patient-specific lower-limb bony anatomy. For Model 2 the generic femur and tibia were deformed according to the patients' femoral neck anteversion, femoral neck shaft angle, and tibial torsion. We deformed the mesh describing the bone surface and all muscle insertions and via points accordingly.

We performed dynamic simulations of gait in OpenSim to obtain muscle and joint contact forces. Hip joint contact forces were expressed in an acetabular coordinate system. A plane was fit to the brim of the acetabulum. Compressive forces acted perpendicular to the plane, whilst those acting within the plane were defined as 'shear'. We determined the effect of torsional deformities from the differences in muscle and joint contact forces between models 1 and 2.

RESULTS AND DISCUSSION

Femoral neck anteversion for TD and CP were similar 38° (SD:9°) and 39°(SD:6°), respectively. External tibial torsion was statistically different (p=0.001) for TD and CP, 40° (10°) and 30° (SD:8°) respectively. Compared to controls both groups had altered kinematics; increased internal hip rotation, external knee rotation and anterior pelvic tilt. Only the CP group had increased internal foot progression. Lower-limb torsional deformities resulted in increased muscle force from the hip adductors (gluteus medius and minimus) in both groups. Increased force from the hip flexors, psoas and rectus femoris for TD and psoas only for CP. The 'shear' component of the hip joint contact force was increased in TD and CP, while only the TD showed an increase in the compressive component (Figure 1). The TD group also had increased mediolateral force at the patellofemoral joint.

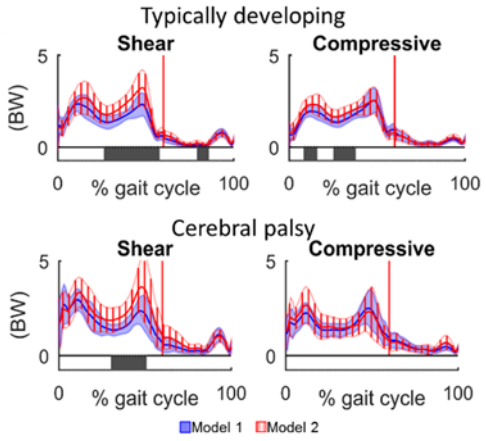

Figure 1: Hip joint contact forces in acetabular coordinate system. The black bar indicates where within the gait cycle there is a significant difference between models. BW = bodyweight.

CONCLUSIONS

We created patient-specific models from EOS imaging and found several similarities between the TD and CP groups. Both groups had increased force from the hip musculature, ultimately leading to increased joint contact forces at the hip. Dissimilarities included increased mediolateral force at the knee (patellofemoral joint) in TD but not in CP. This is likely due to the increased tibial torsion found in the TD group compared to the CP group, and may be linked to the increased knee pain described by TD children.

SURGEONS' MUSCULAR LOAD DURING ROBOTIC-ASSISTED LAPAROSCOPY AND THE EFFECT OF AN ERGONOMIC CHAIR

Tina Dalager[1]*, Trine S. Winther[2], Laura U. Jensen[2], Thiusius R. Savarimuthu[2] and Karen Søgaard[1]

INTRODUCTION

In a cross-sectional study, a high prevalence of musculoskeletal pain was reported among Danish surgeons performing minimally invasive surgery [1]. Robotic-assisted laparacopy is propsed to be less strenous to the surgeon compared to conventional laparoscopy. However, a systematic review found very sparse evidence to support the potential better ergonomics related to robotic-assisted surgery [2]. In the robotic console, surgeons are seated in an regular office chair, that is not fitted to the console and therefore increases the risk of awkward work postures. This study evaluated the use of an ergonomic chair (EC) compared to a regular office chair (OC) during the performance of robotic-assisted laparoscopy in The da Vinci Surgical System.

METHODS

Six surgeons (3 males/3 females) from Odense University hospital, Department of Gynaecology and Obstetrics participated. Mean age was 46±5 years, height 177±7 cm and bodymass index of 22.2±2.4 kg/m^2. Electromyography (EMG), Rapid Upper Limb assessment (RULA) and perceived physical exertion (BORG-10) were continuously measured during surgery. EMG was measured bilateral on the following muscles: Erector Spinae, Upper Trapezius and the neck extensors. RULA is a risk indicator scoring system with a scale from 1-7 (7 representing that action is needed) and was obtained every 10 minutes. BORG-10 was obtained before, approximately midway and at the end of surgery.

RESULTS AND DISCUSSION

Median %MVE for the six muscles showed a non-significant difference between OC and OE (fig. 1). An amplitude probability distribution function (APDF) of median EMG of a mean of the six muscles showed that surgeons experienced a static level of >5.0%MVE, a mean level of >9.5 %MVE, and peak level of >13,5%MVE (fig. 2). The static level was significantly higher for EC compared with OC. RULA showed a non-significant difference in sitting position between OC (4.7±0.54) and EC (4.6±0.53). BORG-10 showed non-significant differences between OC and EC before (0.7±0.7 vs. 0.8±0.7), midway (1.7±1.1 vs. 1.6±1.2) and at the end of surgery (2.2±1.1 vs. 1.9±1.2).

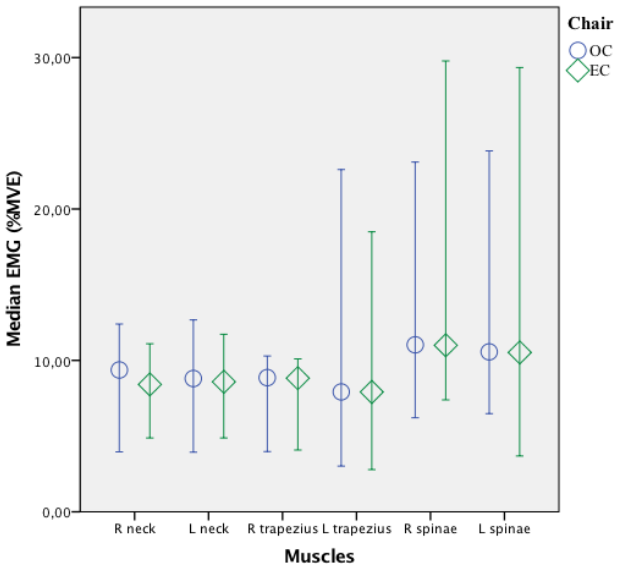

Fig. 1: %MVE for each muscle. Median and 95% CI. R=right, L= left.

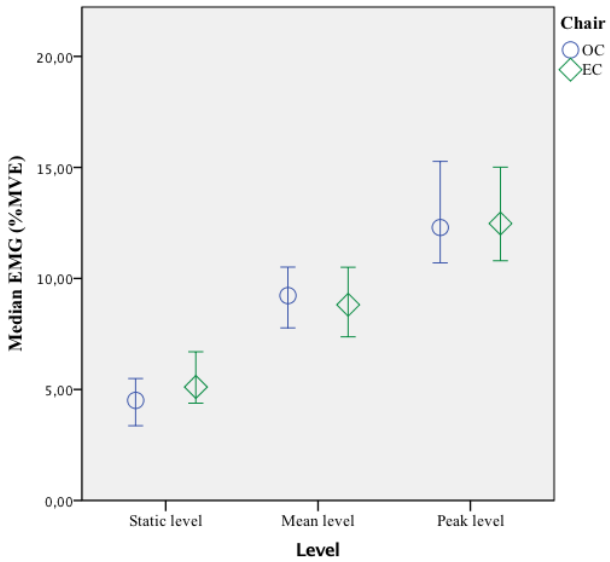

Fig. 2: %MVE of a mean of the six muscles. Median and 95% CI.

Our study demonstrated a general high level of static muscle activity in surgeons performing robotic-assisted laparoscopy. The significant difference between OC and EC for the static level did not favor the ergonomic chair. An explanation may be the surgeon ignoring the use of the ergonomic adjustment, as full attention is on the patient being operated and not the surgeon. The levels for both chairs revealed a high sustained muscle activity that is associated with an increased risk of musculoskeletal pain [3]. Similar levels have been found among other job groups with high musculoskeletal pain prevalence as for instance military helicopter pilot [4].

CONCLUSIONS

The results showed a high sustained muscular load and an adverse but small effect of an ergonomic chair for the static level. A result that may be due to lack of knowledge on how to make use of the ergonomic possibilities. Thus, there is a need to increase the surgeons' awareness of the possible ergonomic improvements in robotic-assisted laparoscopy.

AN EMG-BASED EVALUATION OF VIOLIN PLAYERS WORK-LOAD DURING PERFORMANCE OF SCALES IN INCREASING TEMPI AND A PIECE OF MUSIC

Stephanie Mann[1], Mads Panduro[2], Ruben Wendelboe Hansen[1], Tina Dalager[1], Helene M Paarup[3], Lars Brandt[2], Karen Søgaard[1]

[1]Dep of Sports Science and Clinical Biomechanics, University of Southern Denmark, [2]Dept. of Occupational and Environmental Medicin and [3]Dept. of Clinical Immunology, Odense University Hospital, Denmark.

INTRODUCTION

A study among Danish symphony orcestra musicians shows a high prevalence of musculoskeletal disorders in the upper extremity. Within the last 12 months 83% and 97% of the male and female musicians, respectively, reported muscular pain, for 49% of the males and 63% of the females for more than 30 days. For 73% of the musicians the pain limited or interfered with their playing performance (1). The violin players are the largest instument group in a symphony orchestra and represent a specific risk group prone for pain in the upper extremities (1, 2).

The aim of the study was to investigate the relative load of upper extremity muscles during violin playing of A and E scales in four tempi as well as during a real piece of music.

METHODS

The study was conducted on highly skilled violinists players with the inclusion criteria that skills was at the level to comply with the protocol.

Selfreported pain and function are reported by Nordic Musculoskeletal questionnarie and Disabilities of the Arm, Shoulder, and Hand (DASH) specifically related to musicians.

The protocol consisted of scales and a piece of music. The two scales were A major and E major for three octaves which was played with increasing node values in tempo 60 beat per minute (bpm): 4-part notes, 8th notes, 16th notes, 32 notes. The piece of music was Mozart's Violin Concerto no. 5 in A major played 60 bpm in 4/4 timing.

The whole session was video filmed and will off line be analyzed with the Rapid Upper Limb Assessment to estimate work posture.

EMG was recorded bilaterally from the Upper part of Trapezius (UP), Extensor Carpi Ulnaris (ECU) and Flexor Digitorum Superficialis as well as unilaterally from left Extensor Digitorum Communis (EDC) and right Extensor carpi radialis (ECR). For normalizition maximal EMG activity was measured during maximal shoulder elevation and maximal handgrip. Mean EMG activity in all muscles recorded during playing of scales and the music piece was calculated as the root mean square (RMS) values and normalised to the maximal RMS during MVCs. All comparisons are statistically tested with paired T-test and a level of significance of p=0.05

RESULTS AND DISCUSSION

Study population comprised 11 females and 7 male violinists (one amateur, three conservatory students and 14 professionel symphoni musicians). Professional and non-professional musicians were similar regarding age for start of playing, daily playing hours, use of pain medication and perceived muscle tension. Mean age was 42 years ranging from 21-64 years, height 1.69m (± 0.10) and weight 69.86 kg. (± 14.83). Of these 14 (78%) had experienced pain in the neck and 9 (50%) in the upper back during the last 12 months. Currently, data from 5 violinists are analysed and these preliminary results are presented in this abstract.

Figure 1 shows the %MVE results for each muscle for left and right arm during playing of A and E scale with different tempi. There was no overall significant difference between the A and E scales. As a gross mean across all muscles mean RMS level was 16,7(±14,23) %MVE during playing the A-skala and 16,5(±13,98) %MVE during playing the E-skala. For the left forarm muscles a sigificant increase in activity with tempi was found for both the A scale ($p<0.01$ for all muscles) and E scale ($p<0.01$ for all muscles). For the music piece overall mean activity of the 8 muscles was 15,3 (±11,39) %MVE. The left ECU was the only muscle showing a significantly higher activity level during the music piece compared to scales.

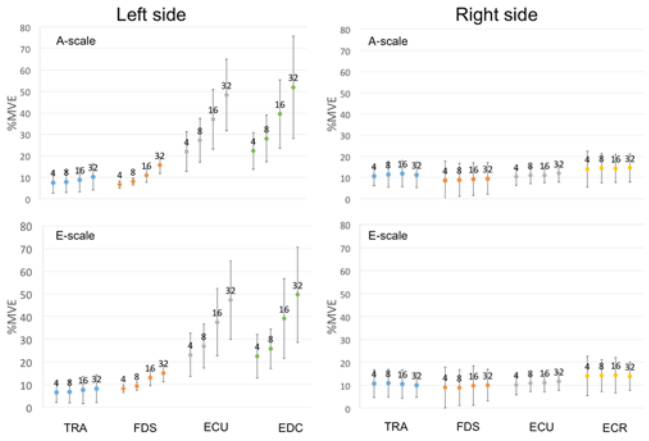

Figure 1. Mean RMS and SD for each muscle measured in right and left side for A and E scale with played tempi indicated above.

CONCLUSIONS

The results in the present study, preliminary on 5 skilled violin players, show a high muscular load especially for the left forearm muscles during the high playing tempi. The use of two different scales and varied playing tempi as a standardised work task seems in general to provide a representative estimate for the load during actuel playing.

THE RELATIONSHIP BETWEEN MOTOR FUNCTION AND EXECUTIVE COGNITIVE FUNCTION DEPENDS ON AGE AND MOTOR TASK COMPLEXITY

[1,2] **Bente R Jensen**, [2]Meaghan E Spedden, [2] Ken Andersen, [1]Anne Sofie B Malling
[1]University of Southern Denmark

INTRODUCTION

Deficits in motor function develop with advancing age. A recent review of longitudinal studies indicates an association between motor function and cognitive function in older adults [1]. It remains unclear if this link is modified over the adult lifespan and likewise if motor task complexity is of significance. A lifespan perspective has been requested since it may aid in understanding the development of these associations in order to optimize prevention endeavors and timing of interventions.

The aim was to examine associations between motor and cognitive function in healthy adults across the adult lifespan as well as to investigate the role of motor task complexity in these associations.

METHODS

Eighty-two healthy adults, 43f and 39m, participated in the study. They were divided into a young (19-40 yrs.), a middle aged (41-60 yrs.) and an old (61-83 yrs.) group. The subjects performed two motor tasks with different levels of complexity and one cognitive task.

The complex motor task required rapid optimization of timing and coordination of multiple body-segments in the medio-lateral direction based on on-line visual torque feedback. The task was to perform 46 medio-lateral weight transfers at maximal speed on a force plate (Amti, USA) with the feet in a standardized position. On-line feedback of external torque production (sagittal plane) and 90% body-weight target limits were provided to the subjects [2, 3].

The simpler motor task was a sit-to-stand task, which is a routine movement and reliant only on internal production of movement. The task was as a five repetition sit-to-stand test performed as fast as possible. The task was performed on a force plate (Amti, USA), chair height was 120% of lower leg length and hands were placed on the contralateral shoulder [3].

The executive cognitive task was a computer version of the Stroop Color Word Test. One of four words (blue, red, yellow or green) was presented, in different colors, on a computer screen. The answer icons appeared in black text and the goal was to click on the answer icon indicating the color of the word. The color word and the answer icons appeared in different areas of the computer screen for random time intervals between 0.8 and 5 seconds. Subjects were instructed to complete the task as quickly and accurately as possible by using the mouse to click on the correct answer icon.

Both motor tasks were repeated three times. If the last trial was the fastest, an additional trial was conducted to ensure maximal performance. The cognitive task was repeated twice.

Performance on the complex motor task was quantified as completion time for 40 medio-lateral weight transfers, where a minimum of 35 reached 85 % body weight targets as determined from torque-time data. For the simpler motor task, completion time for five approved cycles was calculated from vertical force-time data [3]. Performance on the Color Word Test was determined as the number of correct answers given in the period from the fourth to seventy-fourth color word presented.

RESULTS AND DISCUSSION

Correlation analysis showed a significant association between the complex motor task and the cognitive task ($p=0.04$, $R=-0.37$) in the old group, whereas no association existed between the simpler motor task and the cognitive task. In the young and the middle aged group no correlations were found between any of the motor tasks and the cognitive task. The observed association between the complex motor task and the cognitive task in the oldest age group may reflect a decline in underlying shared neural correlates and that motor performance becomes increasingly dependent on cognitive resources with advancing age [4].

At group level the old group performed the complex and the simpler motor task significantly slower than the young and the middle aged group. Furthermore, the old group performed less accurately on the cognitive task than the young and the middle aged group. A decrease in performance with age was expected based on the literature.

CONCLUSIONS

A significant correlation between motor and executive cognitive performance was found for the old group in the complex motor task, suggesting that a link between motor and cognitive function emerges in old age and depends on the degree of motor complexity.

VARIATION IN URINARY CONTINENCE AFTER PROSTATECTOMY IS EXPLAINED BY DYNAMIC FEATURES OF STRIATED PELVIC FLOOR MUSCLE CONTRACTION

[1]Ryan Stafford, [1]Wolbert van den Hoorn and [1]**Paul W Hodges**
[1]The University of Queensland
Corresponding author email: p.hodges@uq.edu.au

INTRODUCTION

Incontinence remains common after prostatectomy, but understanding of variation in recovery between individuals is incomplete. Most attempts to identify features related to incontinence have focused on measures of static anatomy and patient/tumor characteristics, which explain a small proportion of variation in continence status. Previous investigations have not considered dynamic (muscular) features of continence control.

Urinary continence is maintained when urethral pressure exceeds bladder pressure. This is achieved by complex dynamic coordination of multiple smooth and striated muscles. Anatomical studies [1] describe three striated muscle complexes with potential to develop urethral pressure; puborectalis/pubovisceralis (PR) which draws the urethra ventrally and elevates the bladder, striated urethral sphincter (SUS) which draws the urethra dorsally, and bulbocavernosus (BC) which compresses the urethra at the bulb of the penis. Investigation of these muscles is difficult because they are situated deep in the pelvis and typically require invasive methods (e.g. fine-wire EMG recordings). Recently, measures of urethral motion using non-invasive transperineal ultrasound imaging have been validated against invasive EMG recordings of SUS, PR and BC [2].

This study aimed to test whether dynamic features of muscular control of urinary continence provide insight into why some men develop incontinence after prostatectomy whereas others do not.

METHODS

Forty-two men who were either incontinent (N=19) or continent (N=23) after radical prostatectomy (aged 66(7) years) volunteered to participate. An ultrasound transducer was placed on the perineum in the mid-sagittal plane and adjusted such that the pubic symphysis, urethra, rectum and penile bulb were visible. Ultrasound data were recorded during coughing evoked by inhalation of capsaicin, and sustained maximal voluntary contraction.

Single image frames were exported from the video data and analyzed to calculate displacements of pelvic floor landmarks associated with activation of PR, SUS and BC. Anatomical features including urethral length and the resting position of the ano-rectal junction and urethra-vesical junction were also measured. A principal component analysis and multiple logistic regression were then used to consider both dynamic and anatomical factors in a single analysis to understand which combinations of variables best distinguish between men with and without incontinence.

RESULTS AND DISCUSSION

Five principal components (PC) were identified that together explained 72.0% of the data; PC1 and PC2 were significantly different between participants with and without incontinence. PC1 related to shortening of SUS (dorsal motion of mid-urethra) during cough and MVC. PC2 related to BC (compression of bulb of penis) and PR (anorectal junction motion).

A logistic regression model including PC1 and PC2 as predictor variables was assessed. Fig.1 shows probability of continence with respect to different values of PC1 and PC2. The area under the receiver operator curve of the final logistic regression model was 0.97 (95% CI 0.94 -1.00) with a specificity and sensitivity of 91.3% and 84.2%, respectively, and 88.1% correctly classified.

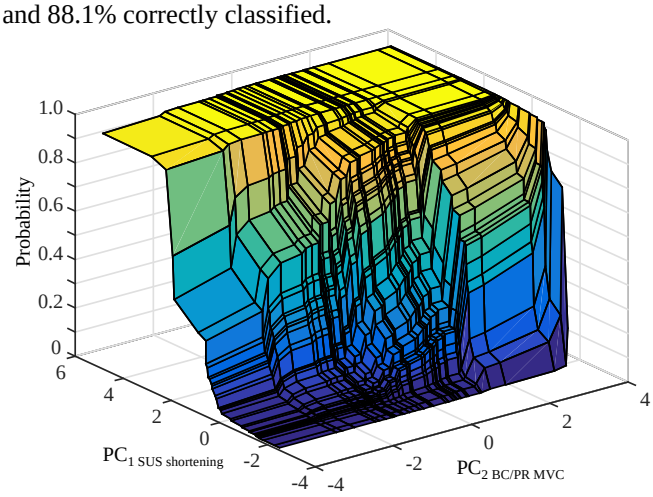

Figure 1: Probability of continence in relation to pelvic floor functioning of the logistic regression model including PC1 and PC2 as predictors and continence status as dependent variables. This graph represents the probabilities for different combinations of pelvic floor features that comprise PC1 and PC2. Z-axis relates to a probability of being continent. Good function of SUS maintains continence regardless of function of BC/PR, whereas good function of BC/PR does not ensure continence in the presence of poor SUS function.

CONCLUSIONS

Dynamic features of pelvic floor muscle activation are strong determinants of continence in men after prostatectomy. Shortening of SUS appears the most critical aspect.

DEVELOPMENT OF A FLEXIBLE LOW COST PRESSURE SENSOR FOR LOWER LIMB PROSTHETIC APPLICATIONS

[1] **Matthew Hopkins**, [1]James Clarke, [1]Ravi Vaidyanathan and [1]Alison McGregor
[1]Imperial College London
Corresponding author email: m.hopkins14@imperial.ac.uk

INTRODUCTION

Major lower limb amputation affects several million people worldwide [1]. Prosthetic limbs are commonly used to restore mobility causing the skin of the residual limb to sustain both axial and shear loads [2]. The application of these stresses through a poorly fitted or misaligned prosthetic limb can lead to instability, discomfort and tissue breakdown preventing further use of the prosthetic limb [2]. A series of thin, flexible and highly customisable pressure sensors have been developed with the intention of aiding in the production of better fitting sockets by providing prosthetists with a direct, quantitative information relating to socket fit and prosthetic limb loading.

METHODS

The sensors employ a simple structure in which two circuitry layers sandwich a pressure sensitive element. The core of the sensor is piezo-resistive Velostat and as force is applied to the material its resistance falls. Adaptable sensor circuitry layouts allow multiplexing of large arrays of sensors with minimal input and output lines. The availability of a multiplexed array provides the potential for comprehensive socket mapping. Individual sensors form part of a voltage divider circuit to permit measurement of the variable resistance of the sensitive element. Four individual sensing elements were produced for testing and validation purposes. A pull-down resistor of 1 kilo-Ohm was used to complete the voltage divider circuit for each sensitive element.

Sensor performance characteristics were determined using the compressive loading of a mechanical test system (MecMesin, 10kN load cell). A bespoke load application adapter, comprised of a 3D printed column fitted with a syringe attached to the machine and an independent pressure sensor. This allowed the syringe chamber pressure to be recorded in real time, coinciding with the loading of the flexible sensors. The plunger of the syringe was modified with a 3D printed attachment equal in diameter to the syringe's chamber.

The four sensors were subject to cyclic loading between pressures of 0 to 400 kPa at a total of four loading rates. Loading occurred through movement of the machine head over a distance of 60mm at rates of 250mm/min, 500 mm/min, 750mm/min and 1000mm/min. This produced a consistent exponential increase in pressure within the adapter chamber. Each loading rate was cycled a total of 20 times. Drift testing was performed directly after application of the loading cycles in which the machine head was set to a fixed displacement and held in position for 5 minutes. This was repeated 3 times per sensor.

RESULTS AND DISCUSSION

Cyclical mechanical testing of the sensors revealed an exponential response between input pressure and voltage output, characterised by the following equation.

$$V_{out} = Ae^{bx} + Ce^{dx}$$ [Equation 1]

The sensor output can be easily mapped via this equation to input pressure for the purposes of calibration with an average sum of squares due to error (SSE) of 8.13 and root mean squared error (RMSE) of 0.12. A total of 15 individual sensor loading segments were averaged for each loading rate. An average was then performed between sensors to produce the characteristic output displayed in figure 1.

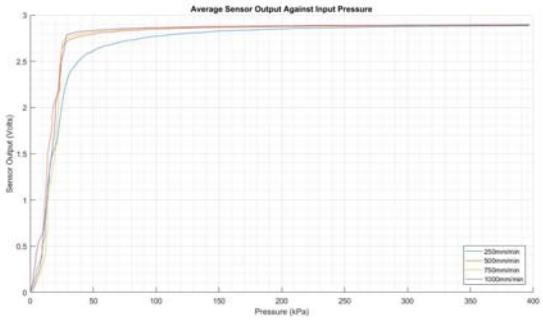

Figure 1: Average sensor voltage response to input pressure. The responses for four loading rates are displayed.

The sensors have a resolution of approximately 0.05 kPa in the 0 kPa to 30 kPa region and approximately 10 kPa in the 30 kPa to 400 kPa region. Sensor drift was minimal, with a minor upward drift recorded at 0.006 V/min, averaged across segments for each sensor and averaged between sensors.

CONCLUSIONS

A thin, flexible and customisable piezo-resistive pressure sensor was designed and fabricated. The sensor is intended for use within a prosthetic socket to provide an indication of stump-socket interface pressures. Experimental tests were performed to validate sensor performance between pressures of 0 to 400 kPa, representing typical reported loading pressure within a socket. The results demonstrate these low-cost sensors provide a consistent response mapped by an exponential equation with minimal drift, offering the potential to be used clinically is socket fitting.

METABOLIC COST OF OPTIMAL CONTROL SIMULATIONS IS UNAFFECTED BY TRANSTIBIAL AMPUTATION ACROSS A RANGE OF WALKING SPEEDS

[1,2]**Elizabeth Russell Esposito** and [3]Ross H. Miller
[1]Center for the Intrepid, Brooke Army Medical Center
[2]Extremity Trauma and Amputation Center of Excellence
[3]University of Maryland
Corresponding author email: Elizabeth.m.russell34.civ@mail.mil

INTRODUCTION

Transtibial amputation (TTA) is typically associated with an elevated metabolic cost of walking. The additional metabolic cost is often attributed to lack of biological ankle muscle function and the associated deviations/asymmetries in gait mechanics that result from walking with a passive prosthesis. However, recent reports suggest the metabolic cost of walking need not unavoidably increase after amputation if an individual is physically fit and has ample access to rehabilitative care [1,2]. Relatedly, achieving "normal" gait mechanics is a common goal of rehabilitation and may be possible with passive prostheses [3], but it is unknown if this goal can occur synergistically with the goal of reducing metabolic cost across a range of speeds.

The lack of actively powered push-off may be particularly detrimental to walking ability at faster speeds, as the ankle plantar flexors play a key role in increasing speed [4]. However, their contributions require metabolic energy consumption which increases the cost of walking. Optimal control simulations can be used to provide insight into the muscle energetics in locomotion and the theoretical limits to performance in goal-directed movements such as walking whilst minimizing gait deviations and the metabolic cost of using a prosthesis. Therefore, the purpose of this study was to compare the predicted cost of walking with minimal gait deviations with and without TTA across a range of speeds.

METHODS

Able-bodied control and TTA walking gaits were simulated using a 2D (sagittal plane) musculoskeletal model (Fig. 1, [5]) with 10 rigid segments and 12 degrees of freedom. The control model had 24 Hill-based muscle model actuators, including five ankle muscles per leg (soleus, gastrocnemius, tibialis anterior, and two biarticular ankle/toe muscles), and the muscular properties of a healthy young adult male. In the TTA model, a unilateral below-knee prosthesis was modeled by removing the muscles that crossed the right ankle joint. To simulate prosthesis inertial properties, the mass of the prosthesis was reduced to 70% of the biological shank/foot mass, and the center of mass was shifted 30% proximally. A passive dynamic-response prosthetic foot was modeled using an ankle stiffness of 400 Nm/rad. The TTA model was otherwise identical to the control model.

Simulations of one periodic gait cycle were performed using direct collocation [5] at five speeds (0.72–1.68 m/s), representing sustainable walking speeds in young, healthy individuals with TTA [1]. Muscle excitations and model states were optimized to minimize the deviation from able-bodied experimental joint angles and ground reaction forces (N=10) plus the gross metabolic cost, calculated using a model of human muscle energy expenditure [6]. Tracking errors were scaled by the between-subjects standard deviation (SD) and metabolic costs by biological body mass.

RESULTS AND DISCUSSION

Both models predicted the expected U-shaped relations between metabolic cost and walking speed, and metabolic costs were similar at all speeds for both models (Figure 1). On average, metabolic cost was 0.3% ± 2.0 less in the TTA model than in the control model. The average tracking errors were 1.1±0.1 SD for the control model and 1.2±0.1 SD for the TTA model (mainly due to the prosthetic ankle attempting to track biological ankle data). In addition, the TTA group's tracking error progressively increased with speed, indicating a somewhat reduced ability to maintain "normal" walking mechanics at faster speeds.

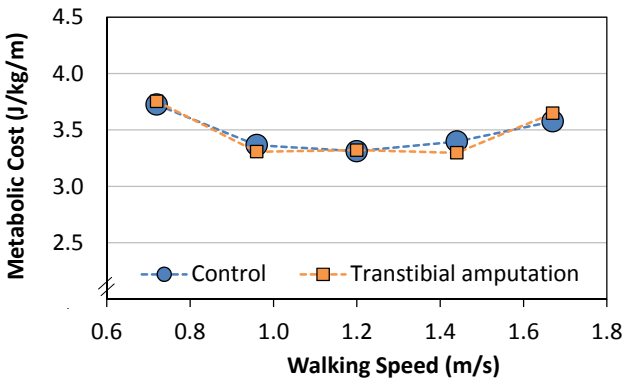

Figure 1: Predicted metabolic cost of walking with and without a simulated transtibial amputation (TTA).

CONCLUSIONS

These predictions, in combination with recent experimental data [1,2], challenge the commonly held belief that the metabolic cost of walking necessarily increases after TTA. The results suggest that individuals with a unilateral TTA can walk with both "normal" gait mechanics and metabolic cost at a range of speeds, provided they are fit and otherwise healthy, indicating that fitness and health may be as or more important than prosthesis design for walking mobility.

OPTIMAL DESIGN OF A SOFT-COUPLED ARM ASSISTIVE DEVICE BY MUSCULOSKELETAL MODELLING

[1] **Miguel N Castro**, [2]Tariq Rahman, [2]Kristen F Nicholson, [1]John Rasmussen, [1]Shaoping Bai and [1]Michael S Andersen

INTRODUCTION

Arm assistive devices, which can be passive or active, play an important role in assisting and rehabilitating users with impartments. Passive devices have the advantage of simplicity and independence of a power source. A passive device can balance gravity exactly by a parallelogram mechanism [1] or multi-articular springs [2]. The stiffness matrix approach [3] guarantees a fully balanced solution, but does not consider other design objectives. This study uses subject-specific musculoskeletal modelling to design and optimize soft-coupled upper limb orthoses for two impaired users with a trade-off between static balancing and compactness.

METHODS

One male subject (age 25), as control, and two adolescents with upper limb impairment (age 18 with arthrogryposis and age 15 with x-linked myotubular myopathy) were modelled in this IRB approved study. These two potential users were selected due to their inability to perform upper limb motion without assistance. The data acquisition took place at the Paediatric Gait Analysis Lab at Nemours/Alfred I duPont Hospital for Children (prior parental permission was given). It consisted assessing the reachable space of both active and passive anatomical ranges-of-motion during quasi-static motion. Furthermore, the maximum force generation capability in multiple, individual directions were assessed using a force sensor (microFET2, Hoggan Scientific, LLC, USA) for at most three static measurements in both directions of the joints of interest.

Eight degrees-of-freedom from the sternoclavicular joint to elbow joint were considered for the upper extremity model built in the AnyBody Modeling System v. 6.0 (Anybody Technology A/S, Aalborg, Denmark). The subjects' models were anthropometrically and in terms of muscle strength scaled to best reproduce measured data and would evaluate the subjects' muscle performance with the orthosis included.

Prior investigation was made from A-gear [2]. An anterior mono-articular spring (AMSS) spanning the shoulder joint was added to the previous configuration of a bi-articular spring attached between a point in the thorax frame vertically above the shoulder joint centre (SJC) and the forearm frame, and a posterior mono-articular spring attached between the upper and lower arm frames (fig. 1). The AMSS stabilizes the shoulder in the absence of a mechanical joint. To understand how its thorax attachment point affects the bi-articular spring, the point was also medially constrained relative to the SJC.

The design optimization problem was defined as the minimization of the maximum muscle activation (MMACT) across all muscles for ten selected static postures matching daily living activities such as eating or reaching an object. The stiffness, origin and insertion coordinates of three zero-free-length springs were considered as design variables (fig. 1). As a simple enforcement of compactness of the orthosis, only the longitudinal coordinate of the spring attachment points in the upper and forearm frames were optimized. This constraint compromises perfect balance.

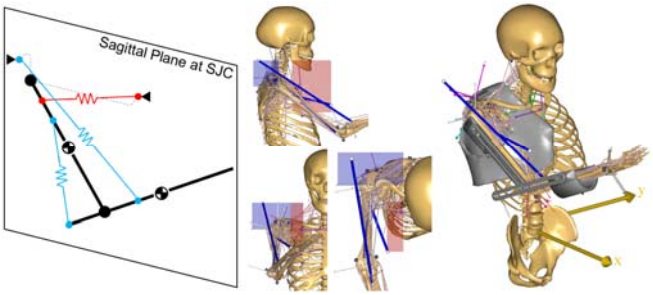

Figure 1: (Left) the two original springs (blue) and the AMSS (red) springs; (Right) the design space and optimized design.

RESULTS AND DISCUSSION

The optimized designs showed that, for all three subjects, the medial origin point of the AMSS moved anteriorly and inferiorly relative to the SJC. To maintain medial-lateral balance, the origin point of the bi-articular spring moved not only upwards, but posteriorly and laterally.

By adjusting the mechanical properties of the orthosis by minimizing the MMACT, the optimized design decreased the required activation for every posture within subjects' residual muscle strength capabilities. The maximum percentages of MMACT while wearing the orthosis for the most demanding postures, such as 90º shoulder abduction and/or flexion, changed from 26% to 10%, 94% to 18% and 273% to 60% for the control, adolescent 1 and 2, respectively. The two adolescents were barely able or not able to perform some of these postures without the orthosis.

The related error in terms of potential energy variation (range between 1.6-3.6 J) seems to be in the same order of magnitude as what results from arm support misalignments [4].

CONCLUSIONS

Contrary to a fully balanced design, this approach leads to a design that still supports the patient where required. By exploring the subject-specific residual muscle function in the optimization process, compact designs may be achieved.

CLINICAL TRIAL OF MICROPROCESSOR-CONTROLLED KNEES IN TRANSFEMORAL AMPUTEES

[1]**Kenton R. Kaufman**, [1]Kathie Bernhardt, and [2]Kevin Symms
[1]Mayo Clinic
[2]Hanger Clinic
Corresponding author email: kaufman.kenton@mayo.edu

INTRODUCTION

The benefits of a microprocessor-controlled knee (MPK) have been well documented in Medicare Functional Classification Level (MFCL) K3 transfemoral amputees (TFA). There have been suggestions that a K2 level TFA will also benefit from this advanced technology by increasing their ambulatory functional level to an unlimited community ambulator (K3) when receiving a MPK [1-5]. Current medical policy restricts MPKs to K3 or K4 amputees and, thereby, potentially limits functional capabilities. Therefore, the purpose of this study was to determine if K2 amputees would benefit from a MPK.

METHODS

Study Design: A prospective clinical trial (A-B-A design) was conducted where only the prosthetic knee was changed. Each subject was tested at baseline using their current NMPK, fit with a MPK and allowed 10 week of acclimation before being tested, and then retested with their NMPK after 4 weeks of re-acclimation. The subjects were randomly assigned a MPK prosthesis from one of four manufacturers (Otto Bock Compact, Ossur Rheo, Endolite Orion, Freedom Innovations Plie). All prosthesis fittings were performed by the subject's own certified prosthetist according to the manufacturer's fitting guidelines with oversight provided by the manufacturer's representative.

Subjects: 50 unilateral transfemoral amputees over age 55 (mean age 69$\pm$9 years with 4 years' experience using a prosthesis) who were MFCL K2 (with 13 K3 exceptions) were studied. Subjects were excluded if they had neuromuscular problems, a partial amputation of the contralateral limb, were on dialysis, had poor prosthetic socket fit, or had residual limb breakdown. The majority of the subjects were using a Medi knee (53%) or an Otto Bock (3R60, 3R80, 3R90, 3R92, 3R93) knee (27%).

Outcome measures: Patient function was assessed in the free-living environment using tri-axial accelerometers (Actigraph GT3X, Pensacola, FL, USA) worn on the waist, thigh, and bilateral ankles for a period of four consecutive days. Patient satisfaction and safety was measured using the Prosthesis Evaluation Questionnaire (PEQ) and PEQ addendum (PEQ-A).

Data Analysis: A one-factor repeated measures ANOVA was used to determine if there was a difference in outcomes between the MPK and NPMK. Statistical significance was attained when the p-value was <0.05.

RESULTS AND DISCUSSION

The subjects demonstrated improved outcomes when using a MPK. Patients reported a significant reduction in stumbles and falls when receiving a MPK (Figure 1). The subjects spent significantly less time sitting when using a MPK. The mean time/day sitting was 60% at baseline, 50% on the MPK, and 63% when returning to the NPMK. Subjects exhibited improved gait entropy (i.e. more complex movements) when using the MPK (baseline=0.17, MPK=0.29, NMPK=0.25). Subjects reported significantly improved appearance, less frustration and greater utility when using a MPK, as measured by the PEQ.

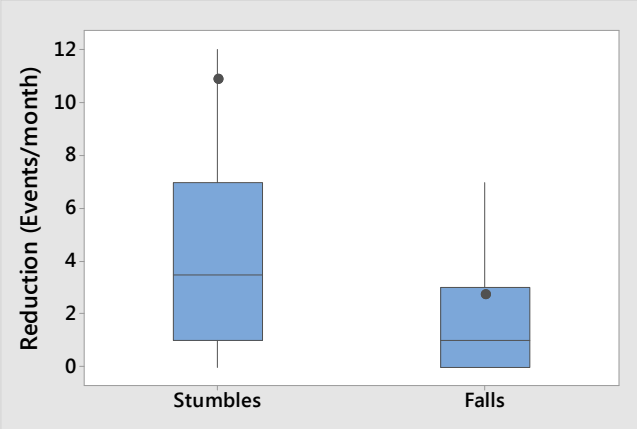

Figure 1: Box plot illustrating a reduction in stumbles and falls when using a MPK. The central line represents the median, the dot represents the mean, and the edges of the box are the 25th and 75th percentiles. The whiskers extend to $\pm$ 1.5 of the interquartile range.

This clinical trial demonstrated that K2 TFAs using a MPK improved their safety and activity, which resulted in increased subject satisfaction. Notably, a reduction in stumbles and falls occurred while the subjects engaged in more physical activity. The increase in activity resulted in a greater exposure to fall risk, but that risk was moderated by the advanced technology.

CONCLUSIONS

The study provides evidence that individuals with TFA and K2 mobility clearly benefit from a MPK.

SKIPPING HAS LOWER KNEE JOINT LOADS AND HIGHER METABOLIC COST COMPARED TO RUNNING

INTRODUCTION

A rising awareness of the many benefits gained from aerobic exercise has led to a 70% increase in the number of people running within the past decade. Runners consistently express a lower risk for cardiovascular disease mortality, BMI, smoking, and alcohol consumption [3]. Unfortunately, it is also well established that running causes a variety of injuries in as many as 79% of all runners annually [4]. While running injuries are considered "multifactorial" in causation, nearly all injuries are attributed to the stresses of repetitive impacts with the ground paired with insufficient recovery time [5,9]. Thus, the nature of the runner-ground interaction is critical in the development of running injuries. There is some evidence that skipping gait has lower ground reaction forces (GRF) than running [1,6] yet has higher metabolic cost than running [8] suggesting that a training program substituting skipping for running may be safer while providing greater aerobic training. The purpose of this study was to compare ground reaction forces, knee joint contact forces and metabolic costs of skipping and running.

METHODS

20 recreationally active, healthy participants (10 males, 22±2 yrs, 23±3 kgm^{-1}) trained in skipping over-ground (1 day) and on a treadmill (2 days) covering at least 3 miles. Tibio-femoral (TF) and patello-femoral (PF) compressive forces were derived from ground reaction forces (AMTI Model LG-6) and 3D kinematics (Qualisys ProReflex 240) while running and skipping along a runway at 2.7 ms^{-1} and a musculoskeletal model [2,7]. The model used both subject-specific and population based parameter inputs to calculate gastrocnemius, hamstrings, and quadriceps muscle forces and force in the lateral knee ligaments which were then combined along with the limb kinematics to calculate TF and PF forces. The two distinct skipping steps (S1 & S2) and the running step (R1) were each assessed with 5 trials per person. Metabolic data (Parvo Medics, Trueone 2400) were collected after six minutes of treadmill running and skipping also at 2.7 ms^{-1}. Participants rested between the conditions. Parameter values from S1, S2, and R1 were compared with 1-way ANOVA, and Scheffe post hoc tests, all $p<0.05$. The university Institutional Review Board approved the protocol and all participants provided written informed consent.

RESULTS AND DISCUSSION

Click HERE to view videos to better understand and compare the two gaits. Skipping had consecutive foot contacts with each limb and single and double support phases while running alternated left and right contacts and had only single support phases. R1 step length (1.10±.17m) was 29% and 45% longer than S1 (0.85±.07m) and S2 (0.76±.14m; all comparisons $p<0.05$).

Maximum vertical GRFs were statistically identical in R1 and S1 (23.7±1.8 v 23.0±2.8N/kg) but these were statistically greater than that in S2 (22.7±1.7N/kg, $p<0.05$). This difference is smaller than previously reported [1] which may be due to our slower gait velocity. Despite having 82% greater vertical displacement through the stride (skip v run: 0.20±.03m v 0.11±.02m, $p<0.05$), skipping had significantly lower maximum TF and PF forces than running (Fig 1). TF & PF were larger in S1 v S2, $p<0.05$. Maximum TF and PF forces were 24% and 65% larger in running compared to the mean of the two skipping steps. Larger forces in running can be largely attributed to longer steps with correlations of r=0.83 and r=0.75 (both $p<0.05$) between step length and TF and PF forces respectively across both gaits and all steps.

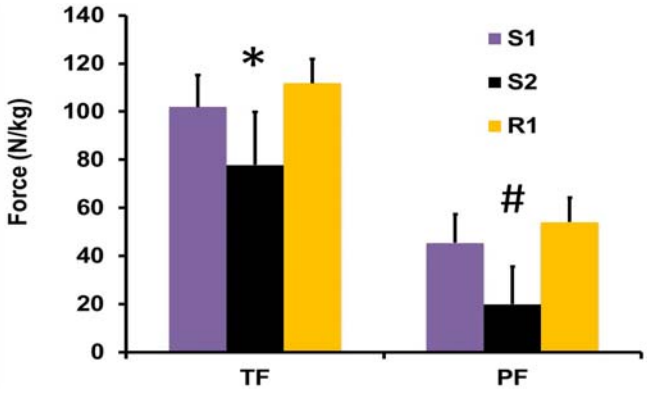

Figure 1. Maximum TF and PF forces in skipping (S1, S2) running steps (R1). *All TF forces significantly different and # all PF forces significantly different, $p<0.05$.

Despite having a double support phase within each stride as in walking, metabolic cost was statistically and substantially higher in skipping v running (41.1±2.5 v 31.6±3.4 ml/kg/min, $p<0.05$), a difference of 29% which agrees with Minetti et al's estimate of 30%. We also attribute this difference to the larger vertical displacement in skipping compared to running. Indeed, vertical displacement was highly correlated to metabolic cost across both gaits, r=0.80, ($p<0.05$).

CONCLUSIONS

In addition to simply maintaining the skill of running, people run to enhance cardiovascular, bone and muscle health. Yet this goal is often hindered by running injuries. These data provide support for the idea that skipping may have a lower injury risk with better fitness and health outcomes than running. We suggest the substitution of an as yet undetermined amount of skipping for running may reduce the likelihood of injury and enhance health.

PRIMARY MUSCLE CONTRIBUTION TO TIBIOFEMORAL JOINT CONTACT LOADS DURING WALKING, RUNNING AND SIDESTEPPING

INTRODUCTION

Inappropriate tibiofemoral joint (TFJ) loading, particularly loading magnitude, has been implicated as a major cause of TFJ degeneration and osteoarthritis [1,2]. External and muscle loading make substantial contributions to TFJ compressive loading during gait. Previous research has shown that net (i,e. total) muscle contribution to TFJ loading is larger than and able to well support the external loads during walking, running and sidestepping gait tasks [3]. Furthermore, muscle group contributions have been examined in walking [4,5] and running gait [6]. While these studies provide valuable information regarding muscle contributions to TFJ contact forces, they have not examined the contribution of individual muscles to all three locomotor tasks. Therefore, the aim of this study was to determine the individual muscle contributions to TFJ contact loading during walking, running and sidestepping gait tasks in a healthy control population.

METHODS

Fifty-five healthy controls underwent gait analysis, while wearing a full body retro-reflective marker set [3]. Surface electromyography (EMG) was performed on 8 major muscles at the knee. These EMGs were then mapped to 13 musculotendon units (MTU): rectus femoris (RF), vastus intermedius (VI), vastus lateralis (VL), vastus medialis (VM), semitendinosus (ST), semimembranosus (SM), biceps femoris long head (BFLH), biceps femoris short head (BFSH), medial gastrocnemii (MG), lateral gastrocnemii (LG) and tensor fascia latae (TFL).

Participants first completed a static calibration trial followed by three repeated trials of each gait task. During each trial, ground reaction forces were measured using two force plates (Kistler Instruments, Switzerland) (1000Hz), EMGs (Zero Wire, Aurion, Italy) (1000Hz) and three-dimensional marker trajectories (Vicon, Oxford Metrics, UK) were acquired (200Hz). Marker trajectories and anthropometrics were used to scale a generic OpenSim [7] model to each participant's dimensions and mass. This model was then used in the EMG-driven modelling framework: Calibrated EMG-informed NMS (CEINMS) [8] to calculate MTU forces, MTU moments, and TFJ contact loads. The relative contributions made by each MTU were calculated by determining the proportion of joint contact loading caused by the MTU moment in both the medial and lateral compartments. The stance phase of gait was divided into three distinct phases based on the TFJ flexion/extension. These were termed weight acceptance (WA), mid-stance (MID) and push off (PO).

RESULTS AND DISCUSSION

During walking WA, we found SM , BFLH, VM and VL dominated the contributions to both medial and lateral compartment loading, with the gastrocnemii dominant during MID and PO phases. During running, contributions of the quadriceps, SM, BFLH and ST increased compared to walking gait during MID and PO phases. Sidestepping WA elicited larger quadriceps and gastrocnemii muscle contributions to medial compartment loading compared to running, and showed smaller gastrocnemii, hamstrings, VI and VL contributions to lateral compartment loading compared to running.

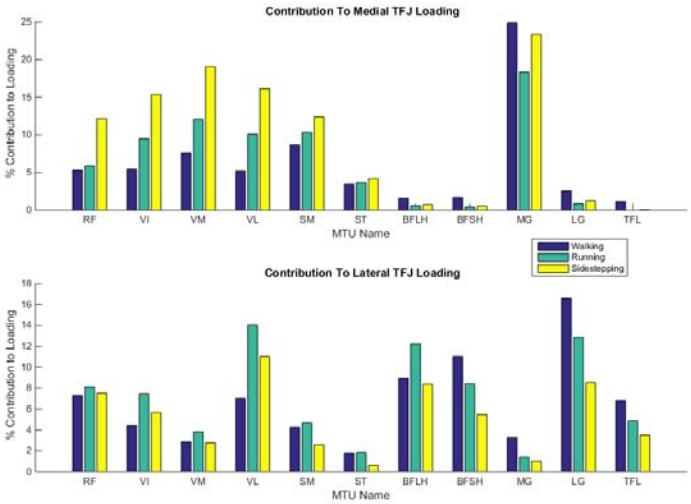

Figure 1. Individual MTU contribution to medial and lateral TFJ contact loading during walking, running and sidestepping gait tasks.

CONCLUSIONS

We found that muscles with an adduction moment arm relative to the TFJ centre primarily loaded the medial compartment, while the lateral compartment was primarily loaded by muscles with an abduction moment arm. The magnitude of the relative muscle contributions to TFJ contact loading changed both between gait task and across the stance phase of individual gait tasks. These changes are thought to be driven primarily by different TFJ kinematics, kinetics and stabilization requirements of the different gait tasks.

HOW INTERNAL KNEE COMPRESSIVE FORCES ARE MOST EFFECTIVELY REDUCED BY APPLIED HIP, KNEE AND ANKLE JOINT MOMENTS

[1]**Jonas S Stoltze**, [1]John Rasmussen and [3]Michael S Andersen
[1]Aalborg University, Denmark
Corresponding author email: jss@m-tech.aau.dk

INTRODUCTION

Valgus or varus braces are often used as treatment for unicompartmental knee osteoarthritis (KOA) with the purpose of shifting the internal knee load from the damaged cartilage and meniscus to the other compartment. The majority of KOA patients suffer from medial cartilage deterioration [1] for which reason a medial load reduction is usually the main goal with brace treatment. This goal is often claimed to be reached in the literature based on a reduced knee adduction moment [2,3] despite a fairly low correlation between these two parameters has been shown [4]. Whether or not the brace succeeds to shift the load, the total compressive knee load is still unaffected. Thus, we wanted to investigate how internal knee joint loads depend on applied moments during gait to obtain information on how to reduce the total compressive knee load most efficiently.

METHODS

The study is based on musculoskeletal (MS) models, from a previous study [5], which included ten healthy subjects (8 males and 2 females, age: 25.7 ± 1.5 years, height: 180.8 ± 7.4 cm, weight: 76.9 ± 10.4 kg). For each subject, full-body 3D kinematics were recorded during three gait trials based on 35 surface-mounted reflective markers (29 placed on the skin and three on each shoe). The trajectories from these were used to drive MS models in the AnyBody Modelling System (AMS), which computed muscle and joint forces while applying joint moments, completely balancing the internal moment at the hip, knee and/or ankle, in both the sagittal and frontal planes. The total compressive joint load was examined for each applied moment and those contributing to the largest load reduction was combined to find the most effective combination of those tested.

RESULTS AND DISCUSSION

The effect on the mean total compressive load during the stance phase and early swing (0-70% gait cycle) from combinations in the sagittal plane, applied varus-valgus moment (KneeAA) and normal gait without any applied moments (Normal) is shown in Figure 1. The curves indicate moments in the sagittal plane to be most efficient regarding knee joint load reduction, which is assumed to be due to compensation of the internal moment from muscle contraction, which are completely balanced by the applied moments. While a complete unload of the muscles is not ideal in practice, the results indicate which approach, among the investigated moments, most efficiently reduces internal joint loads.

In the following, all comparisons are based on the curves in Figure 1 with respect to Normal. The applied moments are referred to as FE (flexion-extension), PD (plantar-dorsi flexion) and AA (abduction-adduction).

A combination of hip, knee and ankle moments in the sagittal plane (HipFE+KneeFE+AnklePD), reduces the first peak (~13% gait cycle) and second peak (~50% gait cycle) with 52% and 60%, respectively. HipFE+KneeFE mainly affects the first peak with a reduction of 56% and KneeFE+AnklePD performs slightly better on the second peak than HipFE+KneeFE with a reduction of 35%. It is worth noting that the KneeAA curve (simulating the effect from a varus or valgus brace) coincides with the Normal curve since this moment only shifts the condyle load.

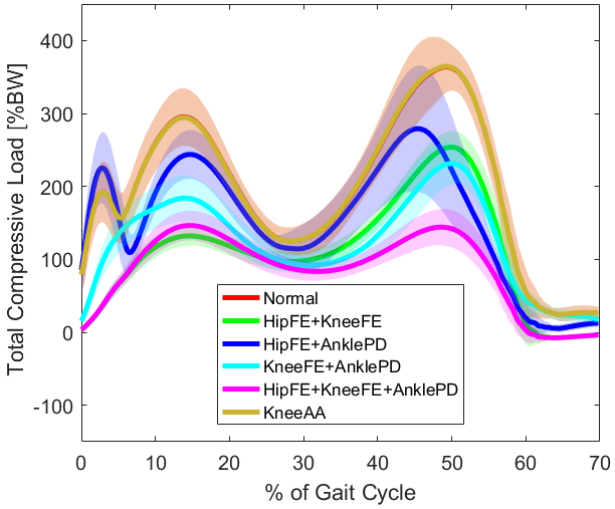

Figure 1: The mean total knee compressive load as percentage of bodyweight (%BW) from 0-70% gait cycle for each combination of applied moments.

CONCLUSIONS

This study indicates that common valgus or varus braces leave the total compressive knee load unaffected during normal gait whereas muscle compensation in the sagittal plane has a much stronger influence on the total knee load. The results can be used as a guide for improving current knee braces on the market to ensure an efficient joint load reduction during gait.

KNEE LOADING AND NEUROMUSCULAR ACTIVITY DIFFERS FOR EARLY AND LATE STAGE OA

[1,2] **Aseel Ghazwan**, [2,3] Chris Wilson, [1,2] Cathy A. Holt and [1,2] Gemma M. Whatling

INTRODUCTION

The determination of knee contact forces (KCF) is valuable for researchers to provide insight into loading mechanisms associated with the progression of Osteoarthritis (OA). The purpose of this study was to estimate KCF in patients with varying degrees of OA severity, using muscle and joint reaction forces derived from OpenSim.

METHODS

3D kinematic and kinetic data were collected from 80, fully consented subjects divided into three groups: 20 healthy subjects, 30 with medial OA awaiting high tibial osteotomy (pre-HTO), and 30 with late stage OA awaiting total knee replacement (pre-TKR). The mean and SD of age, weight and height for healthy, pre-HTO and pre_TKR cohorts were (36.0±9.8, 50.6±7.7, 69.1±9.3) years, (73.0±14.3, 88.2±21.7, 87.4±20.5) kg and (170.8±6.8, 173.5±10.5, 166.2±10.0) cm, respectively. Recorded raw EMG data (Delsys Trigno) were band-pass filtered, rectified, low-pass-filtered and normalized to peak values obtained through activities of daily living (level gait, stair ascent and descent and sit to stand). Gait biomechanics for six trials from each subject were determined using OpenSim v3.3 [1]. The customized generic anatomic model, Gait 2392 Model, was scaled to each participant's anthropometry. It was then used to calculate joint angles, and moments for gait trials using OpenSim inverse kinematics (IK) and inverse dynamics (ID) tools, respectively. Muscle forces were calculated using static optimization and knee contact forces (KCF) calculated using the joint reaction function.

RESULTS AND DISCUSSION

A total of 480 predictions of KCF were generated for 80 subjects, with 6 simulations for each participant. The pre-TKR cohort exhibited a different KCF pattern than the control and pre-HTO cohorts. The KCF from the control and Pre-HTO subjects had two distinct peaks, where the second peak was higher than the first one and it reduced from control to OA subjects which is attributed to decreased gastrocnemius force in OA subjects. In the pre-TKR cohort there is a trend of having a higher mid-stance KCF. This suggests that in subjects with severe OA the higher KCF during mid-stance is attributed to increased counterbalancing role of the quadriceps and hamstrings during dynamic movements to stabilize the knee, where muscle forces are represented as the main contributor of KCF.

Maximum KCF for the pre-TKR cohort is lower than the pre-HTO and control cohorts. Pre-TKR subjects do not have a clearly defined double peak and this may result from a higher mid-stance knee adduction moment as well as both quadriceps and hamstrings producing high muscle forces during mid-stance.

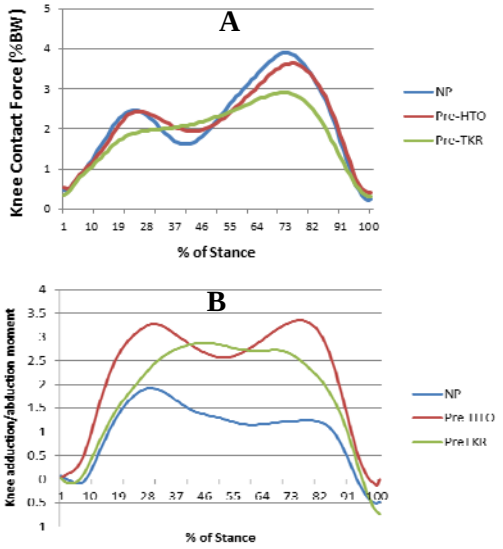

Figure 1: Knee Contact Force during stance phase across varying OA severities - **A**, Frontal plane knee moment during stance phase across varying OA severities – **B**. Values represent mean.

Additionally, several anthropometric, demographic parameters and patient reported outcome measures were also examined across subject groups. Results from linear regression revealed that, increases in Oxford Knee Score and KOOS Symptom outcome measures were significantly associated with an increase in peak KCF. No significant correlation were addressed between KCF and other outcome measures, i.e., WOMAC, PACS, KOOS Pain, KOOS ADL, KOOS Sport/Rec, and KOOS QOL.

CONCLUSIONS

Differences in the patterns and magnitudes of the KCF waveforms provide information on gait changes associated with knee OA severity. The highest KCF was found for the control cohort, followed by early stage OA (pre-HTO) and then late stage OA (pre-TKR). Further, the second KCF peaks are lower in subjects with OA. This suggests that less muscle force is being produced in late stance and therefore the subjects are not driving themselves forward with the same strategy as the control group.

INTRODUCTION

Young subjects who develop medial compartment knee osteoarthritis (OA) 5 years after anterior cruciate ligament reconstruction (ACLR) demonstrate inter-limb differences in knee gait variables early after ACLR (~ 6 months after ACLR) [1]. Elevated peak knee adduction moment (pKAM) and medial compartment force (pMCF) are related to OA progression [2], however, the relation to OA onset is less clear [3]. Elevated cartilage T2 relaxation time measured using quantitative magnetic resonance imaging (MRI) indicate early OA related changes, i.e. deterioration of collagen network and proteoglycan loss [4]. Currently, it is not known whether inter-limb differences in knee variables during gait and cartilage T2 early after ACLR are related. The purpose of the study was to investigate this relationship 3 months after ACLR.

METHODS

10 subjects were enrolled 3 months after unilateral ACLR (6 men, 4 women; mean: age = 24 years, mass = 78 kg, height = 1.7 m). During motion analysis, each subject completed 5 trials at self-selected walking speeds (mean: 1.5 m/s). We captured gait data using retroreflective markers, an 8-camera setup (Vicon, Oxford Metrics Limited, London, UK) and a force platform (Bertec Corporation, Worthington, OH). pKAM and pMCF during weight acceptance were computed using inverse dynamics and a validated electromyography-informed musculoskeletal model [5].

Each subject underwent supine bilateral knee MRI using a sagittal T2 mapping sequence (field of view: 160 x 160 mm, slice thickness = 2 mm, repetition time = 4480 ms, 6 echo times = 12.5 to 75 ms). We calculated T2 maps using exponential fitting (ImageJ, National Institutes of Health, Bethesda, MD). We analyzed the MRI slice corresponding to the center of medial compartment in the frontal plane (primary load-bearing region during gait), which was located based on femoral epicondylar width measurement. The key regions of interest (ROI) were defined as the posterior and central load-bearing tibial cartilage layers in the sagittal plane, differentiated based on menisci boundaries. Each ROI was further sub-divided into deep and superficial cartilage sub-layers. We used students t-test to compare inter-limb differences, and calculated Pearson's correlation coefficients between inter-limb difference for the gait variable vs. inter-limb difference for cartilage T2.

RESULTS AND DISCUSSION

We observed a positive correlation for inter-limb difference (involved minus uninvolved, or INV - UN) between pKAM and T2 values for posterior tibial cartilage (deep: R^2 = 0.5542, superficial: R^2 = 0.4126, Figure 1). This implies that those with greater pKAM in the INV vs. UN knee also have higher T2 relaxation time values (i.e. potentially greater cartilage deterioration) in the INV vs. UN knee.

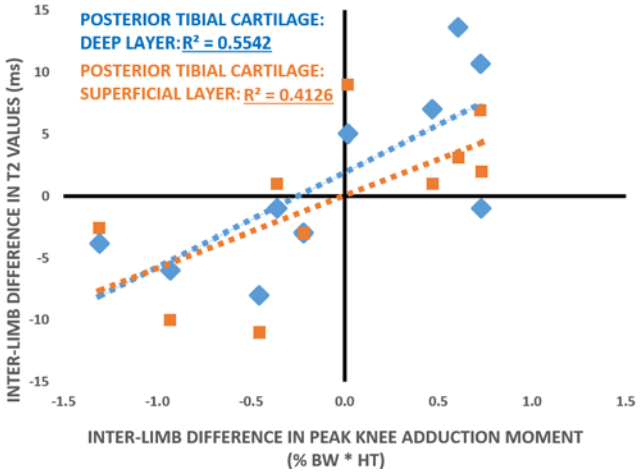

Figure 1: Inter-limb difference (INV - UN) in T2 for posterior tibial cartilage (Y-axis, unit = milliseconds), vs. inter-limb difference in peak knee adduction moment (X-axis, unit = % body weight * height). NOTE: A positive number indicates that value is greater in INV vs. UN knee, and vice-versa.

Inter-limb differences in pKAM vs. T2 in central tibial cartilage, and pMCF vs. T2 in central/superficial regions were not correlated (R^2 = 0.1425 or less). Also, biomechanical and T2 variables were not significantly different between limbs.

CONCLUSIONS

The observed relation between pKAM and T2 values for posterior (but not central) tibial cartilage could be due to excessive anterior tibial translation observed after ACLR [6], which shifts joint contact posteriorly. However, we did not observe a similar relationship for pMCF and T2 values. These results warrant further investigation of a potential link between knee gait biomechanics and cartilage health after ACLR, with both a larger sample size and long-term follow-up. Evaluating inter-limb differences in knee gait and cartilage MRI variables may aid in early OA detection, and inform strategies to delay OA progression after ACLR.

THERE ARE NO DIFFERENCES IN UTC MEASURES OF PATELLAR TENDON QUALITY BETWEEN HEALTHY AND (WEAKER) ACL INJURED KNEES

INTRODUCTION

Anterior cruciate ligament (ACL) injuries are extremely common in contact sports [1]. Deficit on quadriceps strength on the involved limb post ACL injury has been previously described [2]. Other complications related to the ACL injury includes persistent pain and swelling, limited range of motion (ROM), and anterior knee pain. Ultrasound tissue characterization (UTC) has been used to express the quality of tendons based on the stability of the echo pattern [3, 4]. The aim of our study was to assess the quality of the patella tendons in subjects with ACL injury, and correlate tendon quality with muscle strength, amount of days since ACL injury, and knee ROM. It is hypothesized that the patella tendon of the involved leg will present lower quality than the uninvolved leg. And that the longer the period from ACL injury to assessment time, the lower the patellar tendon quality.

METHODS

Thirty-eight male patients (age between 15 to 47 years) sustaining ACL injury (time from ACL injury ranging from 9 to 4094 days) volunteered for the present study and gave a written informed consent. Subjects were submitted to a clinical assessment, isokinetic concentric strength test, and UTC scans. All tests were performed on the involved and uninvolved leg. UTC scans were performed twice (two days apart) for reliability tests. After warm up and familiarization with the procedure, subjects performed 5 maximal knee extension and flexion repetitions in 60^0/s on the Biodex™ Dynamometer (BIODEXTM Shirley, New York). UTC scans (SmartProbe 10L5, Terason 2000, Teratech, USA) (UTC Tracker, UTC Imaging, Netherlands) were performed with subjects in supine with knee flexion of approximately 100^0. UTC acquisition and analyses were performed by one single examiner. Contours were drawn on every 0.5cm throughout the whole patella tendon. The overall tendon, the apex of patella, 2cm bellow apex of patella (mid tendon) and 2 cm before the raise of tibia tuberosity (distal tendon) were determined as areas of interest.

Data presented normal distribution. Thus, paired t-test was used to compare involved and uninvolved legs. Level of significance of $p<0.05$ (*) was set.

Intra-observer reproducibility of both data collection and analysis were performed. Standard error of the measurement (SEM) was calculated in order to obtain the minimal detectable change of all UTC parameters (MDC = 1.96 × SEM ×√2). The program IBM SPSS v.21 was used for all statistical analyses (SPSS Inc, Chicago, Illinois, USA).

RESULTS AND DISCUSSION

There was no difference in patella tendon quality between involved and uninvolved leg (Table 1). There was low or no significant correlation between peak torque, period in days of being injured, ROM and any of the UTC variables studied. The majority of UTC variables appeared to have good to excellent intra-observer reproducibility (Table 1 and 2). The UTC variable that presented difference statistically significant had difference between involved and uninvolved legs inferior than the MDC, thus clinically insignificant.

Table 2: Values of mean, standard deviation, value of significance and intra-class coefficient of reliability for tendon thickness, strength and ROM.

	Involved	Uninvolved	p-value	ICC
Tendon thickness	0.5±0.1	0.5±0.1	0.18	.798
Peak torque	167.3±65.7*	209.9±55.9*	0.000	----
Knee Extension	0.0±4.5*	2.2±2.9*	0.00	----
Knee flexion	138.0±11.3*	145.0±7.5*	0.00	----

CONCLUSIONS

Regardless if the ACL injury is acute or chronic; the quality of the patella tendon on the involved leg seemed not to be affected by the significant smaller values of quadriceps strength and restricted ROM.

LIMB LOADING ABILITY DURING BILATERAL TASKS IN INDIVIDUALS FOLLOWING ANTERIOR CRUCIATE LIGAMENT RECONSTRUCTION

INTRODUCTION

Individuals following anterior cruciate ligament reconstruction (ACLr) have been found to adopt a loading strategy that shifts the mechanical demands away from the surgical limb during bilateral tasks [1]. This loading pattern persists long-term and is attributed to increased risk for re-injury [2] and progression of knee osteoarthritis [3]. Sensorimotor impairments at the surgical knee have been described following ACLr [4]. However, it is not known if individuals following ACLr have the ability to perceive differences in weight bearing magnitude during bilateral tasks. The purpose of this study was to investigate limb loading abilities in individuals following ACLr by comparing loading symmetries among three conditions in which participants performed bilateral tasks 1) naturally (N), 2) following explicit loading instructions without performance feedback (instructed condition, IN) and 3) with limb loading feedback (feedback condition, F).

METHODS

Five individuals post-ACLr (98±16 days) and 5 healthy controls) were enrolled in this study. Participants performed 2 double limb tasks (sit-to-stand (SS) and squat (SQ)) under 3 conditions (natural, instructed, and feedback). Ground reaction forces were collected while participants performed the tasks using BTS P-6000 force platforms (BTS Bioengineering Corp, Milan, Italy; 1000 Hz) in natural and instructed conditions and AMTI force platforms (AMTI, MA, USA; 1000 Hz) in feedback condition. In attempts to examine natural limb loading behaviors, in the natural condition, participants received no instruction regarding weight bearing; and in some conditions did not know they were being assessed. To assess individuals' ability to accurately determine the magnitude of limb loading, participants were given explicit instructions to distribute their weight evenly between limbs while performing each of the tasks in instructed condition. To assess individuals' ability to load their limbs symmetrically, participants were given real-time feedback regarding vertical ground reaction force (vGRF) magnitude under each limb and asked to keep loading even between the limbs. vGRF impulse was calculated for each limb during each task execution determined by L5S1 marker. Limb loading symmetry was quantified as a ratio of vGRF impulse of the surgical / non-surgical limbs (ACLr) and matched limb dominance in healthy controls. Fours trials were averaged in each condition for each task for analysis. Separate 2 (group) x 3 (condition) ANOVAs with post hoc independent and paired t-tests were performed to assess the effects of group and condition on limb loading symmetry ($\alpha = .05$).

RESULTS AND DISCUSSION

As seen in the Figure 1 (representative data across tasks), participants in the control group maintained symmetrical loading across conditions with limb loading symmetry close to 1 (SS: .99 ± .20 (N), 1.03 ± .05 (IN), 1.03 ± .03 (F); and SQ: 1.00 ± .11 (N), .98 ± .05 (IN), 1.02 ± .02 (F)). Differences between control and ACLr groups in the natural condition suggest that individuals following ACLr adopted an asymmetrical loading strategy when they were not paying attention to loading (SS: .72 ± .03 (ACLr) vs. .99 ± .20 (Ctrl), *ES: 7.42*; and SQ: .71 ± .07 (ACLr) vs. 1.00 ± .11 (Ctrl), *ES: 5.3*). Interestingly, when giving visual feedback, individuals post ACLr were able to perform the tasks as symmetrically as controls, suggesting that they are capable of meeting the mechanical demands of the tasks loading (SS: .98 ± .18 (ACLr) vs. 1.03 ± .03 (Ctrl); and SQ: .99 ± .01 (ACLr) vs. 1.02 ± .02 (Ctrl)). Loading symmetry improved in the instructed compared to natural loading condition in the ACLr group (SS: .84 ± .09 (IN) vs. .72 ± .03 (N), *ES: 1.51*; and SQ: .91 ± .32 (IN) vs. .71 ± .07 (N), *ES: .76*). However, they performed with less symmetry in the instructed condition than feedback condition (SS: .84 ± .09 (IN) vs. .98 ± .18 (F), *ES: .66*; and SQ: .91 ± .32 (IN) vs. .71 ± .07 (F), *ES: .25*). The inability to load symmetrically without feedback suggests that individuals following ACLr have impairments in loading sensation or the perception of loading magnitude.

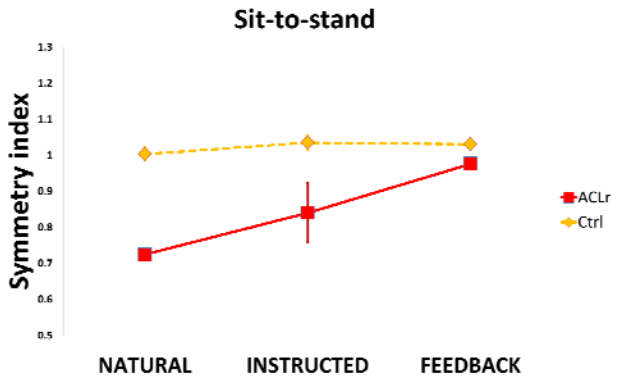

Figure 1: Comparisons of limb loading symmetry between groups of during SS across conditions

CONCLUSIONS

The large effect sizes suggest that despite having the ability to meet the demands of the bilateral tasks individuals 3 months post-ACLr preferentially load the non-surgical limb in more natural conditions. The inability to accurately determine loading magnitude may influence this preference and practice throughout the day may result in reinforcement of asymmetrical loading.

ASYMMETRIC TIBIOFEMORAL KINEMATICS ARE ASSOCIATED WITH ACL RECONSTRUCTION GRAFT GEOMETRY

[1]**Michael F. Vignos**, [1,2]Jarred Kaiser, [1]Geoffrey S. Baer, [1]Richard Kijowski, [1]Darryl G. Thelen

INTRODUCTION

Subtle asymmetries in tibiofemoral (TF) kinematics have been detected in ACL reconstructed (ACLR) knees [1,2]. These altered kinematics shift the cartilage contact regions, which is theorized to initiate progression into osteoarthritis [3]. Thus, restoring normal kinematics with ACLR could prevent early cartilage degradation. Prior *ex vivo* studies have shown that graft tunnel placement impacts the anterior-posterior laxity [4] and internal rotation of the knee [5]. Further, gait analysis has identified potential links between ACL graft orientation and knee rotation [6]. However, conventional motion analysis lacks the precision to capture subtle changes in secondary TF kinematics that may impact cartilage loading. In this study, we used dynamic MRI to investigate links between TF kinematics and ACL geometry during active movement. We hypothesized that non-anatomical graft orientation would be related to asymmetries in anterior tibia translation and internal rotation.

METHODS

The bilateral knees of 18 subjects that underwent a primary unilateral, isolated ACLR were tested (9 M, 24.8±5.7 yrs, 78.9±16.5 kg, 20.2±8.7 months post-op, 9 PT grafts). Bilateral, high resolution MR images were collected and segmented to create bone and ACL geometries for the ACLR and intact knees. The location of the ACL femoral and tibial attachments and the orientation of the ACL relative to the tibia plateau were measured bilaterally (Fig. 1A). Non-anatomical ACL graft geometry was characterized by subtracting the intact from the reconstructed metrics.

During the dynamic MRI protocol, subjects lay supine in the MR scanner with their leg attached to an inertial loading device. Subjects performed cyclic knee flexion-extension at 0.5 Hz for 5 min while dynamic volumetric images were continuously acquired [7]. Images were retrospectively sorted and reconstructed into 60 frames over the motion cycle. Six degree of freedom TF kinematics were measured by optimally registering the bone geometries to the image sets at each frame. We then extracted the TF kinematics at peak knee flexion and extension and the range in TF kinematics through extension. Kinematic asymmetries were determined by subtracting the intact from the reconstructed metrics. We computed Spearman's correlation coefficient (R) between the kinematic and ACL geometry asymmetry metrics with significance set at $p<0.05$.

RESULTS AND DISCUSSION

Sagittal orientation of the ACL graft was correlated with asymmetric anterior translation (R=0.56), internal rotation (R=0.50), and adduction angle (R=0.54) at peak flexion (Fig. 1B). Frontal plane orientation of the ACL graft was correlated with lateral translation at peak flexion (R=0.50), internal rotation at peak extension (R=0.58), and lateral translation range (R=-0.52). Additionally, the superior location of the femoral attachment was correlated with lateral translation at peak flexion (R=0.58) and extension (R=0.56), while the lateral location of the tibial attachment was correlated with internal rotation at extension (R=-0.61).

Our results suggest that non-anatomical ACL graft placement may contribute to asymmetries in *in vivo* knee mechanics. Abnormally high anterior tibia translation was associated with a more vertically oriented ACL graft, which is consistent with a previously observed relationship between the neutral anterior tibia position and ACL orientation [6]. We also found that a more horizontal graft in the sagittal plane was linked with greater external tibia rotation. Given that there is a bias towards external rotation in ACLR knees [1,2], our data suggest that this abnormality may be modifiable via graft placement.

CONCLUSIONS

This study elucidates links between ACL graft geometry and kinematics in reconstructed knees, which may be important to consider when planning ACLR procedures that can best restore normative mechanics.

INTRODUCTION

Abnormal lower limb mechanics after anterior cruciate ligament injury (ACL) have been considered as a risk for the development post-traumatic osteoarthritis[1]. It is possible that long-term impairments and asymmetries following ACL reconstruction (ACLR) may be more evident during high loading activities such as stair ascent and descent than during walking[2]. The aim of the study was to compare knee kinematics and kinetics in sagittal plane of the ACLR knee to the contralateral limb and with uninjured controls during stair ascent and descent.

METHODS

Twenty-three participants (13 women) with ACLR 4.7 (1.8) years (2 – 10 years) post-surgery and 24 age-matched controls were tested during stair ascent and descent over two steps in a gait laboratory. Two steps were used for stairs such that the first step was placed on the floor-embedded force plate. Eleven infra-red cameras were used to capture the motion of participants. Cortex and Visual 3D software were used to estimate bilateral knee angles and external knee moments. Repeated measures ANOVAs were used to determine whether significant group (ACLR vs controls) and side effects (injured vs uninjured; Side 1 vs Side 2) or interactions existed ($p>0.05$). Pairwise post-hoc tests were performed where appropriate.

RESULTS AND DISCUSSION

No significant effects or interactions were found for spatiotemporal variables during ascent and descent. Significant side effects were found for the extension moment ($p= 0.021$) and interaction effects (group x side) ($p= 0.008$) for flexion moments during ascent. Significant group effects were found for flexion angles ($p=0.016$) during ascent and first flexion moments ($p= 0.037$) during descent.

During stair ascent, flexion moments of the ACLR uninjured side were higher than Controls ($p=0.003$) and higher peak extension moments were seen on the ACLR injured side compared to the contralateral side ($p=004$). ACLR injured sides exhibited significantly lower peak knee flexion angles compared to the Controls ($p= 0.004$) (Table 1). During stair descent, the first peak flexion moment for the uninjured sides were significantly higher than controls ($p=0.019$), while no significant difference was found when comparing the ACLR injured sides to the controls ($p=0.261$). No significant effects were found for second peak flexion moments and knee kinematics during descent.

Higher flexion moments on the uninjured side of the ACLR group indicate the compensatory role for the injured side following ACLR. Furthermore, higher extension moments during ascent for the ACLR injured sides may reflect quadriceps avoidance patterns

Table 1.Kinetics, kinematic and spatiotemporal variable during stair ascent and descent (Mean and Standard deviation (SD))

	ACLR group		Control group	
	Injured side	Uninjured side	Side 1	Side 2
Stair ascent				
External moments ($Nmkg^{-1}$)				
Flexion*	-89.2 (26.2)	-104.5 (22.0)	-86.7 (28.7)	-82.2 (26.8)
Extension #	11.7 (15.5)	4.4 (13.5)	7.9 (16.9)	6.7 (14.2)
Kinematics (Angles- degrees)				
Flexion∞	-55.8 (4.4)	-57.2 (4.9)	-59.8 (4.6)	-59.5 (4.7)
Extension	-6.4 (4.8)	-5.8 (3.9)	-6.9 (4.0)	-7.1 (4.8)
Stair descent				
External flexion moments ($Nmkg^{-1}$)				
Peak 1 ∞	-38.5 (19.2)	-47.1 (26.4)	-31.9 (20.4)	-32.4 (13.4)
Peak 2	-66.3 (35.7)	-76.3 (35.4)	-66.6 (27.8)	-65.0 (27.6)
Kinematics (Angles- degrees)				
Flexion	-80.3 (12.4)	-79.7 (9.2)	-83.3 (5.7)	-81.8 (6.8)

* Significant Interaction (Group x Side); # Significant Side effect; ∞ Significant group effect.

CONCLUSIONS

Differences in kinematics and moments in participants with ACLR compared to Controls suggest incomplete recovery or changes in neuromuscular control and joint function up to 10 years following injury. Asymmetric loading during ascent between uninjured and injured sides following ACLR and compensatory mechanisms may potentially indicate risk for osteoarthritis.

INFLUENCE OF MUSCLE ACTIVITY AND CO-CONTRACTION ON PREDICTED HIP CONTACT FORCES

[1]**Enrico De Pieri**, [1]Dana Rahbani and [1]Stephen J. Ferguson
[1]ETH Zurich
Corresponding author email: enrico.depieri@hest.ethz.ch

INTRODUCTION

Muscle co-contraction is the simultaneous contraction of the agonist and antagonist muscles, activating both moment arms about a specific joint in order to regulate joint stiffness and maintain stability. Joint stabilization is particularly important after invasive surgeries, such as Total Hip Replacements (THR), which has been previously associated with higher or abnormal muscle activation [1]. The additional forces exerted by agonist-antagonist muscles can lead to overall higher contact forces at the joint level.

This study aims to quantify how muscle co-contraction affects predicted joint loads in musculoskeletal simulations.

METHODS

The musculoskeletal simulations, run through the AnyBody Modelling System, were based on the *MoCap Lower Body Model* from the AMMR repositories, which has previously been used to predict hip contact forces (HCF) [2]. The model was based on the TLEM 1.1 cadaveric dataset and linearly scaled to match the anthropometry of a healthy subject (height=1.73m, weight= 63kg). Inverse dynamics analysis was based on measured motion capture and ground reaction forces data to simulate gait activity. The indeterminacy of the muscle configuration was solved with a 3rd-order polynomial muscle recruitment criterion.

Co-contraction was implemented by imposing a minimum level of activation (bound) in the antagonist muscle. The muscle recruitment algorithm was then able to compensate for this additional activity by further recruiting the agonist muscle, in order to maintain an unvaried kinetic balance around the joint. The imposed bounds (1, 2, 5, 10%) were chosen within the physiological range of muscle activation occurring during gait. The bounds were added on the major muscle fascicles involved in hip flexion and extension. The bounds were added alternatively on hip extensors, on hip flexors or on both.

RESULTS AND DISCUSSION

The results show an overall increase in the joint contact forces when co-contraction is enforced on hip flexors and extensors. When the lower bounds are applied only on the flexors, an increase of 81% is registered in the contact forces during the loading phase of the stance (Figure 1, middle). Similarly, when the bounds are applied on the extensors, an increase of 141% in the contact forces can be seen in the terminal phase of the stance (Figure 1, bottom). The combination of the two bounds leads to an overall increase of HCF throughout the gait cycle (Figure 1, top). Hip contact forces could reach peak values as high as 7.8*BW during normal gait, more than double compared to the baseline predictions of the model. The main limitation of this study is the implementation of a constant, non-time-dependent level of co-contractive activity of the involved muscles. This choice was mainly motivated by the inconsistency of EMG normalization techniques and the difficulty to measure actual activation levels in-vivo. The simulations were also performed under the assumption of unaltered kinematics.

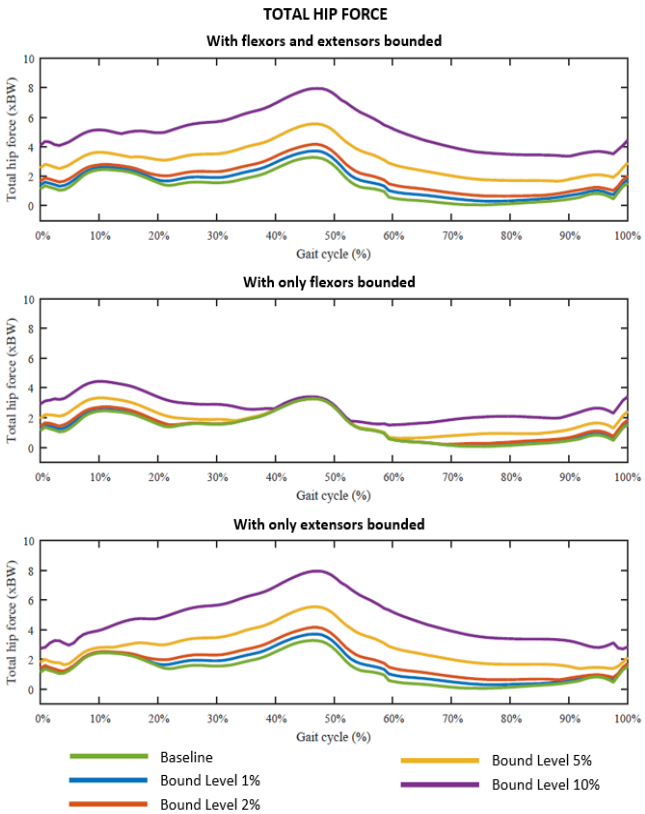

Figure 1: Total hip contact force (HCF) profiles over a gait cycle for different activation bounds levels imposed on hip flexors, extensors, or both. Results are normalized to body weight (BW).

CONCLUSIONS

Co-contraction represents an important parameter to take into account in order to obtain accurate multi-body predictions, as it could lead to significantly higher joint loads. This study provides an estimate of the additional load that could arise at the hip joint in case of increased co-contractive activity of the hip flexors and extensors. In particular, a proper estimation of the co-contraction levels is necessary for an accurate subject-specific modelling, especially for post-operative patients who may also present important muscle deficits and/or asymmetries.

VALIDATION OF A MOTION-CAPTURE-BASED MUSCULOSKELETAL MODEL FOR PREDICTION OF HIP CONTACT FORCES

INTRODUCTION

Accurate knowledge of the contact forces acting at the hip joint is necessary for the improvement of hip implant design and for defining more realistic pre-clinical testing. Although in-vivo measurements have been previously obtained from patients with instrumented prostheses [1], they only represent a small sample of the population, therefore not accurately depicting the whole range of loads that the implants have to withstand. Musculoskeletal models have the potential to overcome this limitation and provide loading values for a broader range of the population, but a thorough validation is necessary to prove the reliability of their predictions [2]. This study aims to quantitatively validate a new musculoskeletal model for the prediction of hip contact forces (HCF).

METHODS

A motion capture based model was implemented in the AnyBody Modeling System and featured detailed muscular geometry based on the cadaveric dataset TLEM 2.0. The lines of action of the major muscle groups surrounding the hip were revised starting from the original MRI scans of the TLEMsafe study [3]. More realistic wrapping surfaces were introduced for glutei, iliopsoas and hamstring muscles, guaranteeing sufficient level arms at every degree of hip flexion. The model was linearly scaled to match the anthropometry of a patient with an instrumented prosthesis, whose synchronized marker trajectories, ground reaction forces (GRF) and HCF data were released for a single gait trial (http://orthoload.com/comprehensive-data-sample/). Virtual markers and force plates were included in the model to match the lower-body marker protocol and laboratory set-up described in the dataset. Inverse dynamics analysis was based on a 3rd-order polynomial muscle recruitment criterion and was given as input the mentioned Orthoload marker and GRF data, previously filtered with a low-pass filter.

The contact forces, computed at the right hip over a gait cycle, were then transformed to the same reference frame [1] and quantitatively compared to the measurements from the instrumented implants.

RESULTS AND DISCUSSION

The results showed good agreement with the overall trend and timing of the predicted HCF (Figure 1). The Root Mean Square Error (RMSE), calculated for the total HCF and evaluated over the whole gait cycle, was found to be 0.293*BW, while the RMSE evaluated separately for stance and swing phase was 0.344*BW and 0.168*BW respectively. The analysis of the single components showed good agreement for the antero-posterior component with an $RMSE_{0\text{-}100\%}$ of 0.04*BW, while the proximo-distal ($RMSE_{0\text{-}100\%}$ = 0.240*BW) and medio-lateral ($RMSE_{0\text{-}100\%}$= 0.280*BW) components were over-predicted mainly during the stance phase. The maximum error during the stance phase was associated with its 1st peak (loading phase), where the resultant force was over-predicted by 0.595*BW, while the error associated with the 2nd peak (terminal phase) was 0.127*BW. The time difference between predicted and measured peak values was negligible (0.017s and 0.001s respectively).

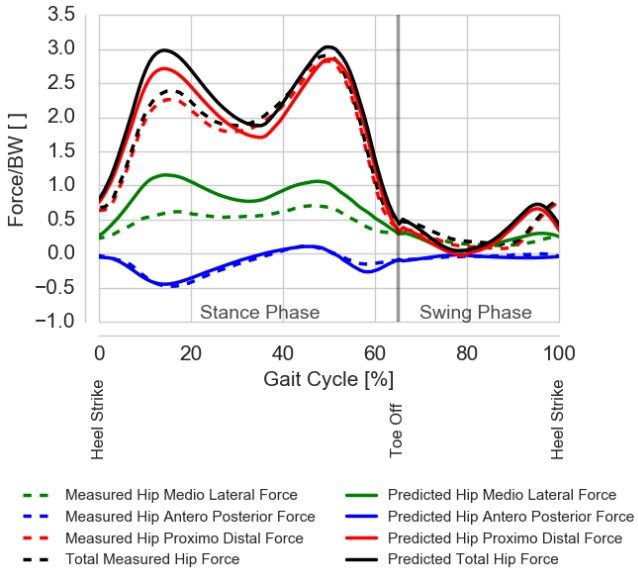

Figure 1: Predicted and measured HCF over a gait cycle.

CONCLUSIONS

This quantitative validation of a musculoskeletal model provides an estimation of the error associated with HCF prediction. The results for a single complete gait trial showed overall a good agreement between predicted and measured HCF, although the over-prediction during the loading phase needs to be further investigated. The release of additional data samples would be beneficial in order to test the model with different kinematic and anthropometric inputs. Alternatively, the model can be further validated with qualitative comparisons based on different motion capture datasets.

INTERNAL STRAIN DISTRIBUTION OF THE HUMAN FEMUR UNDER COMPRESSIVE LOADING MEASURED BY DIGITAL VOLUME CORRELATION

[1]**Mario Giorgi**, [2]Saulo Martelli, [2]Egon Perilli and [1]Enrico Dall'Ara

INTRODUCTION

Understanding the mechanism of osteoporotic femoral neck fractures is important for improving diagnosis and treatments of osteoporosis. Standard mechanical testing can measure the femoral stiffness and strength under different loading scenarios. However, it does not provide information about internal deformations and location of fracture onset. A combination of time-elapsed micro-CT imaging, step-wise loading and Digital Volume Correlation (DVC) has been already used for measuring deformation within trabecular bone specimens [1] and vertebral bodies [2] but its application to images of specimens as big as the proximal human femur is challenging. The goal of this study is to develop a protocol to measure the full 3D field distribution of strain, from the elastic range up to failure, in the entire human proximal femur.

METHODS

Time-lapsed micro-CT cross-section images (29.81 µm/voxel, isotropic) of a human femur step-wise loaded to fracture were obtained from a study conducted at the Australian Synchrotron (Clayton, VIC, Australia). Donor was an osteoporotic female, Caucasian (80 years old, 145 cm height, 104 kg weight, T-score: -3.45). Five load steps (LS) were applied to induce a neck fracture (LS5). The micro-CT images of the entire femoral epiphysis were first obtained in unloaded condition, then at each of the five load steps up to fracture. Images were resampled to 120µm/pixel to reduce registration time; each image was rigidly registered with the unloaded scan as reference (AMIRA, 2016 FEI). A deformable image registration toolkit (ShIRT [3]) was used to compute the displacements at the nodes of an isotropic grid superimposed to the images. Based on previous data (unpublished) to evaluate the precision of the protocol, the analysis was run with a nodal spacing of 50 voxels (cell dimension = 6 mm), which provide a precision on strain measurements of approximately 500µε. Points of the grid not belonging to the bone were removed with a mask. The remaining nodes were converted into 8-nodes hexahedron elements, with the respective computed displacements as kinematic boundary conditions in order to compute the strains and to use the post-processing options of a finite element software package (Mechanical APDL v.15.0, Ansys, Inc, USA) [4].

RESULTS AND DISCUSSION

Figure 1 shows the propagation of both tensile (A) and compressive (B) elastic strain. An increased tensile strain concentration was observed at the superior femoral neck, which corresponds to the region where then the fracture occurred (red arrow); whereas an increased compressive strain concentration was observed in the inferior femoral neck (black arrow). Figure 1C shows tensile and compressive strain of LS1 overlapped to a longitudinal mid-section of the unloaded femur (left/center), and a similar section when fracture occurred (right).

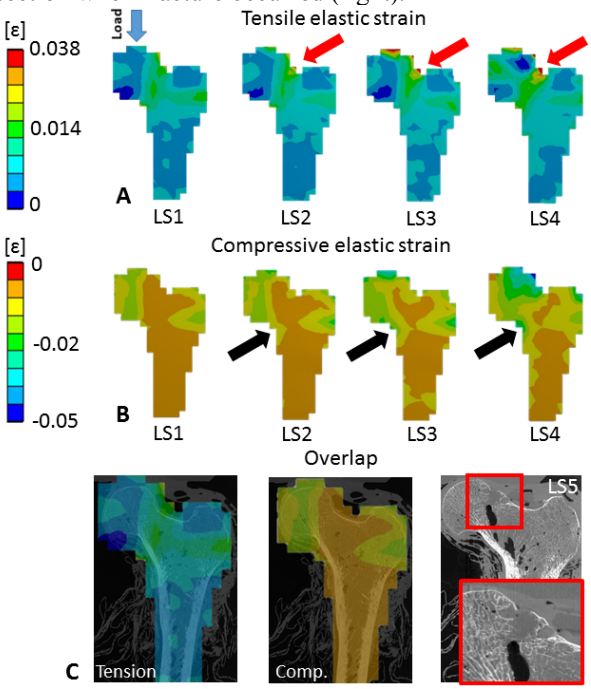

Figure 1: A) Tensile and B) compressive principal strain distribution in the proximal femur metaphysis, obtained with DVC applied on micro-CT images; C) tensile and compressive strain overlapped with a longitudinal mid-section of the femur (left/center), and longitudinal mid-section of the fractured femur (right).

CONCLUSIONS

We successfully developed a protocol to evaluate the full field 3D strain distribution in the proximal femur under compressive loading. DVC provided spatial localization of increased tensile and compressive strains already at low loads within the elastic range, in the femoral neck region where fracture then occurred. This method can be used to study the effect of pathologies and interventions on strain propagation and fracture progression.

INTRODUCTION

In comparison to lumbar spine loading, only very little is known of the hip joint loading arising during manual handling of loads in the workplace. The goal of the present study was analysis of the hip joint loading during different occupational tasks involving manual handling of loads. It was hypothesized that manual handling of heavy loads causes higher peak loads at the hip joints than walking.

METHODS

A combined arrangement of 3D motion capturing (VICON, 12 cameras) and two force plates fitted at floor level (KISTLER) was set up to record lifting, carrying and moving of loads. The test load (interchangeable total weights of 25, 40 and 50 kg) was equipped with two handle bars (height 337 mm above bottom) located symmetrically at the top. During lifting, the load was to be raised from floor level until an upright body posture was reached. During carrying, the load was to be carried symmetrically in front of the body over a short distance (three steps, approx. 2.5 m). During moving of loads, the load was to be transferred on the level on a platform (initial handle height above floor level 520 mm) by picking up on one side of the body and depositing on the other side without movement of the feet (traveled distance of load approx. 0.6 m) followed by the same operation in reverse. A reference task was selected in the form of normal walking (no load, v = 1.2 m/s) under the assumption that this entails no particular risks for the hip joints and can be consistently performed by any healthy person.

Eleven professional male workers [mean age: (42±12) years, mean height: (1.81±0.07) m, mean weight: (91.7±19) kg] from the relevant sectors and familiar with heavy lifting tasks were recruited. The subjects were required to perform each task three times at each loading condition (25, 40 and 50 kg).

Based on the motion analysis data, the hip joint contact forces (HJCFs) were calculated by the AnyBody Modeling System (Vers. 6.0.1) [1]. A finite element analysis (FEA) of the peak load situation of the hip joint model was conducted in order to derive the contact pressure distribution of the hip joint cartilage (ANSYS Workbench 16.0). The anatomical data were derived from CT scans [2]. The cartilage was simulated with the hyperelastic Neo-Hook model. The maximum HJCFs for the different activities were compared by using ANOVA with repeated measures ($\alpha = 0.05$).

RESULTS AND DISCUSSION

Maximum HJCFs were significantly higher for carrying [(497±85)%BW (40 kg), (562±103)%BW (50 kg)] and lateral moving of loads [(526±123)%BW (25 kg), (591±139)%BW (40 kg), (637±148)%BW (50 kg)] than for level walking [(368±78)%BW]. By contrast, no significant increase in HJCF was observed for lifting [(486±119)%BW (50 kg)]. In general, the maximum HJCF was strongly associated with the weight of the load [1].

The FEA revealed specific patterns of pressure distribution for the different tasks (Figure 1). In the manual handling tasks, the location of peak pressure moved dorsally and distally at the acetabulum. The peak pressure reached 15 to 24 MPa for the different manual handling tasks and 15 MPa for walking. The contact area was remarkable smaller during the lifting tasks compared to carrying and moving loads.

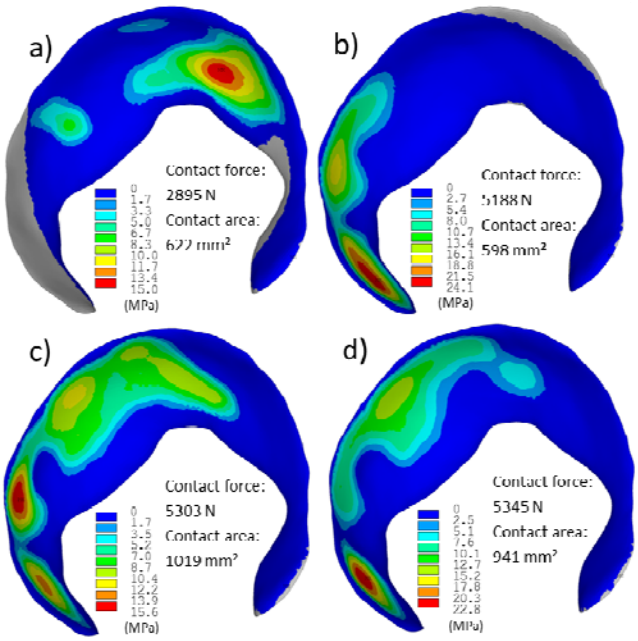

Figure 1: Lateral view of pressure distribution at right acetabulum at instant of maximum HJCF of one representative subject during (a) walking, (b) lifting (50 kg), (c) carrying (50 kg), and moving loads on level (50 kg).

CONCLUSIONS

Higher hip joint loadings were observed in unilateral load situations such as carrying and moving of loads than during level walking. The patterns of pressure distribution at the acetabulum differed completely from those during walking. In total, the increase in hip joint loading remained below 200% of that for reference walking. In conclusion, it is strongly recommended that load handling devices be used when heavy loads are to be handled.

EFFECTS OF VISUAL FEEDBACK IN ORTHOPAEDIC REHABILITATION

INTRODUCTION

Currently, functional outcome following total knee arthroplasty (TKA) is not fully restored, with the majority of TKA patients exhibiting lower functional outcome scores than their healthy counterparts [1]. A contributing factor to limited functional outcome may be the nature of the rehabilitation provided as there is still some controversy regarding the most appropriate methods for rehabilitation delivery [2]. Providing patients with visual feedback during rehabilitation has had a positive effect in other patient populations such as stroke survivors [3] and therefore may also improve the efficacy of orthopaedic rehabilitation. The aim of this study was to develop a visual feedback tool based on real time data from 3D motion capture for routine clinical use. Further aims included determining if provision of augmented feedback was acceptable to patients and whether it had a positive effect on functional outcome.

METHODS

A bespoke, cluster based motion analysis protocol which has been previously validated for calculation of lower limb kinematics [4] was used to develop an avatar of lower limb movement and measure real-time kinematics. Three bespoke feedback scenarios were developed for "step-up", "sit to stand" and "weight transfer" exercises which displayed the patients' movement and a limited amount of useful biomechanical information to help patients complete exercises correctly. Fifteen patients were sequentially recruited into a control group and 15 into an intervention group. All patients completed a baseline gait assessment. Control patients completed rehabilitation exercises as normal and intervention patients completed three of nine exercises with visual feedback. After six weekly rehabilitation sessions, all patients completed an outcome gait assessment. Further, intervention patients completed a questionnaire regarding their experience using the feedback tool. Peak knee extension velocity in swing (PEVS), peak knee flexion in swing (PFS) and total knee flexion excursion (TFE) were compared between groups using an independent t-test ($\alpha = 0.05$).

RESULTS AND DISCUSSION

The majority of patients found use of the tool highly acceptable, were motivated by it and found it an enjoyable addition to their routine care. One aspect which was slightly less favourable was the biomechanical information which was displayed. This issue could be combatted by use of a 'virtual teacher', which has shown a positive effect in previous visual feedback studies [5] and would negate the need for biomechanical information to be displayed while still ensuring exercises were being completed correctly. Table 1 details the results for each group at outcome and the change in each outcome measure between baseline and outcome. There was a positive change in all outcome measures for both groups, with controls achieving similar values to patient data from the literature and interventions achieving similar values to healthy controls from the literature [1]. When examining the change between baseline and outcome, there were no significant differences between groups. However the intervention group showed larger improvements in PFS and TFE in comparison to controls. Subsequent sample size calculations revealed that a group size of 22 would have resulted in a significant difference for TFE and therefore it is likely that the study was underpowered. These results suggest that provision of visual feedback may have a positive effect on knee range of motion in the sagittal plane.

CONCLUSIONS

Visual feedback using motion analysis was successfully delivered in a routine clinical environment and was widely acceptable to patients. Further, provision of visual feedback appeared to lead to improved knee range of motion in the sagittal plane in comparison to control patients. However, larger scale studies are required to confirm these positive effects.

INTRODUCTION

Stroke is one of the leading causes of disabilities worldwide. Chronic stroke survivor must performed intensive rehabilitation program and exercises to maintain optimal function. Currently evaluation and rehabilitation are two distinct fields. Thanks to the development of serious games (SG) in physical rehabilitation [1] and the availability of devices used to control those games (e.g. Microsoft Kinect and Nintendo Wii Balance Board) new possibilities are offered to perform real time functional evaluation during rehabilitation exercises embedded in SG. Therefore the aim of this study was to determine if functional evaluation of the upper limb with patients suffering from stroke is doable directly during physical rehabilitation.

METHODS

22 healthy age subjects (from 60 to 88 years old, 74 (6) years old) and 10 patients with chronic stroke (from 65 to 86 years old, 73 (8) years old) participated in this study. This study was approved by the Ethical Committee of the Erasme Hospital (EudraCT/CCB : B406201526116). A specific rehabilitation SG has been developed coupled to a Kinect sensor to track the motion performed by the patient [1]. The SG aim is to clean a screen covered by virtual mud using the upper limb (flexion and abduction motions as if the subjects were cleaning a window). The time required to clean 90% of the screen was recorded as an indicator of the global performance (i.e., gross motor control analysis). The precision of the motion was also assessed by computing the number of times the subject is putting the cloth in the same position on the screen. The number of frames was equivalent to the amount of positions already cleaned ("cleaned" frames). Result was finally expressed in percentage. The lower the precision score the better the results in term of performance.

RESULTS AND DISCUSSION

Concerning the group comparison statistically significant difference were found for the time (222 (166) Vs 113 (61) seconds for stroke patients and control respectively, $p = 0.01$) and for precision (26 (10) Vs 19 (8) percent for stroke patients and control respectively, $p = 0.04$). Results of the healthy subjects were used to determine the normality corridors. Results for time and precision of the different patients are plotted against normal data in Figure 1.

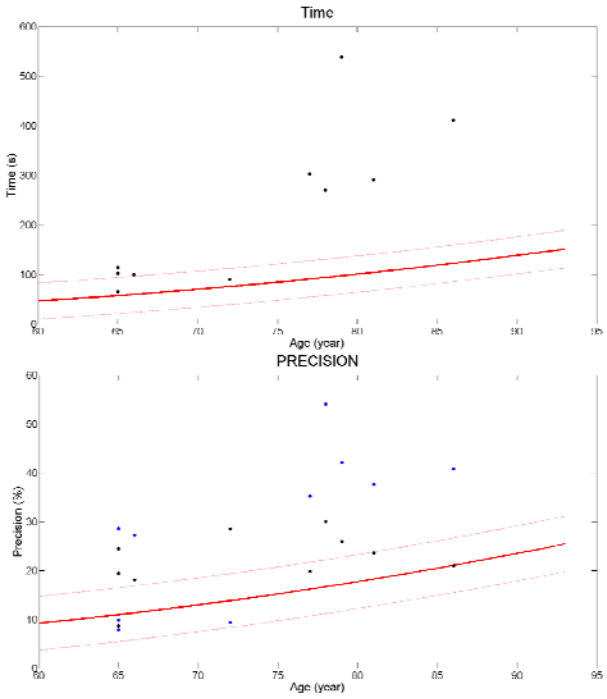

Figure 1: Graphical representation of the results for time and precision. Full and dashed lines are normality corridor obtained with healthy control (mean ± 1,96SD), dots represented stroke patients. For precision black is used for the right side, blue for the left.

The results of this study do not only enable determining a difference between healthy subjects and patients but also an influence of age on motor control. The slopes of the curves presented in Figure 1 are consistent with the physiological data about normal aging. Those two elements indicate that this system can be used to monitor aged patient with or without stroke.
Further studies are needed to evaluate the efficacy of such kind of intervention in the conventional rehabilitation program of those patients.

CONCLUSIONS

Long time follow-up, evaluation and rehabilitation of chronic stroke patients remain a challenge for both patients and physicians. The proposed solution, a coupled rehabilitation and functional evaluation tools, offers new possibilities for rehabilitation: feedback for patients and therapists, and for research.

CAN AUDITORY STOCHASTIC RESONANCE ENHANCE STANDING BALANCE?

Navrag B Singh, Fabienne Riner, Niklas König and William R Taylor
Institute for Biomechanics, D-HEST, ETH Zürich, 8093 Zürich, Switzerland
Corresponding author email: taylorb@ethz.ch

INTRODUCTION

During standing, the human sensory motor system (HSMS) receives afferent information from visual, somatosensory and vestibular receptors to regulate and react to ever changing internal or environmental conditions, resulting in (postural) sway. Here, extremely large levels of sway indicate an inability to produce counteracting joint torques and consequently lead to an increased risk of falling [1]. Stochastic Resonance (SR), where the addition of non-zero noise to a weak input signal enhances detectability, has been used recently to modify the performance of physical or biological systems [2]. Auditory SR could affect sway, most likely through the **vestibular system** located in the inner ear**.** What remains unclear, however, is to what extent auditory SR affects balance?

METHODS

SR was induced via the application of auditory noise via earphones to the ear using a custom-program in LabVIEW (NI USA). **26 healthy young participants** were recruited from the local community. In order to elicit SR, subject-specific auditory threshold was determined psychophysically. Each participant stood quietly on the force plate with eyes closed either compliant surface. The auditory stimulus applied via headphones, comprised of a sine wave (approx. 63dBr) was used for the determination of the threshold with a frequency of 1 Hz, with the sound signal having a frequency of 441 Hz. This original amplitude was then reduced or increased until the threshold was determined upon confirmation from the participant. Gaussian white noise with a sampling frequency of 3000 Hz was then superimposed to the sub-threshold signal.

Each participant stood on the **force platform in a biped quiet stance with eyes closed and arms by their side for 60 s**. The Center of Pressure (CoP) was then calculated from the triaxial forces and moments obtained from the force plate. The CoP was then demeaned, cropped 50s and then low-pass filtered (4th order, Butterworth, 30 Hz cut-off frequency). We **hypothesized that** eliciting SR will lead to a reduction in postural sway in healthy young participants using a more challenging condition (eyes closed, foam board). All statistical analyses were performed within SPSS (SPSS, IBM, USA). In total 42 parameters resulting from the 35 trials of the 26 participants were calculated to quantify postural sway. **Exploratory Factor analysis (FA)** was conducted in an iterative manner using 'FACTOR' and 'VARIMAX' approaches and factors in standardized z-scores derived from the FA were used for further analysis as well as interpretation. A **mixed-factor ANOVA** was conducted to assess the effects of auditory SR on postural sway. The independent variables were ***Condition*** (*4 levels:* ***PreStim 1*** *without stimulation and foam,* ***PreStim 2*** *without stimulation and with foam,* ***Auditory SR,*** *and* ***PostStim*** *without stimulation with foam; repeated 5 times*) and ***Participants***.

RESULTS AND DISCUSSION

4 factors were obtained from the original set of 42 sway parameters, with *factor 1* representing the magnitude in medio-lateral direction (***MagML***), *factor 2* the magnitude in antero-posterior direction (***MagAP***), *factor 3* the velocity (***Vel***), and *factor 4* the frequency components (***Freq***) of sway. The factor MagAP showed a significant increase (***PreStim 1: p<0.001, Cohen's d= 1.2; PreStim 2: p<0.001, Cohen's d = 0.7***), while the factor Vel showed a significant decrease (PreStim 1: ***p<0.001, Cohen's d= -0.6; PreStim 2: p<0.001, Cohen's d= -0.8***) with Auditory SR in comparison to conditions PreStim 1 and PreStim 2 (Figure 1).

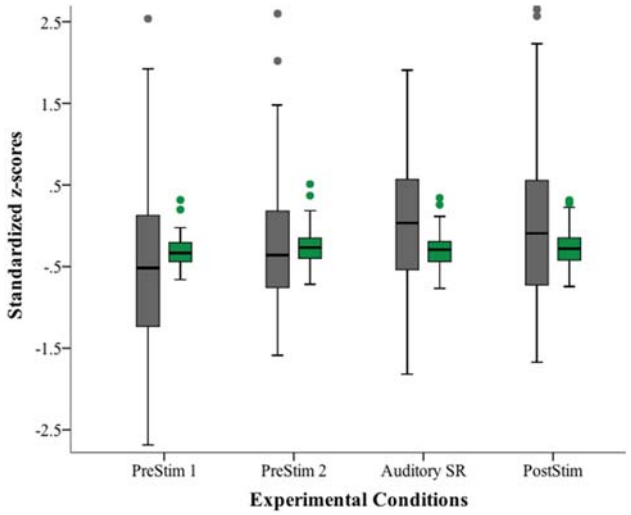

Figure 1: Boxplots illustrating the inverse effects of SR on magnitude (factor MagAP in grey) *versus* velocity (factor Vel in green) of sway with increase in MagAP, but a decrease in Vel compared to PreStim1 and PreStim 2.

These results suggest that auditory SR had parameter-specific effects on sway behavior reducing sway velocity, while increasing sway magnitude in our subjects.

CONCLUSIONS

The application of auditory SR led to modifications that were characterized with inverse effects on distance covered in comparison to the speed of swaying movements. These results indicate that auditory stimulation to elicit SR leads to selective modifications and therefore balance training programs should consider the *intrinsic* characteristics of the individual for attaining subject-specific improvements.

TIBIOFEMORAL CONTACT FORCES CAN BE ALTERED IN GAIT USING REAL-TIME VISUAL BIOFEEDBACK

INTRODUCTION

Inappropriate medial tibiofemoral loading during walking is believed to be a main mechanical contributor to medial compartment knee osteoarthritis (OA) [1]. Medial tibiofemoral contact force (MTFF) is due to a combination of externally applied knee loads and muscles forces. Increased external knee adduction moment (KAM), which is related to increased MTFF, has been associated with fast progression of medial knee OA, development of chronic knee pain, progression of articular tissue pathologies, and poor outcomes after high tibial osteotomy.

Gait retraining to reduce MTFF has been used as a conservative method to reduce pain and improve function in people with knee OA. However, as MTFF cannot be measured *in-vivo* in native knees, KAM has been adopted as a surrogate. During walking, KAM can be modified through kinematic changes to gait and has been correlated with MTFF shape. However, studies using instrumented tibiofemoral prostheses have shown that decreases in KAM do not necessarily result in decreases in MTFF, and only small changes occurred in MTFF in response to gait patterns designed to reduce KAM. The use of MTFF as a biofeedback variable could overcome the limitations of using KAM, which does not account for the action of muscles.

In this study, a calibrated EMG-informed NMS model, i.e. CEINMS [2], was used to estimate MTFF in real-time. Subjects were asked to modify their gait pattern in order to modify CEINMS estimates of MTFF, which was provided as visual biofeedback. This study aimed to first validate the real-time estimation of MTFF against offline calculations, and second to assess the use of musculoskeletal tissue loading as a visual biofeedback variable for gait retraining by evaluating the response of different subjects in distinct experimental conditions.

METHODS

Five healthy subjects participated in the study where a 12-camera motion capture system and an instrumented split belt treadmill were used to collect marker trajectories and ground reaction forces during gait at self-selected speed. These data were then processed using an extended version of OpenSim [3] enabled for real-time [4], which calculated full-body joint angles and moments using inverse kinematics and inverse dynamics, respectively. Joint angles and moments as well as surface EMG were used to run CEINMS in open-loop [5], which estimated MTFF at 200 Hz. The MTFF was visualised on a screen in front of the participant and used as biofeedback.

After familiarisation with the treadmill and visual biofeedback, participants were asked to modify their gait pattern to first reduce and then increase peak MTFF. Suggestions of possible gait strategies previously found to modify external knee loading [6, 7] were verbally provided. These included: walking with toes pointed in or out, increasing or decreasing side-to-side trunk sway, using longer or shorter strides, loading the inside or outside of the foot, changing the step width, and changing the knee alignment, i.e. more medial or lateral knee positioning. Data analysis included a comparison of MTFF estimated offline and in real-time to verify the real-time system.

RESULTS AND DISCUSSION

Peak MTFFs were similar between real-time and offline, with an average RMSE of 0.125±0.069 bodyweights. All subjects were able to increase their MTFF peak, while three were able to decrease it.

Gait strategies differed across participants, and resulted in combined variations of kinematics, kinetics, and muscle activation patterns. A participant increased their MTFF by increasing muscle co-contractions, resulting in increased total muscle activation but reduced KAM. The use of an EMG-informed model was essential to identify changes in muscle forces due to variation in activation patterns, which static optimisation based methods cannot correctly predict.

CONCLUSION

We presented real-time estimation of MTFF and its use as biofeedback variable for gait modification. While the proposed application focuses on the knee joint, the developed system is generic and could be applied to other musculoskeletal structures. Real-time estimation of musculoskeletal tissue loads has the potential to radically transform rehabilitation interventions and training programs as it would enable instant evaluation of the effect of rehabilitation exercises, empowering clinicians to work interactively with the patient to attain a personalised appropriate exercise.

INTRODUCTION

Individuals who suffered an anterior cruciate ligament injury (ACL) also often suffer from long-term consequences [1], and return to play can be as low as 55% [2]. Movement adaptations to avoid pain post injury / surgery can become habitual, well beyond rehabilitation, and might result in non-optimal movement pattern (e.g. asymmetries) that increase the risk of arthritis, restrict quality of life and increase the risk of re-injury/injury of the uninjured limb. Current studies often examine single limb tasks because ACL injuries occur most often during single leg tasks. However, during a biomechanical assessment a subject might consciously mask movement deficiencies due to awareness of the task execution. In contrast to single limb task, double limb exercises (e.g. countermovement jump - CMJ) can shift the focus of the task to solely task outcome and can hold very rich information. The aim of this study was to examine if ground reaction forces (GRF) captured during a CMJ could predict who suffered an ACL injury and who did not.

METHODS

A dataset from the Sports Surgery Clinic (SSC) was made publicly available on BioMech-L, as part of the SSC Data Challenge. The dataset consisted of a test set of 100 individuals with and without unilateral ACL injury (50:50) and a validation set of 10 unlabeled individuals. The data was from active athletes in multi-directional field sports (age 24.7 years, weight 82.16 kg, height 1.83 m) and contained time and bodyweight normalized GRF curves (N/kg) for the concentric and eccentric phases of a countermovement jump task, recorded under each foot individually. Data also included the duration of the flight, concentric jumping and eccentric landing phases. The individuals' anthropometrics, side of ACL injury and dominant side were not included.

The challenge proposed to the BioMech-L community was to predict the class (Normal or ACL) of the 10 individuals in the validation set. The following methods present the most successful approach. The features readily available per individual were used as is (i.e. flight time, duration of concentric phase, landing time and concentric phase). The curves from GRF were processed to determine an asymmetry index for each individual, and for the concentric and eccentric phases independently. The index was calculated as the absolute difference between the areas (using trapezoidal approximation) under the left and right GRF curves. The machine-learning app in Matlab R2016b was used to train various algorithms using the above-mentioned features, and prediction accuracy was established on the test set using 2-fold cross-validation. Class allocation for the validation set was proposed based on results from the algorithms with the best prediction accuracy on the test set.

RESULTS AND DISCUSSION

The machine learning algorithms with the best predictive accuracy on the test set was: quadratic LDA (81% overall, 79% Normal class, 83% ACL class), linear support vector machine (SVM; 81%, 76%, 88%) and logistic regression (78%, 77%, 79%). Table 1 presents the class prediction for the validation set (10 individuals) from the best performing algorithms. The only class allocation discrepancy between methods was for subject 7621 who was classified as ACL by quadratic LDA (perfect prediction) but Normal by linear SVM and logistic regression.

Subject ID	Quadratic LDA	SVM	Logistic regression	True class
Sub_2203	Normal	Normal	Normal	Normal
Sub_2262	ACL	ACL	ACL	ACL
Sub_3476	ACL	ACL	ACL	ACL
Sub_4612	ACL	ACL	ACL	ACL
Sub_4889	Normal	Normal	Normal	Normal
Sub_5368	ACL	ACL	ACL	ACL
Sub_7621	ACL	Normal	Normal	ACL
Sub_8414	Normal	Normal	Normal	Normal
Sub_8572	Normal	Normal	Normal	Normal
Sub_9636	Normal	Normal	Normal	Normal
Validation accuracy	100%	90%	90%	

Table 1: Prediction for the 10 unlabeled individuals

CONCLUSIONS

This study highlights that data from CMJ, including GRF curves collected under each limb individually, may be able to identify 100% of individuals' post-ACL injury - even if no data is available on regarding anthropometrics and injured or dominant side. Results from the predictive models developed in this study may be used as objective criteria or scores for rehabilitation status and support return to sport decisions. An example of binary criteria may be: "as long as the individual remains classified as 'ACL', ongoing rehabilitation is advisable and return to sport delayed". Since the algorithms also return their confidence level for the class allocation, continuous scores may also be derived to monitor rehabilitation progresses. Further research is necessary to establish the usefulness of such scores/criteria in clinical practice.

ACKNOWLEDGEMENTS

We would like to thank the many participants of the SSC Data Challenge (n=20) and the Sports Surgery Clinic for providing the data and their continued support.

REHABILITATION AND MOTOR CONTROL OF THE HAND

Fong-Chin Su
National Cheng Kung University
Author email: fcsu@mail.ncku.edu.tw

INTRODUCTION

The human hand is very unique that enables human to execute a variety of movements, which is very important in successfully performing tasks in our daily life. Compared with other primate, the most critical characteristic of human hand is the ability to perform opposition, touching all other digits with the thumb. The delicate motor performance of hand is controlled by a complicated feedforward and feedback motor control system, including motor planning from the central nervous system and sensory feedback from the peripheral nervous system. If lesions in the central nervous system occur due to diseases or injuries, declined sensorimotor function would appear to influence control mechanism and affect coordination of the hands. Eventually, without the ability to exert appropriate force, hands would have difficulty in manipulating objects and lead to functional limitation or functional loss. Previous studies have reported that an efficient rehabilitation of hands can be achieved by task-orientated practice via a biofeedback system. At present, most of biofeedback training system majorly focus only on finger movement control, few emphasizes on force control. Thus, a serious of studies have been conducted to develop biofeedback training and evaluation systems for finger force control as well as to investigate training effects in patients with impaired hand control. Biofeedback systems including pinch device, pressing evaluation and training system, and grasping training system will be introduced. Scientific findings indicate that both peripheral and central nerve injury patients benefited from the training programs. Improvements are found in sensory status, grip force, finger force control, and functional performance.

EFFECTS OF MOTOR TASK-SPECIFIC THERAPY SYNCHRONIZED WITH VIBROTACTILE CUEING ON SENSORIMOTOR PERFORMANCE OF UPPER EXTREMITY FOR THE CHRINOIC STROKE PATIENTS

INTRODUCTION

Augmented sensory inputs have been demonstrated to have the effect of enhancing motor function of the hand. Through vibrotactile afferent, such as motor unit recruitment, synchronisation, and co-contraction may be responsible for force and power increases[1,2,3]. However, there was still lack of strong evidence to identify the effects of vibrotactile cueing on functional gains for the stroke patients. The purpose of this study was to investigate training effects of motor task-specific therapy synchronizing with vibrotactile cueing on the sensorimotor performance for stroke patients.

METHODS

Participants: Nineteen chronic stroke patients with mild to moderate motor impairment were recruited and completed all the pre-and-post test and follow-up evaluations

Study design: This study was a single-blinded, randomized controlled trial with pretest, posttest, and follow-up assessments (Figure 1).

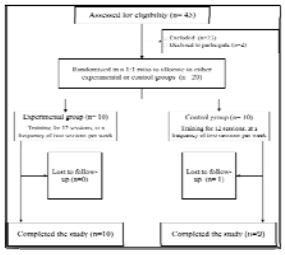

Figure 1: Flow chart shows enrollment of patients and completion of study

Instruments: Vibrotactile therapy system (Figure 2).

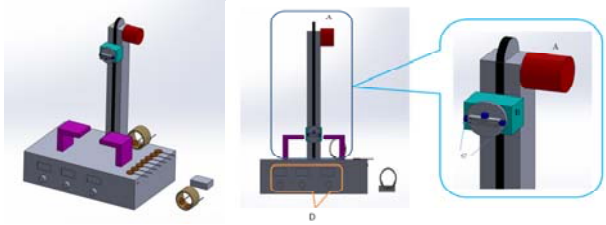

Figure 2: Vibrotactile therapy system used to apply vibrotactile cueing for pinch profiles. (A) Capstan system: deliver a force to produce a sliding movement; (B) A pinch apparatus, an actuator was mounted inside; (C) Load cell, detect the pinch force and (D) controller.

Interventions:

For the patients in the experimental group, each participant will receive 10 minutes' traditional sensorimotor facilitation follow by 20 minutes' task-specific training synchronized with vibrotactile cueing (with frequency of 30 Hz and the amplitude of 2.0 mm) in each treatment session and controls received unilateral task-oriented facilitation. Treatment intensity, which is matched for both groups, was 30 minutes/day, 2 days/ week, for 6 weeks.

Outcomes measures:

Sensory function assessing by Semmes-Weinstein monofilament (SWM) test, the motor performance assessing by Fugl-Meyer motor assessment (FMA) for upper extremity, modified Ashworth scale (MAS) and motor activity log (MAL), as well as hand coordination measured by box and blocks test were recorded at baseline, post-treatment and three months' follow-up.

Statistical analysis: Friedman, Wilcoxon signed ranks post hoc test and Mann-Whitney U test were used in this study.

RESULTS AND DISCUSSION

The baseline data and clinical characteristics of the patients were listed in Table 1.

Table 1: Demographic data of experimental and control groups

	Experimental group (n=10)	Control group (n=9)	*p*-value
Demographic data			
Age (years)	53.6±12.4	61.7±8.4	0.143
Period from onset to 1st evaluation (months)	28.9±23.5	24.9±15.3	0.912
Clinical characteristics			
Fugl-Myer score (total)	46.2±9.6	36.7±17.9	0.278
Modified Ashworth Scale	1.85±0.26	1.50±0.50	0.065
MAL amount of use	29.3±15.3	42.1±43.6	0.905
MAL quality of movement	25.3±14.2	37.2±45.2	0.0842

For the control group, the significant improvement has been found in the wrist component of FMA score (p=0.002*). Differently, there were no significant differences in the improvement of FMA score for the experimental group. However, the change in muscle tone of fingers, how well the subject uses their more-affected arm, touch-pressure threshold sense and results of box and blocks test revealed significant improvement after 12 sessions' treatment for the participants in the experimental group. Moreover, the training effects could be maintained for three months (p<0.05*). Nevertheless, the changes in most of the measuring outcomes there were no significant differences except in the touch-pressure sensibility (p=0.043*) after 12 sessions' treatment between experimental and control group.

CONCLUSIONS

The motor task-specific training synchronized with vibrotactile cueing can have beneficial effects on sensorimotor function of upper extremity in patients with a spastic paresis. The innovative intervention might become a useful tool in neurological rehabilitation.

AGE RELATED DIFFERENCES IN FINGER INDEPENDENCY AND NEUROMUSCULAR CONTROL

[1] **Nathalie van Beek**, [2] Dick F. Stegeman, [1, 3] DirkJan (H.E.J.) Veeger and [1] Huub Maas

INTRODUCTION

The human hand can perform complex actions, necessary in daily life for both fine and gross motor tasks. A gradual decline in finger capability is observed in the elderly from the age of 65 years onwards, which creates difficulties in performing everyday tasks [1]. One important feature necessary for the manipulation of objects is finger independency [2,3]. The aim of this study was to assess the relationship of age and finger independency and the neural control of extrinsic finger flexors and extensors.

METHODS

Eight right-handed young (22-30 years) and elderly (65-80 years) subjects performed single finger flexion movements with the left hand held palmside up in a 45° supination angle. They were instructed to move each finger separately and to not actively resist potential movements of the non-instructed fingers. Muscle activation was assessed using a grid of 90 surface electromyography electrodes (sEMG) placed over the flexor digitorum superficialis (FDS) and the extensor digitorum communis (EDC) muscles. Kinematics of four fingers (index, middle, ring and little finger) were recorded using an instrumented glove (PowerGlove, University Twente [4]).

Finger specific EMG channels were identified by performing a cross-covariance between the EMG envelopes and finger angle during flexion (for FDS) or extension (for EDC). EMG signals were normalized to the maximum EMG amplitude found during all movements. The range of independent movement of the non-instructed fingers was determined as a measure of finger independency. This range was assessed by the percentage of total range of motion of the instructed finger at which the non-instructed finger(s) starts to move. The start of non-instructed finger movement was defined as a change in joint angle of more than 5 degrees, based on reported finger detection thresholds [5]. Here, we only show data for the index finger flexion task. One-way ANOVAs were used to test for the differences between the two groups. P values < 0.05 were considered significant.

RESULTS AND DISCUSSION

In the older compared to the younger subjects, we found higher muscle activity for the FDS of both non-instructed middle and little fingers and a higher activity for the EDC of the non-instructed ring finger (Fig 1A+B). The range of independent movement of the non-instructed middle finger was also lower for the older subjects (Fig 1C). Thus in the older subjects, the non-instructed middle finger moves earlier during index finger flexion.

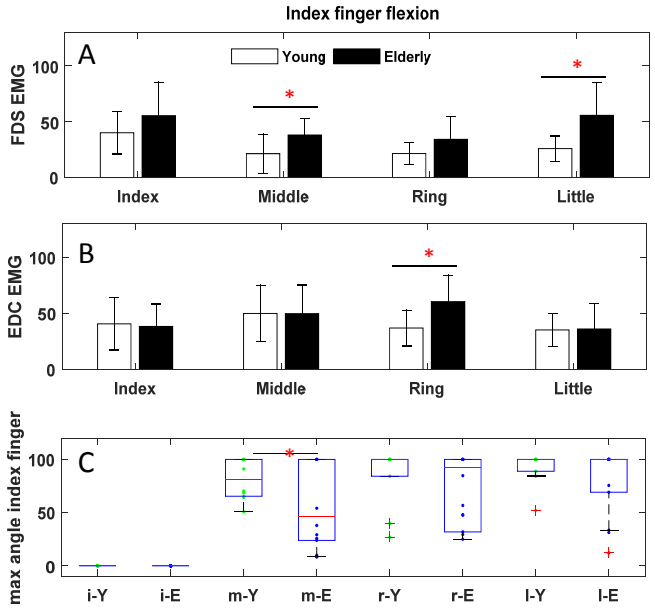

Figure 1. **A+B**: Mean normalized muscle activation of the flexor (A) and extensor (B) muscles for each finger of young (white) and older (black) subjects during index finger flexion. **C**: Boxplots showing the range of independent movement of the non-instructed finger(s) of both young and elderly subjects (i=index,m=middle,r=ring,l=little,Y=young, E=elderly). A y-axis value close to zero means early finger enslaving with respect to the total movement of the instructed finger, whereas a high value means late or no enslaving. The horizontal lines with asterisk indicate significant differences ($p < 0.05$).

CONCLUSIONS

More non-instructed finger movement and flexor muscle activation was found for older subjects when performing single finger index flexion compared to younger subjects. This difference between groups indicates decreased index finger independency and altered neuromuscular control during index finger flexion with aging.

USE OF SENSORIMOTOR INPUT IN REHABILITATION OF DISTAL RADIUS FRACTURES

[1]Dafna Michael, [1] Hani Harel and [1,2]**Ronit Wollstein**
[1]Carmel Lady Davis Medical Center
[2]Technion, Israel Institute of Technology

INTRODUCTION

Proprioception and sensorimotor modalities are used in rehabilitation to treat neurological problems such as cerebrovascular accidents (CVA) and children with cerebral palsy. Rehabilitation of joints such as the knee and ankle also often utilize proprioception sense [1]. In the wrist, proprioceptive loops have not yet been completely defined. Clinically, following distal radius fractures (DRF) there is a temporary sensorimotor loss that should be addressed during postoperative therapy. We designed an evaluation and treatment protocol aimed at sensorimotor evaluation and treatment and trialed it on a pilot series of patients following surgery for DRF. It was our impression that these patients had very good functional results. The purpose of this prospective study was to compare the outcomes of patients following surgery for DRF treated using our specific sensorimotor therapy protocol beyond standard of care, with patients treated after surgery according to postoperative standard of care. We hypothesized that patients treated using our treatment protocol will have better functional results at three months post-surgery.

METHODS

Due to the difficulty in isolating the effect of the different types of input, both the evaluation and the treatment protocols incorporate a comprehensive sensorimotor panel. All patients were treated once a week in therapy and practiced a home therapy protocol. Fifty-five patients following surgery for DRF were randomized into a focused sensorimotor postoperative protocol and the standard of care protocol. Exclusion criteria included inability to attend therapy or comply with the home therapy protocol and patients with preceding injuries and deficits in the wrist and hand. Patients were evaluated initially in the first days after the operation, at 6 weeks and at three months post- surgery.

RESULTS AND DISCUSSION

All patients following surgery for DRF demonstrated similar initial significant deficits in proprioception, stereognosis and the Moberg pick-up test. There was documented sensorimotor and functional improvement in both groups with treatment in range of motion (ROM), strength, and sensorimotor testing. The Disabilities of the Arm, Shoulder and Hand (DASH) score was better in the trial group at three months than in the control group p=0.05. Wrist ROM at three months was significantly better in the trial group (Table 1). We had no cases of chronic regional pain syndrome (CRPS).

	SR-6 weeks	SR-3 months	PR-6 weeks	PR-3 months	P value - 3 months
Ulnar deviation inv/uninv	0.68	0.64	0.48	0.84	0.02
Radial deviation inv/uninv	0.44	0.63	0.37	0.77	0.03
Flexion inv/uninv	0.58	0.84	0.56	1.00	0.001
Extension inv/uninv	0.62	0.78	0.52	0.84	0.03
Supination inv/uninv	0.75	0.85	0.64	0.94	0.03
Pronation inv/uninv	0.98	0.97	0.82	0.99	0.7

Table 1: Comparison range of wrist motion between the two therapy groups.
SR=standard rehabilitation PR=protocol rehabilitation

CONCLUSIONS

1) Patients after surgery for DRF demonstrate significant sensorimotor deficits that should be evaluated and addressed in therapy.

2) These deficits and function improve farther at three months when utilizing a comprehensive sensorimotor treatment protocol. The final results of this study will be presented.

4) These treatment and evaluation modalities should be applied to other conditions of the hand and wrist and perhaps be helpful in the prevention of CRPS.

TREMOR SUPPRESSION IN WRIST JOINT USING ACTIVE FORCE CONTROL METHOD

[1] **Seyedeh marzieh Hosseini**, [1] Adel Al-Jumaily
[1] University of Technology Sydney
Corresponding author email: Seyedehmarzieh.Hosseini@student.uts.edu.au

INTRODUCTION

Tremor is a neurological disorder that categorized by unconscious oscillations of parts of the body. The most famous characteristics for this disability are involuntary, roughly periodic, and approximately sinusoidal. People with Parkinson's disease are the group of patients who have this pathological tremor especially with their upper limbs and therefore have so many difficulties in their daily life. Several research works have been performed to study and control the effects of human hand tremor. Medical and Surgical treatments used to reduce hand tremor. However, the drug treatments and surgery often reduce the progress of tremor, but they have their inherent disadvantages. [1]. In previous works, some researchers used Active Force Control (AFC) method for tremor attenuation in human body parts[2].

This paper proposes a new AFC system based on a piezoelectric actuator. A three-degree-of-freedom musculoskeletal model for studying tremor in the wrist joint is developed. First, simulation of the tremor generation in the model is performed and then the performance of AFC system for suppressing wrist joint tremor is investigated. A single piezoelectric actuator is embedded in AFC system for controlling the behavior of the classic proportional-derivative (PD) controller. MATLAB Simulink is used to analyze the model.

METHODS

In this research, an AFC system for canceling the tremor of the wrist joint is developed. This AFC system uses piezoelectric actuator and a PD controller to attenuate the wrist tremor. Piezoelectric actuators have an effective role in today's technology. The Piezoelectric actuators have small dimension and weight and can be simply driven by voltage. Furthermore, these actuators are easily controlled and can provide a fast response.

The musculoskeletal model for this study contains five muscles; extensor carpi radialis longus, extensor carpi radialis brevis , extensor carpi ulnaris, flexor carpi ulnaris and flexor carpi radialis. Also, the muscle model is developed from the classic Hill-type muscle model. In this model, the response of the muscle to a stimulation signal is made of two parts: activation dynamics and contraction dynamics.

At first, the tremor is simulated in wrist join by functional electrical stimulation (FES). Then an AFC system is used to suppress this tremor. Then the AFC system is simulated in MATLAB Simulink to investigate the wrist behavior in the control system.

RESULTS AND DISCUSSION

As mentioned previously, the proposed system was simulated in MATLAB to investigate the effect of an AFC control system to reduce the wrist joint tremor with the help of a piezoelectric actuator and a PD controller.

Figure 1 illustrates the displacement signal for the tremor of the wrist joint without any control system and the behavior of wrist joint in AFC system for flexion-extension.

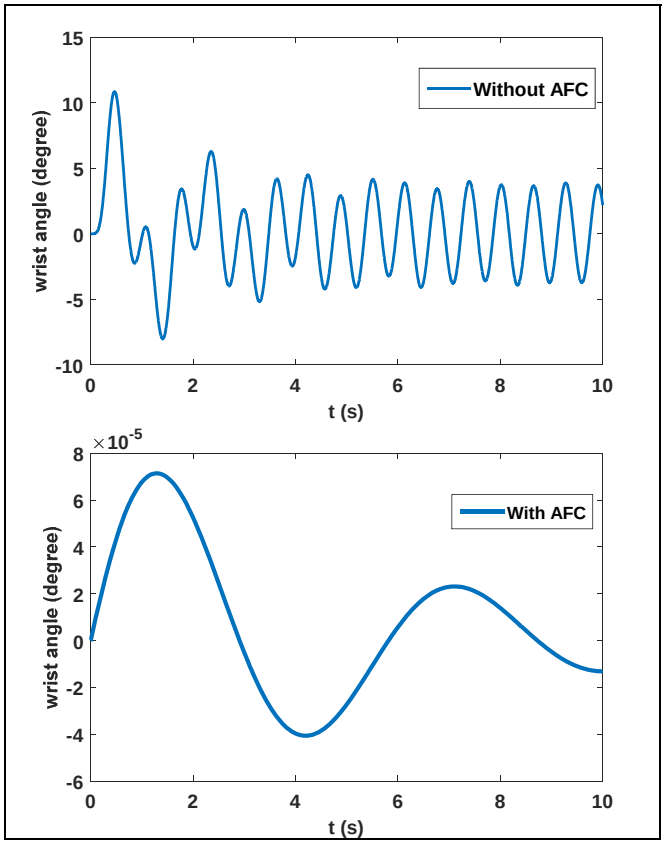

Figure1: The wrist joint tremor without AFC (upper plot) and with AFC (lower plot) in flexion- extension.

Also, the wrist tremor angle for radial-ulnar deviation is between 0 to 10 [deg] that it changes to 0 to 4×10^{-5} [deg] in AFC system. For pronation-supination, the maximum wrist joint angle decreases from 8 to 5×10^{-5}[deg] with the control system.

CONCLUSIONS

This study presents an investigation for tremor suppression from the human wrist joint using active force control method. From simulation results, the AFC method with a PD controller and a piezoelectric actuator has a significant effect on reducing tremor.

PRINCIPAL COMPONENT ANALYSIS TO CLASSIFY ADAPTABILITY TO BAREFOOT RUNNING

[1]**Alessandro Garofolini**, [1]Simon Taylor, and [1]Patrick McLaughlin
[1] Victoria University, Melbourne
Corresponding author email: simon.taylor@vu.edu.au

INTRODUCTION

Increasing participation in barefoot and minimally shod running, or barefoot-like running (BR), is driven by research claims that propose functional and structural benefits due to the influence on the type of foot strike and control of impact load [1,2]. However, obtaining these benefits first requires a level of intrinsic readiness: not all athletes that transition to BR will be successful adapters, thus increasing their risk of injury [3]. Hence, there is a need to use an effective and efficient method to classify an athlete's readiness and intrinsic risk when transitioning to BR [4].

Previously, adaptation has been classified by methods that require kinematic and kinetic data [2]. A simpler approach is proposed here. In this study, we compare a conventional method, where loading rate and foot strike pattern categorize the ability of professional athletes to adapt their barefoot running technique, in order to control impact load. This method is compared against a Principal Component Analysis (PCA) method that classifies groups using only ground reaction force signals. The aim is to evaluate if GRFs and PCA will classify the same groups as the Kinematic-Kinetic method.

METHODS

A sample of 30 AFL football players performed ten trials of a 25m over-ground run at self-selected speed under two conditions, with shoes and barefoot. 3D kinetic and kinematic data were collected from two AMTI force platforms and a 12 camera VICON system captured using Nexus software (Oxford Metrics Ltd, Oxford, UK). Left and right legs were treated as independent subjects. Kinematic and kinetic data were exported to Visual3D (C-Motion, USA) for processing. Derived signals were three ground reaction force components (Fx, Fy, Fz), vertical loading rate, and foot segment angle at initial foot-to-ground contact. Subjects were categorized into one of three groups - according to load adaptation at foot strike using foot angle and relative change in loading rate in response to the barefoot condition - group 1 (no attempt to adapt); group 2 (in-effective); group 3 (effective). Mean running speed was 4.6m/s and was not statistically different between groups. Each GRF signal from the BF condition was time-normalized in Visual3D and used as input for a PCA using Inspect3D (C-Motion, USA).

RESULTS AND DISCUSSION

Analysis of the mediolateral (Fx) and anteroposterior (Fy) GRF did not detect any significant differences between the groups. However, for the vertical component (Fz), the first PC explained 46.8% of the total variance, with higher loading factors at the beginning of stance. The second PC accounted for 25.9% for a cumulative total variance explained of 72.7%. Considering each PC separately, statistical difference among groups was only significant in the first PC ($p < 0.05$). The main separation between adaptable and non-adaptable groups was in the first PC direction. Unlike the Kinematic-Kinetic method, PCA displayed different levels of adaptability in an easy-to-explore and visualize way (Figure 1).

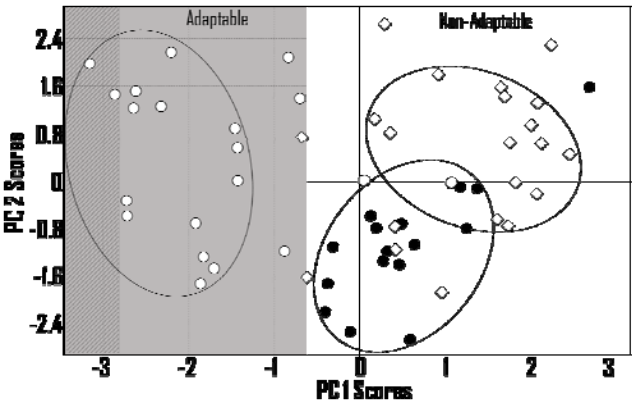

Figure 1: PCA of the GRFz (barefoot). Group 1- no attempt to adapt (●); group 2- in-effective (◊), and group 3- effective (○). Solid grey area represents adaptable subjects score. Within grey area, the hashed area represents scores for subjects not showing any impact peak.

PC1 loading vector explained the change in the shape of the GRFz curve in the first 15% of the stance phase. This correlates with loading rate. PC2 loading vector explained the shape of the peak GRFz however, scores on this component were found to be not statistically different between groups. Poor adaptors (groups 1, 2) demonstrated higher loading rate irrespective of foot strike adopted.

Interestingly, PC1 scores lower than ~ -2.8 (hashed area within the grey area) represent GRF curves with no evident impact peak. This may be a cut-off point where the most efficient adaptability is evident. This insight passed undetected in the Kinematic-Kinetic classification method.

CONCLUSIONS

PCA confirmed that GRFz signals from BR can classify most of the variance between groups that differ in adaptable impact loading. The advantage of using PCA lies in its ability to quantify adaptability of runners in a simpler and more objective way by examining the whole GRFz waveform. In light of these findings, once a larger database is created, and the boundaries of groups are better defined, PCA may be used confidently to determine the level of readiness, and the risk of injury, in individuals who make the transition to BR.

INTRODUCTION

Over the past decade, the idea that barefoot running may be a good alternative to running in a traditionally cushioned shoe has become increasingly popular in both the scientific and lay running communities[6]. This is partially because running barefoot is suggested to promote runners to adopt a mid/forefoot strike pattern and this is suggested to reduce risk of injury[2]. This is supported by evidence that runners will experience a lower initial rate of loading, when running either barefoot or with a mid/forefoot strike pattern[4]. Coinciding with increased interest in barefoot running, minimalist running shoes emerged from industry's need to satisfy the desire for a product that replicates the barefoot condition. Thus, emerged minimalist shoes that are marketed to provide all of the supposed benefits of running barefoot, while alleviating all the discomfort associated with barefoot running[5]. While there is some evidence that minimalist shoes may act as effective simulators of the barefoot condition[7]. Other researchers have questioned the efficacy of minimalist shoe[3]. To the best of our knowledge, no study has yet investigated the differences in gait between traditionally shod runners and those who are habitually adapted to running in minimalist shoes.

METHODS

Thirty-four participants were recruited of which 18 participants were habitual minimalist runners (>6 months experience) and 16 were controls that were habitual cushioned shoe runners (no experience using minimalist footwear). All participants had no experience running barefoot, trained a minimum of 4 hours per week and could run 10km in less than 60 minutes

Biomechanical testing was performed in a barefoot and shod condition. Three-dimensional marker trajectories were recorded using an eight camera Vicon MX motion analysis system. Ground reaction force data were collected with a floor embedded force platform. Sixteen reflective markers were attached using a modified Helen-Kayes marker set using the lower limb PlugInGait model. The speed of over-ground running was set at 12 km·hr^{-1} for both randomized footwear conditions. Five successful trials in each condition were collected. Three-dimensional lower extremity joint angles and net resultant joint moments were calculated for the sagittal and frontal plane, both at ground contact and during peak stance. Initial rate of loading was quantified between 200 N and 90% of the first impact peak of the vertical ground reaction force. Sagittal plane joint stiffness was calculated for both ankle and knee joint[1].

RESULTS AND DISCUSSION

No difference in initial rate of loading was observed between runners when running shod or barefoot, but a moderate effect size was found between groups in the shod condition. Initial loading rate also increased for both groups when running barefoot. Differences in foot-strike angle were observed between groups when running shod, but not barefoot. There were no differences in ankle joint stiffness in either running condition. A decrease in barefoot ankle stiffness was observed in both groups. Minimalist runners presented with higher knee stiffness in both conditions

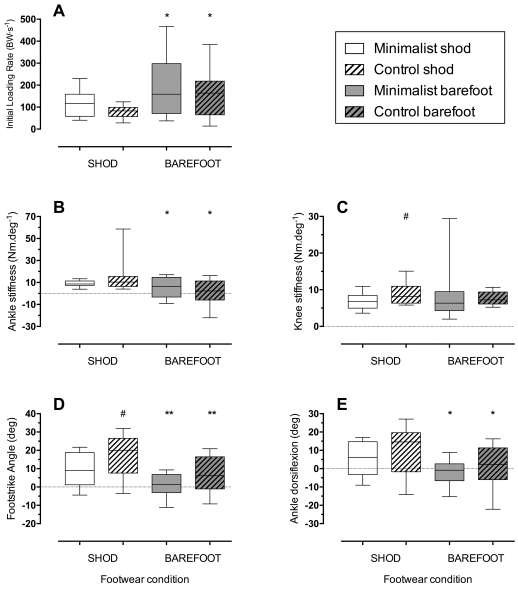

Figure 1: Associations for minimalist and control runners during shod and barefoot running between (A, B) ankle stiffness and loading rate, (C, D) foot-strike angle and loading rate, (E, F) sagittal ankle angle at ground contact and LR and (G, H) ankle stiffness and footstrike angle.

CONCLUSIONS

Habitually minimalist runners do not present with meaningfully lower initial loading rate than traditionally shod runners. Differences in shoe construction incur different mechanical demands, over time runners attempt to adapt to these demands to optimize gait and reduce risk of injury. Two distinctly different groups of runners ran differently when shod, but responded similarly when running barefoot.

INTRODUCTION

As a periodic motion, running generates transient forces that measure up to 2.5 times the athlete's body mass. The transition of these loads to the runner's lower extremities, is mitigated only by appropriate footwear. Recent studies have introduced Finite Element (FE) modelling as an alternative to experimentation, in an attempt to expedite the evaluation of this in situ load transfer. The majority however of these investigations, have either focused on specific anatomical sights (e.g. the heal pad [1]) or utilized static loading conditions. This represents a deficit in the current literature of footwear biomechanics, as midsole systems are subject to severely altering boundary and loading scenarios.

This investigation introduces a dynamic FE model of a running shoe, considering time varying plantar pressure distributions and boundary conditions. The model is used to suggest improvements of material allocation within the midsole system.

METHODS

A commercial running shoe was scanned by means of a micro Computed Tomography device (Werth TomoScope® HV Compact- 225 3D CNC) and its gel based midsole, reverse-engineered at a 200μm accuracy. The resulting 3D model consisted of a polymer foam and two gel inserts (see figure 1), a 12.7ml one placed under the heel and a second one (1.4ml) in the forefoot region of the shoe.

The plantar pressure distribution, occurring during running, was determined by a Footscanner insole 2.39 system (Niceville, FL 32578, USA), whereas the time dependent shoe-ground contact was extracted from high-speed camera measurements (MotionBLITZ EoSens® mini). Both, load and boundary conditions were applied under dynamic conditions to the superior and inferior surface of the cushioning system, as illustrated in figure 1. Three different heelstrike energies were applied (5, 7 and 8 Joule) to assess the impact of strain-rate loading conditions on underfoot cushioning.

The mesh grid of the FE model was verified, through convergence studies, as to its conceptual soundness. The model was then validated against velocity driven impact tests, in accordance to ASTM F1976-06, conducted on an automated device (INSTRON CEAST 9350). Non-linear material properties were assigned to all entities and the model subjected to a dynamic analysis in Abaqus/Explicit (Dassault Systèmes Simulia Corp., Providence, RI, USA). Following the initial simulation an, optimization function was introduced to the model as to evaluate the effectiveness of the gel (heel pad) positioning and shape.

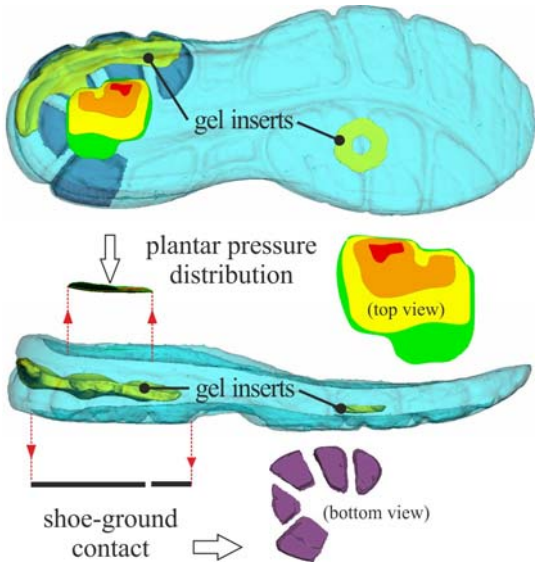

Figure 1: Indicative load step and sub-shoe boundary condition considered during the analysis (0.015s upon heel impact).

RESULTS AND DISCUSSION

The non-linear midsole materials exhibited a strain-rate dependent response, indicating that only limited information can be obtained as to the systems shock absorbing capacity, through quasi-static testing. Modulating the impact energy, confirmed recent experimental findings [2], stipulating that technical footwear systems are tailored to a specific activation energy range. In these terms the energy was decapitated more uniformly throughout the midsole during the 7 Joule impact.

The in-situ developing stress fields suggest that the shock dissipating properties of the heal pad, although notable, could be further optimized as to provide increased cushioning. Both, altered positioning and varying gel volume led to different midsole responses that could be tuned more efficiently to the specific strike pattern.

CONCLUSIONS

The shock absorbing capacity of technical midsole systems, is critical both to athletes and patients in need of prescribed therapeutic footwear. Advanced modeling techniques provide an effective alternative to conventional experimentation, both in the conceptual design and optimization of modern footwear.

THE EFFECT OF THREE INSOLES IN SPORT SHOES ON PLANTAR PRESSURE AND COMFORT DURING SPORT-SPECIFIC TASKS

INTRODUCTION

Practicing sport is a good habit to control body weight and to maintain a healthy cardiovascular system. However, the importance of wearing the correct sport shoes is underestimated and the choice of footwear is often merely dictated by fashion. Foot comfort and the incidence of foot injuries are related both to the type and stress involved in the sport activity. The correct combination of shoes and orthotics may help prevent or decrease these risks. Pedobarographic effects of different foot types in sport shoes [1], and the influence of different insoles/shoes in running [2] have thus far been reported, whereas the biomechanic effects of footwear and plantar insoles during sport-specific tasks have yet to be reported.

In this study, native insoles, i.e. provided with the shoes, were compared to an off-the-shelf sport insole and to a featureless flat insole, in sport-specific tasks.

METHODS

11 young and healthy subjects (age 33 ± 11 years; BMI 22.4 ± 2.9 kg/m^2) performing at least 4 hours of weekly physical activity, were thus far recruited for this study. Each subject was asked to perform a sequence of tasks in an ad-hoc "sport-trial", while wearing their personal trainers. The sequence of tasks performed in the trail were the following: normal walking; fast walking; running; sprints with change of direction; stair ascending; jump off a 0.5 m high platform; jump on the spot, and side-to-side shuttle run.

Three insoles were tested: the native insoles within the sport shoes (NATIVE); a flat insole in latex (FLAT), and off-the-shelf sport insole (OTS-sport). The latter is made of Ethylene Vinyl Acetate (EVA) and the footwear side is covered by anti-slip surface. It features a latex heel insert and metatarsal pad, and medial arch support.

Each subject repeated the trial twice wearing each of the three insoles. The order of tested insoles was randomized for each subject and the test was blind. A VAS questionnaire was filled after each test to score the comfort of each insole [3].

A capacitive 99-sensor insole system (Pedar, Novel GmbH) sampling at 50 Hz was used to measure plantar pressure at rearfoot, midfoot, forefoot, toes, hallux and total foot. Six steps (3 left, 3 right) during all motor tasks were processed for each subject. Analysis of the pedobarographic parameters, e.g. peak pressure (PP, kPa) and pressure-time integral (PTI, kPa*s), and statistical analysis were performed using an ad-hoc software written in Matlab (MathWorks, Inc.).

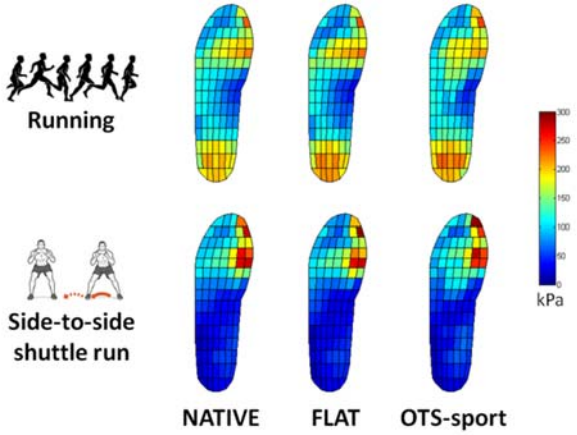
Non-parametric paired Friedman test and Tukey-Kramer post-hoc were used to assess the statistical differences in pedobarographic parameters and comfort between the three insoles (α=0.05).

RESULTS AND DISCUSSION

Statistically significant differences in comfort were found between OTS-sport and the other two insoles (NATIVE = 7.0 ± 2.3; FLAT = 7.5 ± 2.3; OTS = 4.2 ± 2.6; $p < 0.05$).

Significant differences in pedobarographic parameters were detected between tasks at the same plantar region, and between the three insoles for the same task. For example, side-to-side run showed plantar loading mainly at the forefoot (Figure 1). In fast walking, the OTS-sport showed larger PP and PTI at the rearfoot than NATIVE (PP: NATIVE = 280 ± 90; FLAT = 302 ± 81, OTS = 328 ± 78; $p < 0.05$) but no significant differences at forefoot. In running, the OTS-sport showed the largest PTI and PP at forefoot (PTI: NATIVE = 50 ± 19; FLAT = 47 ± 13; OTS = 53 ± 11; $p < 0.05$).

Figure 1: Color-map of the intersubject mean peak pressure



(kPa) in each sensor during running and side-to-side shuttle run, for the three insoles.

CONCLUSIONS

No standard protocol to test sport shoes and orthotics has thus far been designed and validated. In this study, an ad-hoc sport-trial was designed and proposed to allow the acquisition of in-shoe plantar pressure during different sport-specific tasks. The effect of three insoles on plantar pressure and comfort was herein investigated.

In general, NATIVE and FLAT insoles did not show major differences in terms of comfort and pressure parameters. The presence of a metatarsal pad in the OTS-sport insole appeared to affect negatively the insole performance.

This study provides an insight on the effects of foot orthotics on plantar pressure magnitude and distribution in sport shoes, and novel information on the forces acting on the foot in different sports, which may also help with the selection of the most appropriate combination of footwear/orthotics.

A NEUROMUSCULAR CONTROL COMPARISON USING WALKING STICKS AND WALKER DURING GAIT IN ADULT SCOLIOSIS PATIENTS

[1]Rumit Singh Kakar, [2]Isador Lieberman, [1]Joshua M. Tome, [3]Ram Haddas
[1]Ithaca College, Ithaca, NY; [2]Texas Back Institute, Plano, TX; [3]Texas Back Institute Research Foundation, Plano, TX

INTRODUCTION

Patients with Degenerative adult scoliosis (ADS) demonstrate an altered gait pattern due to its association with progressive and asymmetric degeneration of the disc and facet joints, which typically lead to stenosis, back and leg pain, weakness, and numbness.[1-3] For many patients with ADS a walking aid is beneficial due to increase of energy cost and a decrease in the muscular efficiency.[4] Walkers are frequently prescribed in an effort to improve balance, mobility, and reduce lower back pain, but the literature demonstrates conflicting evidence regarding their effectiveness.[4-5] Anecdotal evidence suggests use of walking sticks rather than a walker promotes a more upright posture (Figure 1) to halt deformity progression, improve line of sight, and help maintain surgical correction of the kyphotic deformities postoperatively. The purpose of this study was to evaluate the impact of different assistive devices on neuromuscular control of the pelvis and lower extremities during gait in preoperative ADS patients.

Figure 1: *Gait with walking sticks (left) and walker (right)*

METHODS

Twelve patients with symptomatic ADS who have been deemed appropriate surgical candidates performed walking gait under 3 testing conditions; 1. with walking sticks (WS), 2. with walker (WK), and 3. without any assistive device (ND). Ag/AgCl surface EMG electrodes were placed on 5 muscles: external oblique (EO), gluteus maximus (GM), erector spinae (ES) at level of L1, rectus femoris (RF), and semitendinosus (ST). EMG data were recorded using a Delsys® system (2000 Hz) along with locations of 51 markers using 10 camera Vicon® (100 Hz) as the patient walked barefoot at his/her self-selected speed along a 10m walkway for 5 acceptable trials. RMS EMG was scaled to the peak value of the BASE RMS EMG. Repeated measurements ANOVA ($p < .05$) was used to determine differences between walking devices on peak RMS activation, duration of activation, onset timing and time to peak for each muscle.

RESULTS AND DISCUSSION

Duration of activation for RF was significantly different between the 3 conditions ($p = .047$; $F(1.1,6407.3) = 5.028$). Post-hoc pair wise comparisons revealed longest RF activation for WS followed by ND (mean difference= 1.7ms) and then WK (mean difference= 33 ms) but no statistical differences were found ($p = .128$-$.161$). RF activation during WS suggests that the muscle is assisting in controlled knee extension and hip flexion especially around stance-to-swing transition phase, which is similar to that observed in ND and that reported in literature for gait in able-bodied individuals. [6] Subjectively, during WS patients were more cautious in their gait, yet they stood taller and increased their range of motion in the lower extremities. No other comparisons for peak activation, duration of activation, onset timing and time to peak showed significant differences between conditions ($p = .150$-$.966$). Although magnitudes of differences were small for the variables, the lack of statistical significance of the majority of muscles among conditions may be due to high inter-participant variability (Table 1) and altered activation patterns due to low back pain induced muscle guarding (mean VAS = 6.6).

Table 1: EMG duration (mean ± SD) for 100% of gait cycle.

Muscles	EMG duration (ms)			*p* value
	Walking Stick	No Device	Walker	
EO	58.3 ± 13.8	66.7 ± 15.7	82.6 ± 48.4	0.195
GM	60.3 ± 15.6	66.1 ± 22.0	91.0 ± 61.9	0.195
ES	62.4 ± 9.5	66.7 ± 13.7	94.9 ± 64.5	0.178
RF	61.4 ± 10.5	63.1 ± 12.2	94.6 ± 44.1	***0.047***
MH	67.3 ± 19.1	71.8 ± 15.5	104.3 ± 65.1	0.130

CONCLUSIONS

The results suggest that walking sticks can possibly improve the neuromuscular control of the pelvis and lower extremity resulting in gait mechanics comparable to that of able-bodied gait without any assistive device. Further research is warranted to understand effect of assistive devices in facilitating normal positioning and neuromuscular control during walking in adult degenerative scoliosis patients.

CHANGES IN ELECTROMYOGRAPHIC SIGNALS DURING GAIT IN PERSONS WITH GASTROCNEMIUS MEDIAL HEAD PARALYSIS

[1,2] Dongho Park, [3]Yeon-Jae Seong, [3]Eun Sang Kim, [2]Ja Young Choi, [2]Dong-wook Rha

INTRODUCTION

The gastrocnemius (GCM) is an important muscle for walking. The GCM is composed of the medial and lateral heads and is connected to the calcaneus of the heel by the Achilles tendon, which it shares with the soleus muscle. Previous studies have analyzed the activity of both the medial and lateral heads of the GCM as a unit. However, functional differences between the medial and lateral heads were suggested according to their different locations in the lower leg [1] and structural characteristics such as muscle thickness, fascicle length, and pennation angle [2].
In this study, the function of the GCM medial head was analyzed in subjects who underwent medial GCM nerve block for calf reduction, by comparing pre- and post-procedure computerized gait analysis.

METHODS

1. Subjects

The study group consisted of 10 healthy adults scheduled to undergo tibial nerve branch block to the medial GCM head for aesthetic calf reduction using 400-kHz radio-frequency nerve ablation.

2. Gait analysis

Gait analysis was performed using a computerized opto-electric gait analysis system (VICON MX-T10 Motion Analysis System, Oxford Metrics Inc., Oxford, UK; sampling frequency 100 Hz) to measure kinematic data. Subjects were instrumented with 16 reflective markers per the VICON Plug-in-Gait model. Data were recorded while subjects walked at a comfortable speed on an 8-m pathway [3].

3. Electromyography (EMG) measurements

Surface EMG (MA300-XVI, Motion lab systems, LA, USA; sampling frequency 1000 Hz) was recorded simultaneously with the gait analysis. Surface electrodes were placed on the rectus femoris, hamstring, and medial and lateral GCM according to SENIAM guidelines [4]. Data were filtered by a 10 to 500 Hz band-pass filter and time-normalized by dividing one gait cycle into 16 equally-spaced intervals. Root mean square (RMS) values were calculated for each muscle during each time interval. Pre- and post-procedure RMS values of each muscle were expressed as a ratio of the maximum pre-procedure RMS value [5]. All data were averaged for three left and three right gait cycles.

4. Data analysis

Pre-procedure and 1-week and 3-month post-procedure data were compared using repeated ANOVA. Two-sided *p*-values <0.05 were considered statistically significant.

RESULTS AND DISCUSSION

1. Gait analysis

All kinematic data of the ankle, knee and hip joint in the sagittal, coronal, and transverse planes revealed statistically insignificant changes.

2. Electromyography measurements

All EMG data except that of the rectus femoris muscle revealed statistically significant changes (Figure 1).

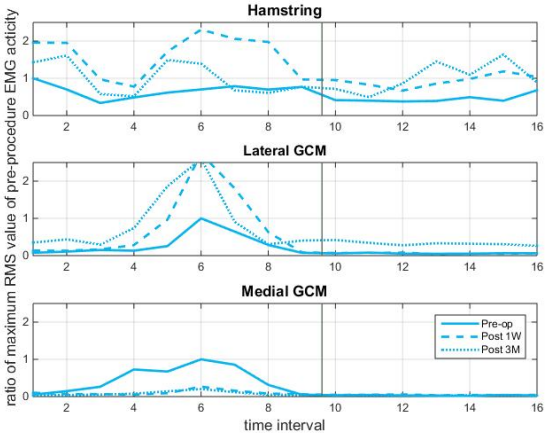

Figure 1: An example of changes in linear envelope muscle activities after medial GCM nerve block.

RMS values during mid-stance phase of the GCM medial head were lower post-procedure compared to pre-procedure values (p<0.05). Contrarily, GCM lateral head RMS values at this phase were higher post-procedure compared to pre-procedure values(p<0.05). The hamstring muscle also showed a statistically significant increase in RMS values during initial contact, mid-stance, and late swing phases post-procedure (p<0.05).

CONCLUSIONS

Our study revealed that decreased activity of the GCM medial head did not change the kinematics of gait significantly. However, the activities of the GCM lateral head and hamstring were significantly increased when the activity of the GCM medial head was decreased.
This implies that GCM lateral head and hamstring compensate for the function of the medial GCM head to maintain normal gait pattern.

JOINT MOMENT STRATEGIES DURING STAIR DESCENT IN CLAUDICANTS WITH PERIPHERAL ARTERIAL DISEASE

[1] **Stephanie L King,** [1] Natalie Vanicek, [2] Thomas D O'Brien
[1]Sport, Health and Exercise Sciences, University of Hull, Hull, UK
[2] Research Institute of Sport and Exercise Sciences, Liverpool John Moores University, Liverpool, UK

INTRODUCTION

Peripheral arterial disease and intermittent claudication (PAD-IC) is a chronic atherosclerotic disease of the peripheral arteries which obstructs the blood supply to working muscles. Physical function is impaired [1]; reduced calf strength has been associated with mortality [2], and ankle joint powers are altered during level walking [3]. Stair descent is a daily task that is integral to active and independent living, but is more physically demanding than level walking, It is not yet known how those with PAD-IC overcome these increased task demands despite these physical limitations. It was hypothesised that PAD-IC patients would adopt strategies to redistribute kinetics away from the ankle joint.

METHODS

Twelve participants with PAD-IC (six bilateral and six unilateral; 64.7±7.1 years) and 10 healthy controls (61.6±3.6 years) were recruited and instructed to descend a five-step staircase whilst 3D kinematic data of the lower-limbs were recorded synchronously with kinetic data from force plates embedded into the staircase on steps two and three (step five being the top landing of the staircase). Peak moments and powers were quantified during weight acceptance (WA) and controlled lowering (CL) phases of continuous, steady-state gait during. Support moments were calculated as the summed moments of the hip, knee and ankle with the relative contribution from those joints to the peak expressed as a percentage. As a trend towards slower walking speeds existed in those with PAD-IC (0.65±0.08 $m \cdot s^{-1}$ vs 0.79±0.14 $m \cdot s^{-1}$ among controls P=.060), a univariate analysis of variances was performed on key variables with walking speed a covariate.

RESULTS AND DISCUSSION

The hip moment profiles within the PAD-IC cohort revealed very wide variability (Figure 1a) with 73% demonstrating hip extensor moments during weight acceptance whilst the remainder and controls utilized typical hip flexor moments (Figure 1b). The hip extensor strategy PAD-IC sub-group (HExt) demonstrated reduced posterior ground reaction forces (P=.008 and P=.096 respectively) and reduced knee extensor moment (P=.058 and P=.042 respectively) during WA compared to both hip flexor strategy (HFlex) and controls. The HExt group also demonstrated trends towards increased ankle contribution to peak support moment during WA compared to controls (45% vs 28%) and significantly higher ankle contribution compared to both HFlex and Con groups during CL (44% vs 33% and 31% respectively).

The shift towards greater utilization of the hip extensors in those with PAD-IC was surprising and, contrary to the hypothesis, this strategy redistributed the demands away from the knee extensors, and not the plantarflexors. The elderly typically redistribute joint moments away from the ankle plantarflexors in order to operate within safe physical limits [4]. Given that further velocity-dependent weakness in the ankle plantarflexors exist in this population [5], the greater reliance on this muscle group seems counter-intuitive. It is unclear whether strength has been maintained in the hip extensors and the strategy therefore acts as a compensation reflecting greater controlled lowering, or if strength has declined similarly to that reported elsewhere [6]; this strategy may place those with PAD-IC at risk for falls.

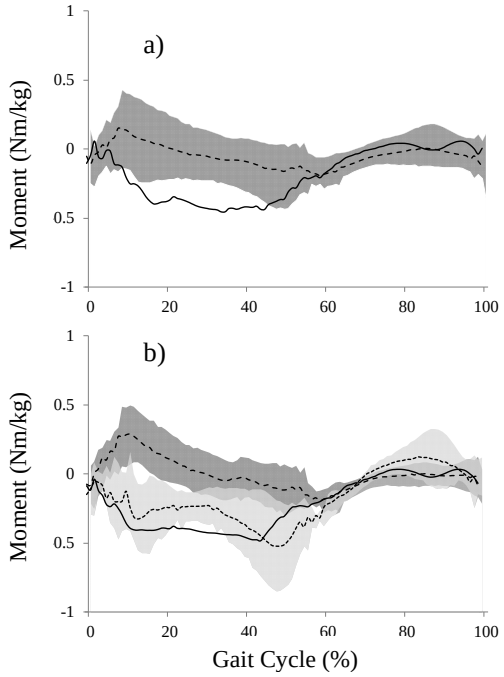

Figure 1. Group mean hip moments for a) PAD-IC (dash) and control (solid) groups and b) HExt (dash), HFlex (dot) and control (solid) groups. +ve indicates internal extensor

CONCLUSIONS

The revelation of an alternate hip extensor strategy during stair descent has important implications for function and safety in those with PAD-IC. Targeted interventions on plantarflexor strengthening are warranted and further exploration of the relationships between strength capabilities of muscle groups and movement strategies are required to determine the safety of the strategies identified.

CORRELATIONS BETWEEN THE KINEMATIC DATA AND EMG FIRING IN STROKE SURVIVORS DURING DIFFERENT HEIGHTS OBSTRACLE CROSSING

[1,2] Chenming Ma, [1]Na Chen, [1,*]Le Li
[1] Department of Rehabilitation Medicine, Guangdong Engineering Technology Research Center for Rehabilitation Medicine and Clinical Translation, the First Affiliated Hospital, Sun Yat-Sen University, China

INTRODUCTION

Stroke is a leading cause of disability. Obstacle crossing which requires precise swing foot control and body balance is impaired following stroke. To understand the performance of the stroke survivors during obstacle crossing, Lu et al. investigated the kinematic strategy stroke survivors took, which was different compared with the healthy controls [1]. Hahn et al. compared the muscle activation level of the lower limb muscles between the elderly and the young during obstacle crossing and found age-related muscular changes which may lead to high risk of falls [2].

In this study, we examine the correlation between the kinematic and electromyography (EMG) data of the stroke survivors during obstacle crossing compared with the healthy controls. And we suppose that the result of correlation could explain the motor control mechanisms during obstacle crossing following stroke.

METHODS

Seven stroke survivors and seven gender-, age- and height-matched healthy subjects were recruited in this study. Thirty-five spherical infrared-reflective markers were attached to corresponding place of the subject's whole body. Circular silver-silver chloride (Ag-AgCl) electrodes were attached to the surface of the rectus femoris (RF), biceps femoris (BF), tibialis anterior (TA), medial gastrocnemius (MG) of the lower limbs of the subjects in both sides. The maker positions were recorded using Vicon Motion Systems, the EMG signals were recorded using Noraxon pre-amplified wireless transmission modules.

Then subjects were instructed to walk at their self-selected speed with bare foot along an eight-meter walkway with an obstacle on the midway. The stroke survivors used their affected leg as the leading limb to step across the obstacle, while the healthy controls used their dominant leg. The obstacle height was set to three conditions (10%,20%,30% of leg length). The three height conditions were in random order. We analyzed the kinematic data such as joint angles, toe-obstacle clearance, and distance between center of mass (COM) and center of pressure (COP), also the EMG data such as the muscle activation level, co-contraction index and mean power frequency. Then we performed the Pearson correlations to examine relationship between them.

RESULTS AND DISCUSSION

There was a significant positive correlation between the muscle activation of BF and knee flexion/extension ($r=0.821$, $p<0.05$) and knee rotation ($r=0.781$, $p<0.05$) in stroke survivors during 30% obstacle height crossing. However, no significant correlation between them was found in healthy controls.A significant positive correlation was found between the co-contraction of RF and BF and the knee abduction/adduction ($r=0.788$,$p<0.05$) in stroke survivors during 10% obstacle height crossing. While in healthy controls, there was a significant positive correlation between the co-contraction of TA and MG and the ankle dorsiflexion/plantar flexion ($r=0.795$,$p<0.05$) during 30% obstacle height crossing. For the stroke survivors, there was a significant positive correlation between toe-obstacle clearance and the muscle activation of BF during 20% ($r=0.928$,$p<0.01$) and 30% ($r=0.946$,$p<0.01$) obstacle height crossing, which was not found in the healthy controls(Fig.1). Also, there was a significant positive correlation between the activation level of BF and distance between COM and COP in the anterior/posterior direction in stroke survivors during 10% ($r=0.872$,$p<0.05$) and 30% ($r=0.815$,$p<0.05$) obstacle height crossing, while no significant correlation between them was found in healthy controls.

For stroke survivors, the muscle strength was damaged following stroke, and the proximal control is more efficient than distal control. Thus they activated BF greater to control the knee joint to ensure enough clearance distance compared with the healthy controls. However, the activation of the BF increased the distance between the COM and COP, which might lead to instability and falls.

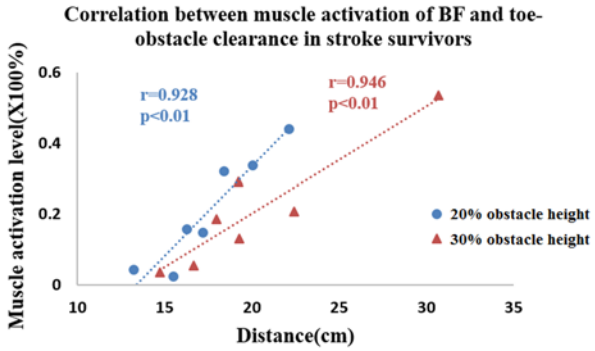

Figure 1: Correlation between muscle activation of BF and toe-obstacle clearance in stroke survivors during 20% and 30% obstacle height.

CONCLUSIONS

In this study we examined the correlation between the kinematic and EMG data in stroke survivors during obstacle crossing compared with healthy controls. We found that the stroke survivors controlled the proximal joint to elevate the toe negotiating the obstacle due to a lack of muscle strength following stroke. But this increased the COM-COP distance, which might lead to instability and falls.

IN VITRO INDEPENDENT MULTI-AXIAL LOAD CONTROL FRETTING-CORROSION INVESTIGATION ON THE HEAD NECK JUNCTION OF HIP JOINT IMPLANTS UNDER WALKING GAIT LOADINGI

[1] **Hamidreza Farhoudi**, [1]Reza H Oskouei, and [1]Mark Taylor
[1]Flinders University

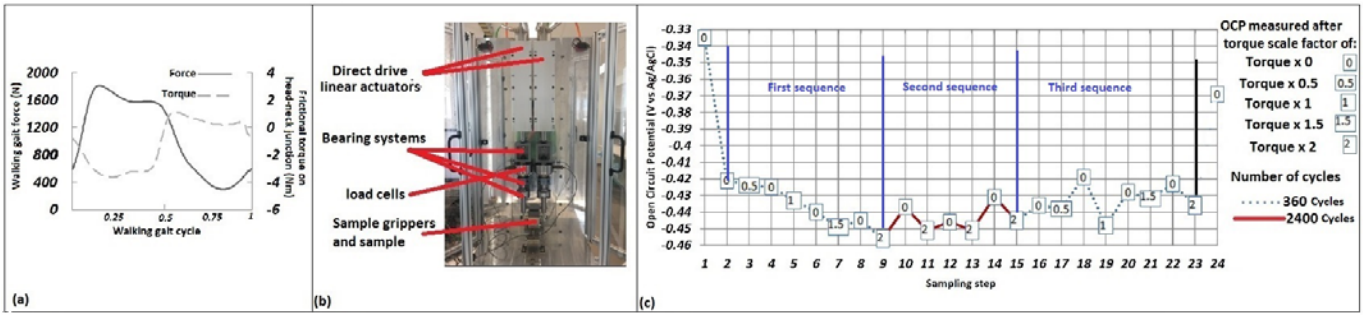

Figure 1: a) Gait vertical forces and frictional torques of walking activity. b) multi-axial load control fretting-corrosion testing set-up. c) Open Circuit Potential (OCP) results after different loading steps; for example, " …1.5" means the OCP on y axis was measured after 360 cycles (blue dot lines) of loads of Figure 1.a while its torques multiplied by 1.5 (value in the square).

INTRODUCTION

The contemporary modular design of head-neck interface of hip joint implants may suffer from early retrieval surgeries, partially caused by local tissues reaction to ions emitted from fretting-corrosion of the head-neck under mechanical loads of daily activities and in *in vivo* corrosive environment surrounding the implant.

In this study, for the first time, a realistic multi-axial load control fretting-corrosion test was conducted on a CoCr-CoCr head-neck interface and the effect of frictional torques on the corrosion intensity was investigated.

METHODS

Previously reported vertical forces[1] and frictional torques[2] in the walking gait cycle were applied (Figure 1.a) by two direct drive linear actuators (Figure 1.b). Forces of each actuator were calculated by solving the following equations simultaneously:

$F_1(t) + F_2(t) = F_{total}(t)$ equation 1.a

$[F_1(t) - F_2(t)] \times D = Torque(t)$ equation 1.b

where $F_1(t)$ and $F_2(t)$ are the forces of the first and second actuators, respectively, at time *t*. D is the perpendicular distance between the applied forces and $F_{total}(t)$ and Toque(t) are the force and torque of the walking gait activity, respectively, at time *t*.

A three electrode arrangement was used for measuring Open Circuit Potential (OCP). A 12-14mm CoCr-CoCr head-neck junction (working electrode) was submerged in a Ringer's solution while it was cyclically loaded. Another cylindrical piece of CoCr was located in the solution as the counter electrode and OCP of the CoCr-CoCr head-neck was monitored against an Ag/AgCl reference electrode located near the head and neck inside the solution.

The initial OCP (step 1, Figure 1.c) was the mean OCP over 60 seconds while the sample was unloaded. Then the gait vertical forces were applied continuously and the frictional torque was scaled by different factors of 0, 0.5, 1, 1.5 and 2. The mean OCP was measured for last 10 cycles in each step. In the first sequence, torque was scaled to 0, 0.5, 0, 1, 0, 1.5, 0 and 2, each applied for 360 cycles. This was followed by the second sequence scaling to 0, 2, 0, 2, 0 and 2 each applied for 2,400 cycles (red solid lines, Figure 1.c). The third sequence was a repeat of the first sequence. In step 24, the OCP was measured 60 seconds after unloading.

RESULTS AND DISCUSSION

In the first sequence where torques varied each 360 cycles, scale of 0.5 and 1 of frictional torque did not change the OCP slope compared to the absence of torques (two adjacent scale of 0s), while scaled torques of 1.5 and 2 changed the slope. In the second sequence, where the torque varied each 2,400 cycles, in all three steps of scaling torque by 2, the OCP decreased compared to the absence of torques, which suggests torque scale 2 intensified corrosion. In the third sequence, which was a repeat of the first sequence, the junction corrosion was intensified even in the presence of 0.5 and 1 scale torques which suggests the corrosion sensitivity of junction to frictional torque increased after cyclic loadings.

CONCLUSIONS

In this study, for the first time, the fretting-corrosion response of a head-neck interface was studied in response to the real multi-axial *in vivo* loads rather than a qualitative displacement control testing. For the examined specimen, higher magnitudes of torque (scale of 1.5 and 2), which are likely to occur in poor lubrication conditions of the hip bearing couple, intensified fretting-corrosion of the junction. Also, the fretting-corrosion sensitivity of the junction increased after applying cyclic loads.

ACKNOWLEDGEMENTS

The authors would like to acknowledge the Premier's Research and Industry Fund's Catalyst Research Grant (Government of South Australia), and thank Technical Services at Flinders University for their support in manufacturing the testing apparatus and Mr. Khosro Fallahnezhad for his great assistance in performing the experiments.

INTRODUCTION

Musculoskeletal (MS) models are used by the scientific community to gain insight on how external forces and movements influence the human body internally. This allows researchers to quantify muscle, ligament, and joint contact forces without the use of invasive methods. Despite the complex knee structure, the knee is often idealized as a hinge joint. However, many studies have revealed tibial-rotation trends with respect to knee flexion [1]. A handful of researchers have already incorporated secondary kinematics into MS modeling [2-4] but only rarely on a subject-specific basis. The level of knee joint complexity that is required for a MS model to mimic reality and accurately simulate human movements is up for debate especially when the model is applied for critical applications. This stresses the importance of thorough validation by quantifying uncertainty and errors in the computational model when compared to ground truth data. The EOS bi-plane x-ray system (EOS Imaging SA, Paris, France) is a valid alternative to the reference standard, computed tomography (CT), for lower-limb torsion measurements while also substantially decreasing patient radiation exposure [5]. The aim of this project was to validate the predicted secondary knee joint kinematics of a novel, subject-specific moving-axis knee models during a knee bend under loaded conditions using EOS technology.

METHODS

Various magnetic resonance imaging (MRI) acquisitions were acquired from five adult males to enable subject-specific (SS) MS model development of each. Manual segmentation was performed on full lower limb MRI (femur, tibia, patella, and talus bones) with Mimics (Materialise, Belgium) and these surfaces were used to obtain SS joint centers though analytical shape fitting methods [4]. Segmented articular cartilage surfaces from two detailed knee MRI scans at roughly 0 and 90 degrees flexion were used to define novel tibiofemoral (TF) and patellofemoral (PF) moving-axis (MA) joints using AnyBody Modeling System v6.0 (Anybody Technology A/S, Aalborg, Denmark). The model applies a linear interpolation scheme (Figure 1, top) between the extension (EFC) and flexion facet centers (FFC) of the medial and lateral contact surface of the tibiofemoral and patellofemoral joints estimated from the two MRI scans at 0 and 90 degrees of flexion to estimate the secondary joint kinematics [6].

To validate the SS knee models, EOS Imaging technology was employed to capture secondary knee joint kinematics of each subject during a quasi-static lunge. The 2D bone contours were segmented from the frontal and lateral x-rays of the femur, tibia, and patella structures. Custom MATLAB code was used to register the 3D STL to the bi-planar contours to determine the bone position in the EOS scanner (Figure 1, bottom).

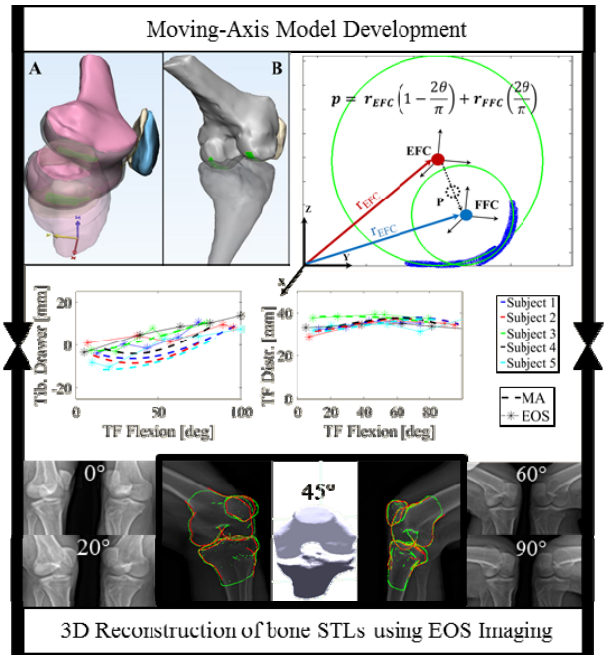

Figure 1: MA model and EOS reconstruction workflow to obtain clinical translations [7]. θ: TF flexion angle.

RESULTS AND DISCUSSION

EOS reconstructions were considered "gold standard" when determining how well the MA knee model mimic reality. Root mean square errors of TF anterior drawer (5.58 ± 1,91mm) and joint distraction (2.28 ± 1.16mm) indicate acceptable agreement. Other clinical translations such as tibial internal rotation, adduction/abduction, and lateral tibia dislocation also provide reasonable comparisons with EOS outputs.

CONCLUSIONS

We developed a new approach to modeling the TF and PF joints in MS modeling. Initial results indicate that a linear model based off two passive MRI scans can accurately represent secondary kinematics of a loaded knee joint. In addition, this study provides groundwork necessary to further validate knee models of varying complexity.

BAYESIAN INVERSE KINEMATICS: IMPROVED ANGULAR DISPLACEMENT ESTIMATES IN RIGID PLANAR ROTATIONS

[1]**Todd C Pataky**, [2]Jos Vanrenterghem and [3]Mark A. Robinson

INTRODUCTION

A variety of least-squares methods have been proposed in the literature for minimizing measurement error when estimating joint center-of-rotation (COR) and angular displacement from a set of noisy marker displacements [1,2]. This paper introduces a Bayesian approach which instead *maximizes* the probability that a stochastic, forward-kinematics system would produce the observed data. By incorporating a non-linear model of measurement error directly in the inverse kinematics computation, it is conceivable that the Bayesian approach can successfully distinguish large from small measurement error to yield improved COR and/or angular displacement estimates.

METHODS

A planar model consisting of a rigid marker plate and a rotating body segment was created for a computational simulation study (Fig.1a). The plate was positioned 40 cm from the joint center and contained a variable number of markers placed approximately 4 cm apart. A total of 1000 simulations for each combination of three marker sets (3, 4 and 5 markers), three angular displacements (1, 5, and 10 deg), and three Gaussian noise standard deviations (0.1, 0.5 and 1.0 mm) were conducted, yielding a total of 27,000 datasets. A Bayesian network consisting of COR, segment length, angular posture and measurement error (Fig.1b) was constructed using PyMC [3]. Markov Chain Monte Carlo simulation was used to optimize model parameters, and thereby maximize the parameter's posterior distributions' maxima, which is approximately equivalent to maximizing the probability that the stochastic system would produce the observed data. The Bayesian results were compared to the best result from two least-squares methods [1,2].

RESULTS AND DISCUSSION

For very small error (0.1 mm) Bayesian inverse kinematics (BIK) and the least-squares techniques yielded similar angular displacement error, but BIK performed much better when measurement error was larger (Table 1). BIK nevertheless produced COR errors larger than 2 mm much more frequently than the least-squares methods (Table 2). Additionally, BIK was computationally demanding, requiring ~25 s per iteration, compared to ~1 ms for the least-squares methods. Results were qualitatively identical for four- and five-markers (not reported here).

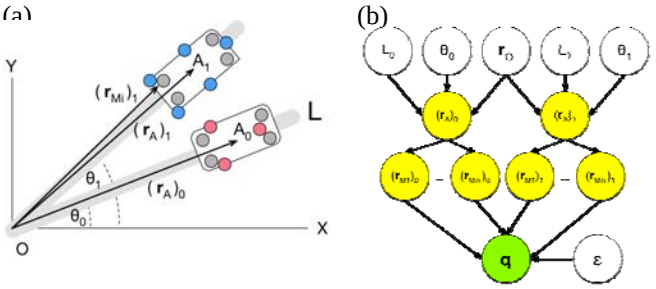

Figure 1: (a) Rotating rigid body with rigid marker plates; three- (red), four- (grey) and five-markers (blue) shown. (b) Bayesian model; white, yellow and green circles represent stochastic, deterministic and observed variables, respectively. Measured marker positions **q** are determined when the numerical values of the stochastic variables and measurement error (**ε**) are known.

CONCLUSIONS

Our simulations suggest that BIK has the potential to reduce angular displacement estimate errors in noisy marker datasets, but also that BIK may yield worse COR estimates. Alternative Bayesian models (e.g. with rigidly fixed segment lengths) may improve COR estimates. We are currently investigating alternative models and all models' implications for three-dimensional rotations and inverse dynamics computations.

REDUCTION OF SOFT TISSUE ARTEFACT AT THE KNEE USING AN ADAPTIVE BONE-PIN MARKER DEFINED RANGE

[1]**Kenneth B Smale**, [1]Brigitte M. Potvin, [1]Mohammad S. Shourijeh, and [1]Daniel L. Benoit
[1]University of Ottawa, Canada
Corresponding author email: dbenoit@uottawa.ca

INTRODUCTION

Even as major advancements in musculoskeletal modelling are being made, this method is still susceptible to error produced by soft tissue artifact (STA) during human movement. The purpose of this study was to apply angle-dependent, adaptive bone pin (BP) defined kinematic constraints to an OpenSim model to determine the difference in knee joint kinematics and kinetics between constrained and unconstrained conditions.

METHODS

Thirty-five healthy, active, young adults participated in this study (17 males, 26.4 ± 6.3 years, 1.76 ± 0.06 m, 72.6 ± 9.8 kg). Participants wore tight-fitting clothing and were outfitted with a cluster marker set. Kinematic data were collected using a 10-camera motion capture system (Vicon, UK) and captured at 100 Hz while kinetic data were sampled at 1000 Hz using one force plate (AMTI, USA). Once a static pose was collected, participants completed 3-4 successful side cut movements. Participants were instructed to complete the task at their self-selected speed, hit the force plate at a 45° angle and leave the force plate again at a mirrored 45°.

All data were processed through a Matlab (Mathworks, USA) – OpenSim (Simtk, USA) application program interface. Rajagopal's model [1] was modified to include six degrees of freedom (dof) at the knee. The model was scaled using the static trial and motion trials were processed with the Inverse Kinematic (IK) and Inverse Dynamics (ID) tools to achieve the no bone pin (unconstrained; NoBP) solution.

Kinematic bone pin data from Benoit et al. [2] were collected for 3-5 trials of walking, hopping, and cutting motions from six healthy, active, young adult males. From all trials of each participant, a mean and 95% confidence interval (CI) for each knee dof were taken and these 95% CIs were then averaged to determine the new bone pin defined range that each dof is constrained to. Thus, every sagittal plane angle is associated with a specific range for the remaining five knee dofs in which the IK solutions are confined to. The original scaled models for each participant were then subjected to IK once more where the calculations were completed at each time step (0.01s) and the sagittal plane knee angles were used to define the instantaneous constraint ranges that were applied to the five remaining dof for that instant in time. These IK results were then used in the ID tool to obtain the bone pin constrained (BP) results.

To test the IK and ID results of the two conditions (BP vs. NoBP), statistical parametric mapping was used to apply paired sample T-tests with α=0.05. Cohen's d effect sizes were calculated for each significant range based on the time point with the peak difference (PD) between BP and NoBP. Cohen's d of 0.2 were considered small, 0.5 considered medium, and >0.8 considered large.

RESULTS AND DISCUSSION

In the BP condition, the knee was more adducted from -10 – 96% stance (PD: 13.3°, d = 3.80, p < 0.001) and externally rotated from -10 – 100% of stance (PD: 9.0°, d = 1.45, p < 0.001). As for tibia translations with respect to the femur, BP IK results had the tibia more anterior from 11 – 72% stance (PD: 1.9 mm, d = 0.74, p = 0.049) and 85 – 100% stance (PD: 2.0 mm, d = 0.59, p = 0.01); more medial -10 – 100% stance (PD: 4.1 mm, d = 4.22, p < 0.001); and distracted from -10 – 97% stance (PD: 15.7 mm, d = 7.22, p < 0.001; Figure 1).

With respect to the ID solutions, the knee also had significant differences for all six dof between the two conditions but only had a moderate effect size 11 – 85% stance when the BP condition solved for a greater medial force (PD: 1.02 N/kg, d = 0.54, p < 0.001).

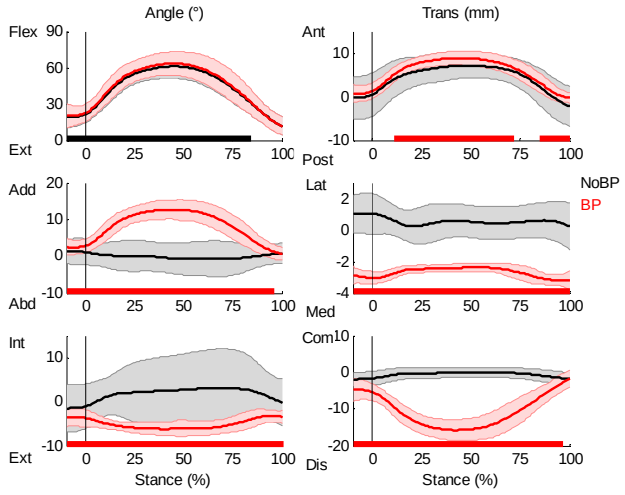

Figure 1: Knee joint angles and translations during the side cut. Movement is -10% to 100% stance with contact represented by a black vertical line Black horizontal bars indicate significance (p < 0.05) but low effect size (Cohen's d < 0.5) while red horizontal bars indicate significance (p < 0.05) and Cohen's d > 0.5. BP: Bone pin constraints; NoBP: No bone pin constraints.

CONCLUSIONS

The BP derived, adaptive kinematic constraints provided reasonable reduction of STA and provided clear representations of the side cut maneuver. This is evidenced by the correction of misclassified joint angles such as the knee frontal plane angle during the side cut. These results are easily implemented into a Matlab-OpenSim application program interface and have a considerable clinical implication in identifying physiologically realistic motions of the knee joint during dynamic tasks.

POWER IMBALANCE RESOLVED WITH NOVEL 6 DOF *SEGMENTAL* POWER ANALYSIS

Anahid Ebrahimi[1], John Collins[1,2], Jill Higginson[1] and Steven Stanhope[1]
[1]University of Delaware
[2]Naval Medical Center, San Diego
Corresponding author email: anahide@udel.edu

INTRODUCTION

Segmental powers are indicative of energy flow between segments. This power can be calculated using segment endpoint dynamics or by the rate of energy change. Robertson and Winter used a planar, linked segment model to evaluate energy flow, although they noted a difference in segmental power and rate of energy change, as have others [1,2]. Later, a more robust 6 degree-of-freedom (DOF) *joint* power analysis accounted for missed axes of joint rotation (movement at segment ends) [3]. However, such an analysis has yet to be characterized at the segmental level and the power difference has not been characterized.

Historically, calculating moments and forces at segment ends assumes a fixed axis of rotation. Thus, the purpose of this study was to develop a novel approach to calculate 6 DOF segmental powers which allows for movement at segment ends. A deeper understanding of the errors and accuracy of power calculations is imperative to our interpretation of energetic measures in the study of human movement.

METHODS

In inverse dynamics calculations, the proximal segmental force (F_p) for any segment *m* is
$\vec{F}_{p,m} = [\sum_{n=1}^{m}(m_n\vec{a}_n - m_n\vec{g})] - \vec{F}_{grf}$, where $\vec{m}$, $\vec{a}$, $\vec{g}$, and $\vec{F}_{grf}$ represent the segment mass, segment center of mass acceleration, gravity, and ground reaction force, respectively.

The proximal segmental moment (M_p) is
$\vec{M}_{p,m} = [\sum_{n=1}^{m}(I_n\vec{\alpha}_n + \vec{\omega}_n \times I_n\vec{\omega}_n + \vec{r}_{COM,n} \times (m_n\vec{a}_n - m_n\vec{g})] - \vec{\tau}_{grf} - \vec{r}_{grf,m} \times \vec{F}_{grf}$, where $\vec{I}$, $\vec{\alpha}$, $\vec{\omega}$, and $\vec{\tau}_{grf}$ represent the moment of inertia, angular acceleration, angular velocity, and ground reaction torque, respectively. The $\vec{r}_{COM,n}$ and $\vec{r}_{grf}$ are vectors from the proximal segment end to the center of mass of the nth segment and to the center of pressure, respectively (Figure 1).

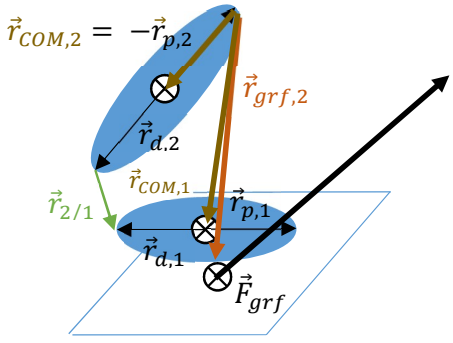

Figure 1: Example of selected vectors used in inverse dynamics calculations for a multi-segment model. Here, segments 1 and 2 represent the foot and shank.

Segmental power (P_m) is calculated as
$\vec{P}_m = \vec{M}_{p,m} \cdot \vec{\omega}_m + \vec{M}_{d,m} \cdot \vec{\omega}_m + \vec{F}_{p,m} \cdot \vec{v}_{p,m} + \vec{F}_{d,m} \cdot \vec{v}_{d,m}$.

Proximal and distal segment velocities are given by
$\vec{v}_{p,m} = \vec{v}_m + \vec{\omega}_m \times \vec{r}_{p,m}$ and $\vec{v}_{d,m} = \vec{v}_m + \vec{\omega}_m \times \vec{r}_{d,m}$
where $\vec{r}$ is the vector from the center of mass to the proximal (p) or distal (d) end of the segment. The segment velocity is represented by $\vec{v}$. The translational kinetic, gravitational potential, and rotational kinetic segmental energies are used to calculate the rate of energy change, $\frac{d}{dt}\vec{E}_m$, as follows:
$\frac{d}{dt}\vec{E}_m = m_m\vec{a}_m \cdot \vec{v}_m + m_m\vec{g} \cdot \vec{v}_m + (I_m\vec{\alpha}_m + \vec{\omega}_m \times I_m\vec{\omega}_m) \cdot \vec{\omega}_m$.
Segmental power minus rate of energy change result in a difference, which we define as the power imbalance, $\Delta\vec{P}_m$:
$\vec{P}_m - \frac{d}{dt}\vec{E}_m = \Delta\vec{P}_m$.

We used kinetic and kinematic data from an individual (67.5kg, 1.61m) walking on an instrumented treadmill at a typical speed (1.29 m/s) to quantify this power imbalance.

RESULTS AND DISCUSSION

The power difference for the left shank was as high as 24.2 W and 20.9 W for the left thigh during stance. The difference in the left foot ranged from 0.17-0.6 W when also accounting for the distal foot segmental power [4]. However, when allowing for movement between segment ends (i.e., a 6 DOF model), our thorough mathematical analysis reveals a term in inverse dynamics that when included is the power imbalance: $\Delta\vec{P}_m = \vec{F}_{d,m} \cdot (\vec{\omega}_m \times \vec{r}_{m/(m-1)})$, where $\vec{r}_{m/(m-1)}$ is the vector from the distal end of the mth segment to the proximal end of the adjoining segment (Figure 1). This term may be interpreted as the velocity related to the movement of the segment ends in the direction of the joint force vector. After including this term in the calculations, the power difference for the left shank ranged from -0.8 to 0.6 W and -2.8 to 2.1 W for the left thigh. The remaining difference may be due to noise related to experimental error in the signal.

CONCLUSIONS

This study resolved the historical power imbalance between segmental power and rate of energy change by including a term to account for movement at segment ends. This novel 6 DOF segmental power approach facilitates improved accuracy in consideration of energetic flow at segment ends.

LIGAMENT AND CONTACT FORCES MUST INTERSECT THE INSTANTANEOUS HELICAL AXIS DURING THE KNEE NATURAL MOTION: AN EXPERIMENTAL ASSESSMENT

[1] **Michele Conconi**, [1]Nicola Sancisi and [1]Vincenzo Parenti-Castelli
[1]University of Bologna
Corresponding author email: michele.conconi@unibo.it

INTRODUCTION

The femoro-tibial unresisted motion follows a well-defined path [1], also called knee natural motion, that is determined by the constraints exerted by ligaments and contacts. To have unresisted motion, the constraints must produce no work against the allowed motion. Experimental evidences indeed showed that it is possible to identify some fibers in the knee ligaments that remain isometric along the natural motion [2], thus producing no elastic work. Generalizing this reasoning, the work produced by each of the passive constraints for the instantaneous act of motion, i.e. about the instantaneous helical axis (IHA), must be zero or, in terms of screw theory, the knee twist must be reciprocal to all the passive constraint wrenches [3], independently from their number or type.

We hypothesized that ligaments and contact wrenches correspond to pure forces. This reasonable assumption is supported by the work presented in [4,5], where it led to the synthesis of parallel mechanisms capable to replicate the knee natural motion. In this condition, if the femoro-tibial twist corresponds to a pure rotation about an instantaneous floating axis, all the constraint forces must intersect the knee IHA in order to produce no work, as also shown in [6].

The aim of this work is to experimentally prove this property by analyzing the relation between the line of action of passive constraints and IHA in the natural motion of two in-vitro and one in-vivo knee joint.

METHODS

We investigated two in vitro and one in vivo knees. The in vitro natural motion was measured by means of a sterephotrogrammetric system, with markers rigidly connected to the bones, within a custom made rig [7]. The in vivo subject natural motion was measured by means of planar fluoroscopy. In all the cases the motion was recorded in a rage of flexion greater than 125°.

Ligaments origin and insertion areas were reconstructed from MRI, as well as the shape of articular surfaces, that was segmented and reconstructed as stereolitography (STL). The ligaments were modeled as a single fiber cables, whose attachments were determined as those points within the measured insertions that guarantee the smallest variation in the ligament lengths during the whole natural motion (ligament isometry).

The application point of contact forces was determined as the projection on the condilar surfaces of the centroid of the portion of the articular surfaces whose distance from tibia plateau was below a given threshold of 5 mm. The direction of contact forces was found as the mean of the normals of the STL triangles of condilar surfaces lying below the prescribed threshold, weighted by the distance of the triangle centroid from the tibia surface.

RESULTS AND DISCUSSION

In each legs was possible to find the isometric fiber for each ligaments (i.e. elongation <5%), including the LCL.

The mean pitch for the knee IHA over the whole natural motion was lower than 0.05 mm/° for all the three legs, thus making the assumption of an instantaneous pure rotational motion for the knee reasonable.

The mean distance for each of the six passive constraints from the knee IHA during the natural motion is reported in Table 1. The small values of the mean distances can reasonably be considered as an experimental proof of the intersection among knee twist and the constraint wrenches.

Table 1: Mean distance between knee IHA and constrain wrenches (mm). The in vivo leg is denoted with a *.

	ACL	PCL	MCL	LCL	MedCon	LatCon
Leg 1	1.23	2.20	3.86	1.18	2.05	1.42
Leg 2	1.24	1.79	3.44	2.01	1.17	0.75
Leg 3*	2.02	3.01	3.34	4.25	1.52	2.90

CONCLUSIONS

The experimental analysis confirmed that passive constraints intersect the IHA during the knee natural motion, thus producing no work against the knee flexion. As a consequence, as long as the knee motion is close to the natural one, it is possible to study its energetic equilibrium without considering the contribution of ligaments and contact forces.

This result also guarantee that all the knee passive constrains are compatible with the knee having at least one DOF, including the LCL whose contribution is usually discarded [2].

This relation among axis of motion and passive constraints, which is general and potentially extendible to other joints, can be exploited for the evaluation of the healthiness of a joint and/or for the design of better treatments and prostheses.

RESEARCH IN DIFFERENT GRAVITATIONAL CONDITIONS
AN OVERVIEW

INTRODUCTION

Gravitation defines the force of material attraction and determines human life and movement on our planetary terrestrial habitat. Therefore, gravitational loading plays an essential role in terrestrial motion influencing posture, locomotion or force generation [1,2]. For instance, gravity guides our upright orientation in space, determines neural activation of the skeletal muscle to provide an adequate antigravity muscle tone and subsequently, influences biomechanics of motion in the Earth's gravity field.
But what happens when gravity is changed? This paper aims to illustrate a methodological overview to illustrate the dependency/adaptability of human movement for conditions above and below Earth gravity.

METHODS

For a basic understanding, similar conditions of partial and hyper-gravity were experimentally achieved by simulation of varied loading such as water immersion partial and overweight weight-bearing in sledge systems, counterweights, body weight support or elastic straps attached to floor or ceiling. These approaches have in common that forces (F=m*a) were altered by changing the mass (m), but not the acceleration (a), which is the analogue of gravity [4].

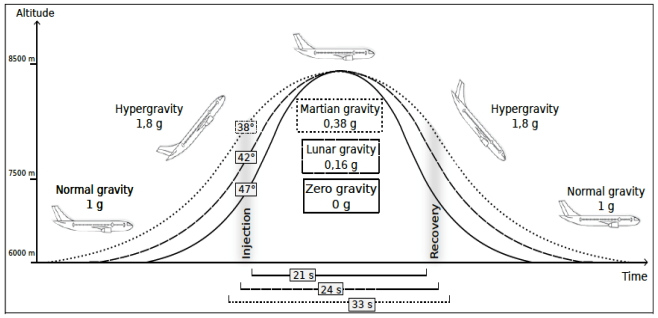

Figure 1: Parabolic flight maneuver and the corresponding gravity levels: the level flight (Earth gravity) becomes a steep climb flight inducing hypergravity (1.8g), followed by either zero (0g), Martian (0.38g), or Lunar (0.16) gravity and another hypergravity phase before returning to a level of normal gravity flight again.

Confounding side effects such as changes in inertia, acceleration and reduced freedom of movement due to hardware constrains have been reported and thus, a conclusive statement about the consequences of gravity on motor control was limited [3]. The execution of experiments in environments with real variation of gravity include interplanetary space missions and parabolic flights (Figure 1), but still have a scarcity value [3, 4]. However, they provide a deep insight and a basic understanding about how humans adapt to gravitation different from the terrestrial one.

RESULTS AND DISCUSSION

It has been demonstrated that gravity levels below Earth gravity induce shifts in movement techniques and change motion patterns with sensory and motor significance. Those adaptations have been identified as (i) a shift in locomotion from walking to bouncing [1] (ii) a general reduction of somatosensory and vestibular input in favor of a predominant visual cues and (iii) an overall degeneration in response to long term exposure to zero gravity. The few experiments executed in gravity levels above the Earth's 1g showed opposed findings.

CONCLUSIONS

Gravity is of major importance for human life [1,2]. Changes in gravitation trigger biomechanical adaptations that rely on sensorimotor and structural changes. These changes include altered sensory processing and differing inter- and intramusclular activation affecting all relevant structures and systems of the human body associated with movement control. Those effects have been reported in settings of acute and chronic exposure to gravitational load variation.
Experiments using methodological simulation of partial unloading or overloading did not achieve adequate conditions to mimic gravitational variation.

LOAD DEPENDENCY OF BALANCE CONTROL – KINEMATIC AND NEUROMSUCULAR CHANGES IN RESPONSE TO GRAVITATIONAL UNDER AND OVER LOAD

[1]**Kathrin Freyler,** [1]Albert Gollhofer, [1] Anne Krause and Ramona Ritzmann [1]
[1]University of Freiburg
Corresponding author email: kathrin.freyler@sport.uni-freiburg.de

INTRODUCTION

Load variation has a significant impact on balance control and is associated with changes in neuromuscular activation, compensatory reflex activation and joint torques [1,2]. Previous studies dealing with over (OL) and under loading (UL) used water buoyancy or additional weight along with negative side effects such as increased friction and inertia, resulting in substantially modified test paradigms. To minimize effects occurring beyond loading, most reliable test conditions can be achieved by a gradual change of the gravitational force. The aim of this study was to identify the gravity-induced load dependency of balance control and the underlying neuromuscular mechanisms.

METHODS

Balance performance was recorded in unipedal stance under normal loading (NL, 1g), UL (0.16g; 0.38g) and OL (1.8g). Center of pressure (COP) displacement and frequency distribution (low 0.15-0.5Hz (LF), medium 0.5-2Hz (MF), high 2-6Hz (HF)) [3] as well as ankle, knee and hip joint kinematics were assessed. Electromyographic activity of muscles encompassing the ankle, knee and hip joint was recorded and co-contraction index (CCI) of antagonistic muscle pairs was calculated. Spinal excitability was determined in the soleus muscle by means of H/M-recruitment curves (H/M-ratios).

RESULTS AND DISCUSSION

Compared to NL, OL caused an increase in ankle joint excursion, COP HF domain and H/M-ratio. Concomitantly, hip joint excursion and COP LF decreased. Compared to NL, UL caused modulations in the opposite direction: UL decreased ankle joint excursions, COP HF and H/M-ratio. Concomitantly, hip joint excursion and COP LF increased. COP and antagonistic co-contraction of muscles encompassing the ankle, knee and hip joint was augmented both in UL and in OL compared to NL (Figure 1).

CONCLUSIONS

Subjects achieved postural stability in OL and UL with great difficulty compared to NL. This reduction in postural control in UL and OL was accompanied by modified balance strategies and compensatory reflex activation. With increasing gravitational loading, a shift from hip to ankle strategy was observed [4]. Concomitantly, the COP frequency distribution shifted from LF to HF and H-reflex sensitivity was gradually enhanced. It is suggested that in OL, augmented ankle joint torques are compensated by quick reflex-induced postural reactions in the distal muscles [2]. In contrast, UL is associated with diminished joint torques and thus, postural equilibrium may be controlled by the proximal segments to appropriately adjust the center of gravity above the base of support [3].

PARTIAL UNLOADING DURING BALANCE TRAINING IMPROVES POSTURAL CONTROL SIMILAR TO TRAINING WITH FULL BODY LOAD

[1]Albert Gollhofer, [1]Anne Krause, [1] Ramona Ritzmann and [1]Kathrin Freyler
[1]University of Freiburg
Corresponding author email: ag@sport.uni-freiburg.de

INTRODUCTION

Balance training (BAL) is successfully implemented in therapy as a countermeasure against postural dysfunctions. From literature, it is well known that in improvements in balance control are associated with a decreased co-contraction of antagonistic muscles concomitant with a reduction in spinal excitability [1,2]. However, for patients suffering from motor impairments or reduced mobility, BAL with partial unloading (PART) of the bodyweight may be the only approach for therapy. This study aimed to compare the effects of a 4-week BAL intervention with PART on postural control with BAL under full body load.

METHODS

32 subjects were randomly assigned to the control group (CON, full body load) or the PART group (partial load equal to 40% of the bodyweight). Partial unloading was applied by means of elastic straps connected to a body-harness attached to a ceiling-mounted height-adjustable system.

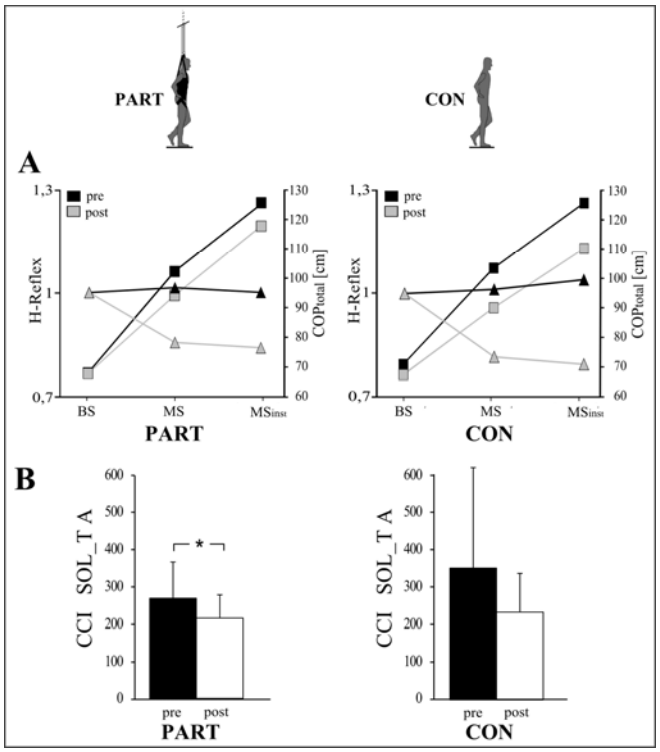

Figure 1: (A) The COP_{total} displacements (squares) and H-Reflex amplitudes (triangles) are displayed for the PART and the CON group before (black) and after (grey) the interventions. For both groups the training-induced decrease in COP_{total} displacement was accompanied by a reduced H-reflex sensitivity. (B) Changes in co-contraction index of SOL/TA in response to the interventions. *indicates a significant difference ($P < 0.05$).

Before and after the training, the centre of pressure (COP) displacement and electromyographic activity of the soleus (SOL), the gastrocnemius medialis (GM), the tibialis anterior (TA) and the peroneus longus (PER) were recorded during bipedal stance (BS), monopedal stance (MS) and monopedal stance on an instable surface (MS_{inst}). Co-contraction index (CCI) of SOL and TA was calculated according to [3]. Additionally, soleus H-reflexes were elicited to evaluate changes in the excitability of the spinal reflex circuitry.

RESULTS AND DISCUSSION

Compared to normal BAL, a BAL with partial unloading resulted in similar adaptations in postural control, revealing three main results: (i) for both groups, the COP displacement was reduced (pre vs. post PART -6±13% $p<0.05$; CON -10±15% $p<0.05$) after the intervention (Figure 1). This reduction in COP displacement was accompanied by (ii) a decreased CCI of SOL and TA (PART -20±40% $p<0.05$; CON -34±35% $p=0.07$) and (iii) a decrease in H-Reflex sensitivity (PART -10±28% $p<0.05$; CON -11±48% $p<0.05$, Figure 1). GM and PER remained unchanged.

CONCLUSIONS

As a main outcome, we found that BAL with partial unloading led to a reduced COP displacement indicating an improvement in stance stability. Further, a decreased co-contraction of the antagonistic muscles TA and SOL and a reduced spinal excitability of the SOL motoneuron pool point towards an optimized neuromuscular control during balance tasks after both training interventions [2,4]. Hence after BAL with partial unloading, adaptations within the central nervous system were comparable, and we observed fundamental changes regarding postural control strategies generally known from regular BAL [1].

These results could in particular help to establish new training modalities within the area of rehabilitation for specific target groups to achieve a faster recovery. BAL with partial unloading is suggested to be an appropriate alternative especially for patients with motor dysfunctions or after surgery unable to train with full body load.

THE ROLE OF GRAVITY ON NEUROMUSUCURLAR CONTROL: CORRELATION OF MUSCLE ACTIVITY AND RATE OF FORCE DEVELOPMENT

[1]**Ramona Ritzmann**, [1]Kathrin Freyler, [1]Anne Krause and [1]Albert Gollhofer
[1]University of Freiburg
Corresponding author email: ramona.ritzmann@sport.uni-freiburg.de

INTRODUCTION

With a diminished load of 62% and 84% on the Mars and Moon [1], bipedal locomotion in its common terrestrial forms is challenged in hypogravity [2]. Space research showed that bouncing is the preferred locomotor technique on our astronomical neighbours. During bouncing, the stretch-shortening-cycle (SSC) describes the muscular activation pattern. The SSC is defined by a stretching of a pre-activated muscle-tendon complex immediately followed by a muscle shortening in the concentric push-off phase [3, 4]. This study aimed to identify gravity-dependent changes in kinematic and neuromuscular characteristics of the SSC during bouncing in hypogravity. For that purpose, neuromuscular control of lower limb muscles as well as correlations between the muscles' pre-activation, reflex components and the force output have been assessed in Lunar (LG), Martian (MG) and Earth gravity (EG).

METHODS

Experiments were executed during a CNES/ESA/DLR parabolic flight campaign. In eight subjects, peak force (F_{max}), ground contact time (GCT), rate of force development (RFD), jump height (H), momentum and jump frequency were measured. Electromyographic activities (EMG) in M. soleus (SOL), gastrocnemius medialis (GM), tibialis anterior (TA), rectus femoris (RF) and biceps femoris (BF) were assessed before (PRE) and during bounces for the reflex phases short-, medium- and long-latency response (SLR, MLR, LLR).

RESULTS AND DISCUSSION

With gradually decreased g-forces F_{max}, RFD, and momentum and jump frequency were reduced, while GCT and H increased ($P<0.05$, Figure 1 top). Concomitantly, EMG activity decreased in GM for PRE, SLR, MLR and LLR, in SOL for SLR, MLR and LLR ($P<0.05$) and in RF in LLR ($P<0.05$, Figure 1). For SLR and MLR, F_{max} as well as RFD were positively correlated to SOL EMG ($P<0.05$). For PRE and LLR, RFD and F_{max} were positively correlated to GM EMG ($P<0.05$, Figure 1 bottom).

CONCLUSIONS

Findings emphasize that biomechanically relevant kinematic adaptations in response to gravity-variation were accompanied by muscle- and phase-specific modulations in neural control [3, 4]. Gravitational variation is anticipated and compensated by a gravity-adjusted muscle activity. Importantly, pre-activation and reflex phases were differently affected: in the reflex phases SLR and MLR, SOL is assumed to contribute to the decline in force output with decreasing load and complementary in PRE and LLR, GM seems to be of major importance for force generation [2, 3, 4].

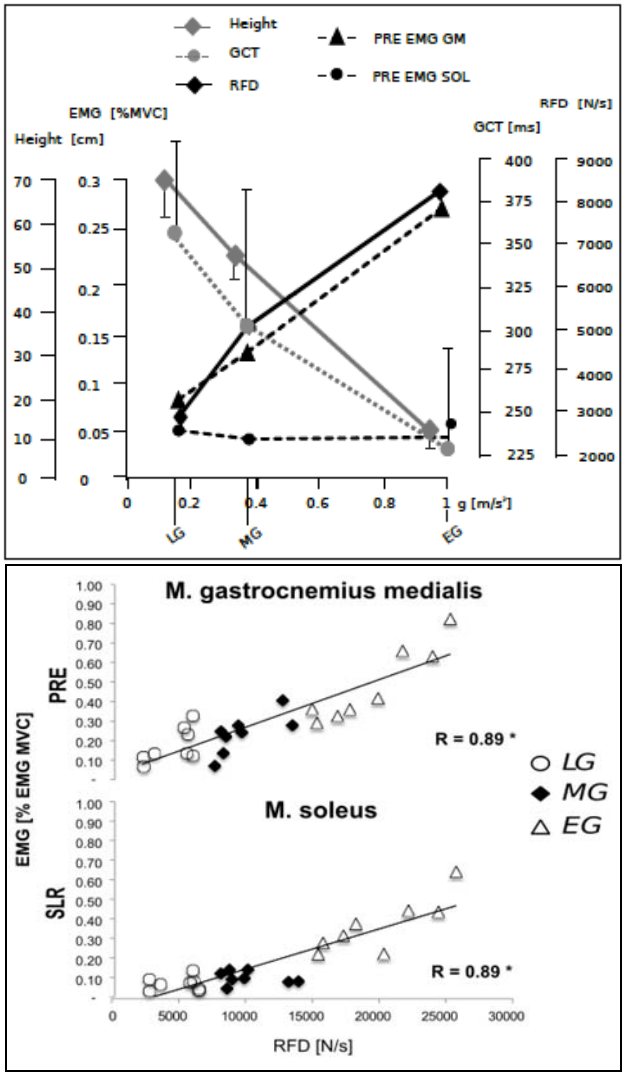

Figure 1: TOP - grand mean and standard deviations of the jump height, electromyographic (EMG) activity during pre-activation in the SOL and GM, GCT, and RFD for gradually increased gravity levels from LG to MG to EG. BOTTOM - bivariate correlations and correlation coefficients among the variables RFD with the normalized muscle EMGs in the relevant EMG phases PRE and SLR.

INTRODUCTION

A primary objective of life sciences in space is to ensure the health of the crew and to guarantee a safe return to earth. This will certainly become a challenge with prolonged duration of the mission. Given the lack of a regular load provided by gravity, a long-term stay in microgravity leads to degeneration of the locomotor system. The extensor musculature of the lower extremities is particularly affected by this. Therefore, effective countermeasures to maintain neuromuscular function are essential.

In general, the preservation of muscle mass and muscle strength necessitates intense strength training, with high loads on the musculature. So far, however, there is no information regarding whether a full activation of a muscle, and thus the generation of high muscle forces, is possible in microgravity. Therefore, the **aim** of the current project is to perform a deeper examination of muscle function during high-load resistive exercise in microgravity in order to better understand (1) what may impact upon the efficacy of high-load resistive exercise countermeasures in spaceflight and (2) the underlying neuro-muscular mechanisms.

METHODS

Eighteen healthy subjects were tested during three parabolic flight campaigns (1st Cooperative DLR-CNES-ESA PFC, 62th ESA PFC, 28th DLR PFC) after giving informed consent to the experimental procedure, complying with the rules of the local scientific board.

Maximum voluntary force generation (MVC) and rate of force generation (RFD) of the ankle extensor and leg extensor muscles were examined during microgravity and normal gravity using a custom-made dynamometer (Fig.1) equipped with two 3D force plates (AMTI, Watertown, USA). As secondary outcome measures activation of nine muscles and fascicle shortening of the gastrocnemius medialis muscle were assed using electromyography and ultrasonography. The ability to fully activate the calf muscles during a volitional effort and some neuromuscular properties (M-Wave, V-Wave) are studied by applying a brief supramaximal electrical stimulation to the nerve commanding the ankle extensor muscles. Changes in ankle and knee joint angle were assessed with two electronic goniometers. Maximum hand-grip force was measured as a control condition.

Microgravity and normal gravity were compared using dependent samples t-tests. Significance was accepted for $p<0.05$.

RESULTS AND DISCUSSION

Maximum force generation and muscle activation during MVC showed no significant difference between microgravity and normal gravity for plantarflexion exercise as well as for leg extension exercise (leg press). Alike no significant difference were found in grip strength. These results indicate that high intense resistive exercise is possible in microgravity.

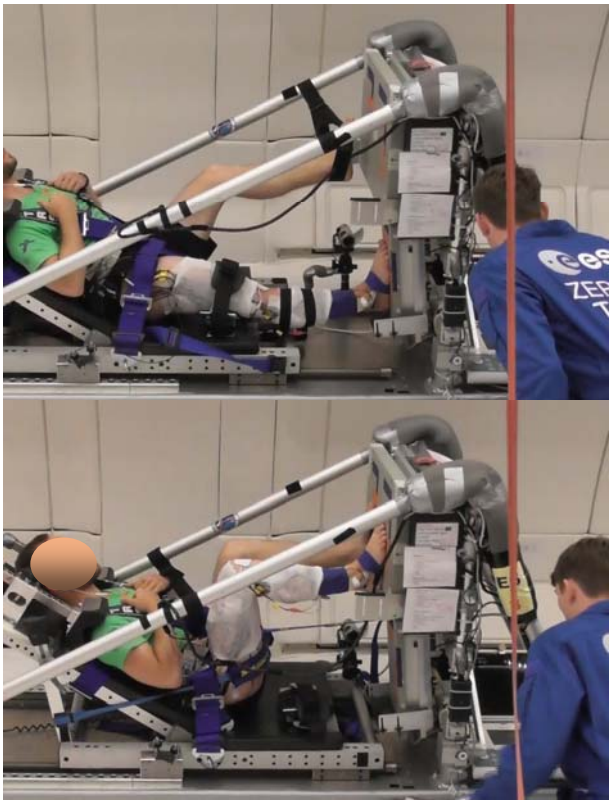

Figure 1: Custom-made dynamometer to perform plantarflexion (top) and leg extension (leg press) (bottom) exercises.

USER-CENTRIC AFFORDABLE STANDING WHEELCHAIR FOR DEVELOPING COUNTRIES

Vivek Sarda, Swostik Sourav Dash, **Sujatha Srinivasan**
Indian Institute of Technology Madras, Chennai, India
Corresponding author email: sujsree@iitm.ac.in

INTRODUCTION

A majority of conventional wheelchair users lack control over their lower limb musculature and require considerable effort, assistance and/or aids to get to a standing position. The ability to attain and maintain a standing position is greatly beneficial to the health, self-esteem and sense of well-being of a wheelchair user. In addition to enabling the individual to perform numerous tasks that he/she might not be able to perform while in a sitting position, a standing posture provides multiple health benefits like improvement in blood circulation to the lower limbs, control of bowel movements, healing of pressure sores, prevention of muscle spasticity and contractures, and improvement in respiratory function, skin integrity and bone mineral density [1].

Powered or customized designs of standing wheelchairs are expensive and are out-of-reach of wheelchair users in developing countries. We have developed a completely mechanical standing wheelchair, which functions like a regular wheelchair for mobility, and which further allows the user to raise oneself into the standing position with the muscle power of the upper limbs. The effort required to operate the standing mechanism is equal to or lower than the effort required to propel the wheelchair. Affordability is achieved by creating a novel mass-manufacturable mechanical design that incorporates the customizability required to accommodate a wide range of wheelchair users.

METHODS

The requirement in the design of a user-operated standing wheelchair is that the user should be able to independently, and in a controlled manner, actuate the wheelchair from sitting to standing position and vice-versa. The standing functionality is achieved using a linkage based mechanism where the user actuates a handle using the hands. In addition to optimal linkage dimensions, a key design element is a gas-spring which reduces the effort to be applied by the user for actuation.

The first design (D1) was created to validate the functioning of the standing mechanism. The link lengths and gas spring specifications were calculated for a person of average height and weight. A proof-of-concept prototype was built and when tested by able-bodied users, the standing functionality worked satisfactorily. The next goal was to get the design tested by actual wheelchair users. This required the design to include safety features, and incorporation of adjustability in wheelchair dimensions and the gas spring to customize the device for users of different heights and weights. Most users could operate the standing functionality in this design (D2) with ease once it was adjusted to their height and weight. A key learning during the trials of D2 was the need to provide mobility outdoors to enable users to undertake economic activities and be more independent. Based on this learning, the base of the new design (D3) was made longer with three wheels, thereby making the wheelchair stable even in outdoor use on uneven terrain. Further, the mechanical complexity was reduced and industrial design inputs have addressed the ergonomics, user interface aspects, and aesthetics of the design. When D3 was tested with wheelchair users in rural areas, they could use the standing functionality with ease and propel the wheelchair comfortably on rough terrain.

RESULTS AND DISCUSSION

Figure 1: Evolution of the design of the standing wheelchair: D1, D2, and D3.

The standing wheelchair design has evolved considerably through three design iterations (Figure 1). The last two designs have been tested by over 50 people with spinal cord injury. Most users found the wheelchair safe and easy to operate. During the trials, we learnt that providing outdoor mobility is an important enabler to wheelchair users.

CONCLUSIONS

A novel design of a standing wheelchair that minimizes user effort and accommodates a wide range of user body heights and weights has been designed. The design has been refined over the past two years with extensive inputs from users and clinicians. The design is simple, easy to operate, customizable, and is being received well by almost all users. Currently, the commercialization partner is working on DFM and other pre-production aspects.

ACKNOWLEDGEMENTS

We acknowledge the generous funding support from the Wellcome Trust, UK, which has enabled the rigorous development and user-testing. We thank the Association of People with Disability, Bangalore, and Christian Medical College, Vellore for their involvement in the user trials. We gratefully acknowledge the inputs and contacts provided by the Spinal Foundation, a self-help group for persons with Spinal Cord Injury.

LOCATIONS OF THE MAXIMUM RESIDUAL LIMB/SOCKET INTERFACE PRESSURES DURING WALKING

INTRODUCTION

The Pressure Cast (PCAST) technique has been developed to reduce skill reliance in transtibial socket manufacture [1]. The PCAST socket is a total surface bearing socket manufactured using a hydrocast technique, which has been successfully used by people with transtibial amputations over extended usage periods [1]. However the sites of high pressure and loading within the socket remain unknown. Interface pressure measurements for hydrocast sockets have been previously reported in the literature, with examples shown and referenced in [2]. These data however have largely been generated through gross averaging over large regions, or are the isolated values of discrete load cells. Hence, the exact sites and magnitudes of maximum pressures within the socket are unknown. This study used a novel analysis technique to identify the sites and magnitudes of high pressure areas at the residual limb-socket interface in PCAST sockets during walking.

METHODS

Thirteen volunteer participants with unilateral transtibial amputations were cast and fitted with unrectified PCAST sockets with cotton socks the only soft interface at the socket wall. All participants then completed a usage period of 5 months and were regular users of, and satisfied with, the PCAST socket. The pressure data was collected using a calibrated pressure measurement system (Tekscan Inc., USA) with a sensor array of 96 sensels sampling at 200 Hz. Sensors recorded pressure on the anterior, posterior, medial and lateral aspects of the limb whilst the participants completed 7 walks at self-elected speed, of which data from 15 consistent gait cycles was extracted. For each sample frame, the magnitude and site of the maximum pressure for each limb aspect was recorded. The anatomical point of interest for each limb aspect (namely, the medial tibial flare, anterior distal kick point, fibula head and popliteal fossa) was set as the origin and maximum pressure sites were displayed relative to this point. High pressures were considered as those in the upper quartile of measured values for each limb aspect. In order to visualise the concentration of the high pressure sites, the distribution was analysed over three confidence intervals: 95%, 75% and 50%, as determined by the covariance of the points.

RESULTS AND DISCUSSION

Figure 1 shows the locations and magnitudes of each maximum pressure point recorded for each frame of 15 gait cycles for all participants. On the medial and lateral aspects, the distribution of maximum pressure points are centred around the apices of the medial tibial flare and the fibula head with higher pressures on the lateral aspect. The anterior aspect was characterised by a longitudinally spanning distribution, along the midline of the sensor correlating to the bony tibial crest of the residual limb. The peak pressure recorded over all trials occurred along this midline. Posteriorly, the maximum pressures are more sparsely distributed and are the lowest of the aspects, with the centre of the distribution translated distally from the popliteal fossa. The anterior and lateral aspects recorded the highest peak pressures. The distal tibia and fibula head are traditionally recognised as less load tolerant regions of a residual limb, however this study found the greatest interface pressures during walking are experienced in these regions. Given the high satisfaction of the participants after an extended usage period, as determined using the Satisfaction with Prosthesis survey, it is suggested that this pressure distribution is acceptable for these participants, of whom only one had vascular comorbidities. The use of the PCAST socket, however, may not generally be appropriate for users with vascular or peripheral neuropathy complications. Future analysis will track the sites of the high pressure regions for each stage of the gait cycle and explore any correlations with user satisfaction.

CONCLUSIONS

The residual limb/socket interface pressures at anterior, medial, lateral and posterior aspects of the residual limb show that a uniform pressure over the limb-socket interface does not exist when using a PCAST socket. Consistent regions of high pressure were seen at the bony prominences of the fibula head and tibial crest suggesting the socket may not be appropriate for all users.

EFFECTS OF SLOPED WALKING WITH A POWERED ANKLE-FOOT PROSTHESIS ON INDIVIDUAL LEG WORK

[1] **Jana R. Jeffers** and [1,2]Alena M. Grabowski
[1]University of Colorado Boulder
[2]Department of Veterans Affairs Eastern Colorado Healthcare System

Corresponding author email: jana.jeffers@colorado.edu

INTRODUCTION

People with a leg amputation are typically prescribed a passive-elastic prosthesis; however, these devices are only capable of 1/2 the mechanical work of a biological ankle during level-ground walking [1]. Use of powered ankle-foot prostheses has resulted in normalized preferred walking speed, metabolic cost and biomechanics – specifically step-to-step transition work, and unaffected limb knee adduction moment – during walking on level-ground over a range of speeds [2]. However, the biomechanical effects of using a powered prosthesis for sloped walking remain unclear.

Thus, we sought to determine the effects of using a powered ankle-foot prosthesis on individual leg work during uphill and downhill walking. We hypothesized that affected leg positive work would increase and unaffected leg negative work would decrease with use of a powered compared to passive-elastic prosthesis and that individual leg work would be the same as that of non-amputees.

METHODS

Ten healthy adults with a unilateral transtibial amputation (6M, 4F, age 42±11yrs) participated and provided informed consent according to the US Department of Veterans Affairs institutional review board. After a certified prosthetist from BionX Medical Technologies aligned and tuned the powered prosthesis (BiOM T2) to each subject, we placed reflective markers on subjects' lower limb anatomical landmarks. We iteratively tuned the BiOM using a tablet provided by the manufacturer at each slope until prosthetic ankle range of motion, peak moment, peak power, and net work were nearly equivalent to the unaffected leg values and matched non-amputee averages within one standard deviation [3]. Subjects then walked 1.25 m/s on a dual-belt force-measuring treadmill (Bertec, Columbus, OH, USA) for at least 45 seconds on slopes of 0°, ±3°, ±6°, and ±9° while we measured full body kinematics at 100 Hz, and ground reaction forces at 1000 Hz.

We calculated individual leg work over an entire stride using the individual limbs method [4]. We calculated average data from 10 strides with a custom script (Matlab, Mathworks, Natick, MA, USA). Ground reaction forces were filtered using a fourth order recursive Butterworth filter with a 30 Hz cutoff and kinematic data were filtered using a sixth order recursive Butterworth filter with a 7 Hz cutoff.

We used repeated measures ANOVAs with prosthetic foot as the independent variable and individual leg work as the dependent variable with a significance level of 0.05. We compared individual leg work from subjects with an amputation (SWA) to non-amputee data with t-tests and a Bonferroni-corrected level of significance.

RESULTS AND DISCUSSION

There was no significant effect of prosthetic foot type on individual leg positive work (Fig 1A) or individual leg negative work except at -3° ($p=0.04$, Fig 1B). There were significant differences between SWA individual leg positive work and non-amputees (Fig 1A). At -9° and 0°, SWA using the powered prosthesis had significantly lower ($p<0.01$) affected leg positive work than non-amputees (Fig 1A). At -3° and +9°, SWA using a passive prosthesis had to generate significantly more ($p<0.01$) unaffected leg positive work than non-amputees (Fig 1A). At -9° and -3°, SWA using a passive prosthesis had to absorb significantly more ($p<0.01$) unaffected leg negative work than non-amputees (Fig 1B).

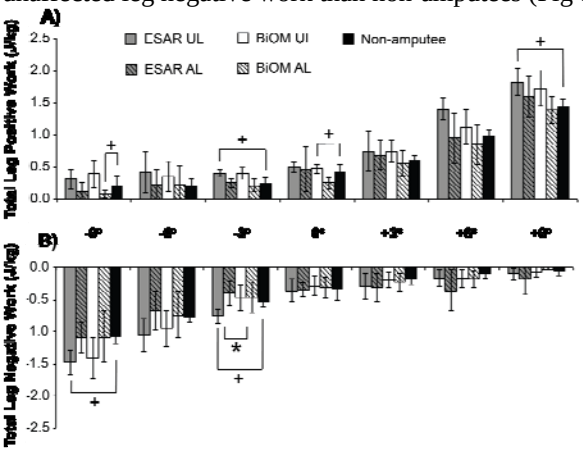

Figure 1: Average (SD) individual leg A) positive and B) negative work (J/kg) performed and absorbed by the unaffected (solid) and affected leg (hashed) of subjects using passive (gray) and powered (white) prostheses. Non-amputee data from [3]. *indicates a significant difference between prostheses. [+]indicates a significant difference from non-amputees.

CONCLUSIONS

Use of a powered ankle-foot prosthesis significantly reduced the magnitude of unaffected leg negative work at -3°, and normalized unaffected limb positive work at -3° and +9°, indicating that generating prosthetic ankle power may improve sloped walking biomechanics on specific slopes.

INTRODUCTION

The purpose of this ongoing study is to isolate the effects of the metatarsophalangeal (MTP) and ankle joint stiffness, and their interplay, on walking biomechanics. The effects of ankle stiffness (in prostheses) and quasi-stiffness (in the biological limb) have been documented in prior literature; however, the effects of MTP joint stiffness - hereafter referred to as toe joint stiffness - are less well characterized. The toe joint undergoes a dorsiflexion range-of-motion in late stance (sometimes referred to as the forefoot rocker phase) comparable to ankle range-of-motion during walking [1]. Walking models also predict that toe joint articulation may improve mechanical cost of transport [2]. However, limited experimental data exist on the effects of toe joint stiffness, or its interaction with ankle stiffness, since toe joint stiffness cannot be easily varied within the biological foot or in commercial prostheses. Here we custom-designed and tested an adjustable prosthetic foot to isolate toe joint, and ankle-toe stiffness effects. This research is expected to provide insight on the functional benefits of toe joint articulation, and may inform optimal toe joint properties to incorporate into prosthetic foot design.

METHODS

We designed and fabricated a (right and left) pair of adjustable foot prostheses with a sagittal rotational degree-of-freedom to approximate the ankle, and a single rotational degree-of-freedom to approximate the composite toe (MTP) joint axes in the biological foot. This design allows us to independently adjust ankle and toe joint stiffness, and other parameters such as toe length and shape.

Four healthy, non-amputee subjects (2 males, 2 females, 22±3 yrs, 74.8±5.3 kg, 1.76±0.07 m) have thus far participated and provided informed consent for this gait analysis study. Subjects wore the foot prostheses bilaterally below simulator boots (which immobilize the biological ankles). Subjects walked at 1.0 m/s on a split-belt, instrumented treadmill while we recorded ground reaction forces (GRFs) and lower-limb kinematics. Each subject walked with 20 different ankle and toe joint stiffness combinations, which spanned above and below normal ranges [3]. Ankle joint stiffness was varied from 40 to 200 N·mm/deg·kg. Toe joint stiffness was varied from 0 to 10 N·mm/deg·kg, and we also tested an infinitely stiff (locked joint) condition. GRFs were used to compute center-of-mass (COM) power through the individual limbs method [4]. COM Push-off work was computed as one key outcome metric, based on prior literature (e.g., [4, 5]).

RESULTS AND DISCUSSION

Preliminary findings suggest that both toe and ankle joint stiffness affect COM Push-off dynamics, and that the effect of toe joint stiffness is more pronounced with stiffer ankles. We observed that COM Push-off work increased with toe joint stiffness. Given a constant toe joint stiffness, a medium ankle stiffness (100-160 N·mm/deg·kg) resulted in the highest COM Push-off work. Additionally, the effects of toe joint stiffness were larger as ankle stiffness increased, as evidenced by the larger range of COM Push-off work: 4 J at the lowest ankle stiffness vs. 7 J at the highest ankle stiffness (Figure 1).

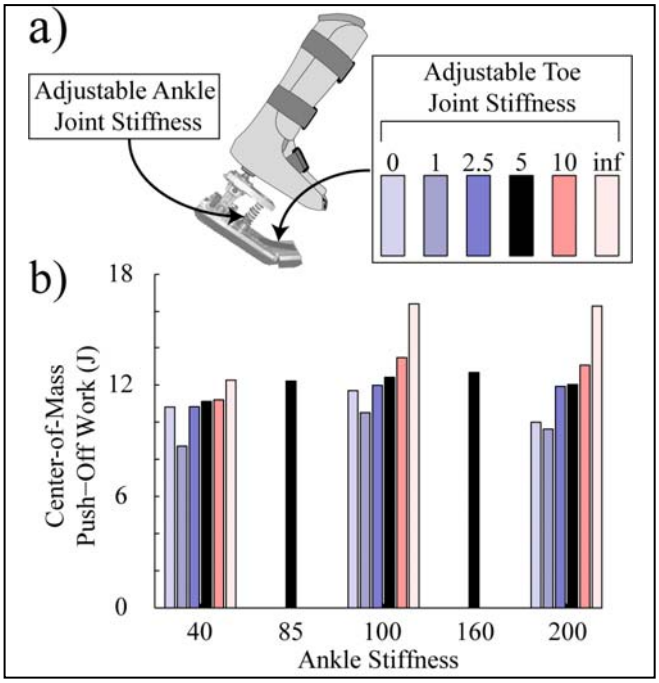

Figure 1: a) Adjustable foot prosthesis, and b) center-of-mass (COM) Push-off work during walking at 1.0 m/s for different ankle and toe joint stiffnesses (N=4). All stiffness values are reported in units of N·mm/deg·kg.

In this ongoing study, we also plan to examine ground reaction forces, joint kinematics and kinetics, and metabolic cost. Statistical analysis will be performed after additional subjects are collected. Other foot parameters such as toe shape, toe length, and foot length will also be varied. Results from this work will be used to inform a follow-up study on individuals with transtibial amputation.

CONCLUSIONS

Toe joint stiffness affects Push-off dynamics in gait, and the magnitude of this effect increases with ankle stiffness.

EVALUATION OF MOTION ASSIST FOR STAND-UP AND SIT-DOWN POSTURAL TRANSITION BY PERSONAL STANDING MOBILITY QOLO IN HEALTHY SUBJECTS

[1] **Hideki Kadone**, [2]Yukiyo Shimizu, [1]Wietske Scholtens, [1]Shigeki Kubota, [2]Tomoyuki Ueno, [1]Yasushi Hada, [1]Kenji Suzuki and [1]Masashi Yamazaki

INTRODUCTION

Qolo [1] is a personal mobility vehicle which assists sit-to-stand and stand-to-sit postural transitions as well as navigation in standing posture for those with motor disability in the lower limbs. Qolo has two characteristics. First, its mechanism to assist the postural transition is composed of passive gas-springs and a rigid link structure without electric actuators or controllers, contributing to keep it small, lightweight and low-cost. Second, it assists the postural transition in total coherence with natural postural transition movement in humans.

Natural postural transition motion from sitting to standing starts by bending the trunk forward and therefore moving the center of mass forward to move it into the support area above the feet as well as to reduce the necessary moment around the knee joint during the stand-up motion. Qolo's passive springs are configured so that the extending moment around the knee joint applied by the springs are smaller than the flexing moment applied by the upper body when the trunk is upright, but at the same time greater than that when the trunk is bended forward. By this mechanical configuration of moment equilibrium, Qolo can naturally assist the sit-to-stand postural transition exploiting the natural control of the moment around knee joint loaded by the upper body. A mechanical relationship vice-versa is considered for stand-to-sit postural transition.

In this study, to evaluate the motion assist by Qolo for sit-to-stand and stand-to-sit postural transitions, we conducted experiments with healthy subjects to compare the necessary muscle activity in postural transitions with and without Qolo.

METHODS

Eight healthy subjects (mean (SD): age 29.1 (5.5) y, height 174.5 (6.5) cm, weight 65.1 (7.3) kg) participated in the experiments. The participants performed sit-to-stand and stand-to-sit postural transitions three times with using Qolo (Figure 1) and then without using Qolo. During the experiments, the participants were equipped with wireless EMG sensors (Delsys Trigno Lab) on the bilateral extensor muscles; quadriceps for knee extension, gluteus maximus for hip extension, erector spinae for trunk extension. Markers of a motion capture system (VICON MX) were attached on the ankle, knee, hip and shoulder joint centers to record sagittal motion in synchronization with the EMG, in order to detect the start and end of the transition motions later in the EMG data processing. EMG data were band-pass filtered, rectified and evaluated according to maximum value of local integration by a moving window of 100ms width.

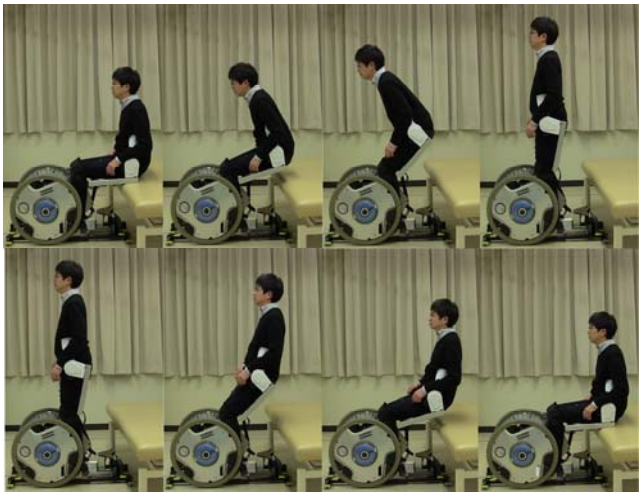

Figure 1: Sit-to-Stand (above) and Stand-to-Sit (below) postural transition assisted by Qolo. In our experiments, we asked healthy participants to perform the transitions with and without using Qolo to evaluate the effect of the device by the activity of extensor muscles.

RESULTS AND DISCUSSION

In postural transitions using Qolo in comparison with those without using Qolo, maximum activation of quadriceps, gluteus maximus and erector spinae were respectively smaller by 74% ($p<0.01$), 48% ($p<0.01$) and -4%($p>0.1$) in sit-to-stand transition and 53% ($p<0.05$), 30% ($p<0.01$) and 23% ($p>0.05$) in stand-to-sit transition. Significant reduction in the knee and hip extensor muscles during postural transitions using Qolo was observed. With the assist of Qolo, the healthy participants could perform the postural transitions with significantly reduced usage of the lower limb extensor muscles, indicating the possibility that patients with significant reduction in the lower limb muscle control might be able to perform the postural transitions using the device. On the other hand, the trunk extensor muscle did not show significant difference, which is reasonable since the device leaves motion of the upper body free.

CONCLUSIONS

We evaluated the effect of Qolo in assisting sit-to-stand and stand-to-sit postural transitions in healthy subjects. Using the device, the postural transitions were possible with significantly reduced usage of the lower limb extensor muscles. It indicates the possibility that patients with significant reduction of lower limb muscle control might be able to perform the postural transitions using Qolo.

HOW TO FACE THE FUTURE

Mike Seymour
Sydney University

mikesfxguide@gmail.com

How effectively can we produce an interactive photorealistic human face? What will it take to make this viable as a new form of Human Computer Interfaces (CHI)?

Can we deploy the latest cinema and game technology to make realistic digital companions and embodied conversational agents? For some time, the entertainment industry has been sampling, simulating and replicating human faces with increasing accuracy allowing for greater emotional fidelity and general realism. This research spans complex skin simulation, facial expression decomposition, complex muscle, eye and hair replication coupled with extremely high speed computing.

This work has a special relevance for aged care and in related medical applications such as stroke victims, and those with memory issues or mental impairment. It also has deep implications for education, information dissemination, people with disabilities and their relationship with the evolving area of embodied cognition. We need to find new ways to provide interaction for people in ways other than just typing, and with a metaphor other than that of the 'desktop'. Face to Face communication is central to human experience and for many sections of the population, a digital face may prove a much better metaphor for computer human interaction than just folders and files.

Unfortunately, due to a theory known as the Uncanny Valley, unless we can produce extremely accurate actors, agents and avatars, we know that the user audience will reject them. We seek to offer a startling glimpse into the future, by highlighting the very latest technology from a complex new international research effort, which aims to not only produce believable faces, but allow them to interact with you, in real-time.

So how do you make the world a better face?

CELL MECHANICS APPROACHES TO LIQUID BIOPSY & PRECISION MEDICINE: FROM BENCH TO BEDSIDE

Chwee Teck Lim PhD
Department of Biomedical Engineering Mechanobiology Institute National University of Singapore

Email : ctlim@nus.edu.sg

There are approximately 5 billion cells in one milliliter of blood with red blood cells accounting for >99% of all cellular components. Besides blood constituents, pathogenic microorganisms or diseased cells such circulating cancer cells can also be present in peripheral blood. In fact, this is of clinical significance as their presence in blood can present possible routes for disease detection and diagnosis. Here, we address these issues and demonstrate that cell mechanics related biomarkers such as cell size and deformability can be effectively used for diseased cell detection for diagnosis from blood using microfluidics by leveraging on its many inherent advantages such as high sensitivity and spatial resolution, short processing time and low device cost. We will present examples of diagnosis of cancer via the detection and retrieval of circulating tumor cells from peripheral blood of patients via a routine blood draw (aka liquid biopsy). These simple, efficient and cost effective approaches will be imperative in realizing diagnostics as well as the enrichment of clinical samples for subsequent downstream molecular analyses. Currently, our technology has been commercialized and being used in Australia, USA, Europe and Asia.

PROSPECTIVE EVIDENCE OF ALTERED FRONTAL PLANE KNEE PROJECTION ANGLE AND Y- BALANCE TEST IN MILITARY RECRUITS WITH PATELLOFEMORAL PAIN

INTRODUCTION

Patellofemoral pain (PFP) is a common knee injury and accounts for up to 43% of injuries military recruit suffer from [1]. Altered knee alignment seems to contribute to the occurrence of PFP [2]. Knee valgus is associated with increased quadriceps angle, increasing the lateral force acting on the patella [2]. Two-dimensional frontal plane knee projection angle (FPKPA) has been successfully used to assess dynamic knee alignment during weight-bearing activities in patients with PFP.

Excessive knee valgus could be the influenced by deficits in lower limb neuromuscular control, balance, and proprioception. The Y Balance Test (YBT) is a functional test that assesses performance during single-leg balance with reaching task in anterior (ANT), posteromedial (PM), and posterolateral (PL) directions to determine lower extremity movement asymmetry and balance deficits [3].

With the current emphasis on injury prevention, prospective studies of the underlying mechanics that result in PFP are imperative. Thus, the purpose of this study was to assess the FPKPA and YBT of male recruits who go on to develop PFP after a 6-week basic military training compared to a healthy control group who did not develop any injuries.

METHODS

One-hundred and thirty-five male military recruits, 18-20 yr volunteered to participate in the current study. Athletes were excluded if a current injury limited the participant's ability to participate in testing.

The FPKPA of the athletes was assessed during single-leg squatting. A digital camcorder (HC-V160 Panasonic Corporation, Japan) was positioned parallel to the ground and placed perpendicular to the frontal plane of the participant. Reflective markers were attached to the anterior superior iliac spines, the medial and lateral epicondyles of the knee, and the midpoint between the medial and lateral malleoli. The subjects were asked to perform a 3 single-leg squats to 60° of flexion of the knee. To determine the FPKPA, the single-leg squats were analyzed using the software MAXTRAQ 2D (Innovation Systems, USA). The FPKPA was defined by connecting the markers related to the anterior superior iliac spines, the midpoint between the femoral epicondyles, and the midpoint between the malleoli.

The lower quarter version of the YBT (YBT-LQ) was performed barefoot. The YBT Kit (Perform Better, USA) was used. The subjects were allowed to have six practice trials on each leg prior to formal testing. While maintaining single leg stance in the center of the platform, the subject was instructed to reach with the free limb in the ANT direction for three trials, followed by three trials in PM direction and then three trials in PL direction, all named in relation to the stance foot. The maximal reach distance was recorded at the most distal point. Asymmetry was calculated by the absolute difference in centimeters between right and left leg reach distance in ANT, PM, and PL [3]. Following the biomechanics data collection, a detailed injury history was recorded. For the next 6-week, participants reported any injuries. Only injuries reported as PFP that were clinically diagnosed by a physician or physical therapist were included in the analysis. Independent t-test was used. The alpha test was set at 0.05.

RESULTS AND DISCUSSION

Of the 135 recruits followed, 14 (10.4%) were diagnosed with PFP and included in the data analysis. The PFP group and control group were equally matched for age, body mass and height ($P > 0.05$) The FPKPA and YBT results are presented in Table 1.

Table 1- FPKPA and YBT ANT, PM, and PL reach asymmetry for PFP and Control groups.

	PFP group	**Control group**
FPKPA (deg)	-3.64 (5.87)*	0.28 (8.81)
ANT asymmetry (cm)	3.02 (2.33)	2.45 (1.94)
PM asymmetry (cm)	5.01 (3.66)	4.44 (3.66)
PL asymmetry (cm)	4.21 (2.87)*	1.59 (2.33)

* $P < 0.05$

Our results corroborates with previous study that showed that female runners who developed PFP showed greater hip adduction [2]. However, we used a 2D analysis to evaluate knee valgus, which is more accessible when screening larger populations. Also, YBT asymmetry has been shown to predict lower limb injuries [3] and we identify that PL asymmetry is greater in those males who develop PFP.

CONCLUSIONS

The results from this study provide prospective evidence of increased knee valgus and asymmetry in the posterolateral direction in the YBT in recruits who go on to develop PFP. These results suggest that injury prevention programs should address lower limb alignment, neuromuscular control and balance to prevent PFP.

CHANGES IN PATELLOFEMORAL JOINT MECHANICS IN THE PRESENCE OF QUADRICEPS MUSCLE IMBALANCE

INTRODUCTION

Patellofemoral pain (PFP), defined as anterior knee pain, is one of the most common chronic diseases of the knee joint [1, 2]. Despite its prevalence, debate as to the etiology of PFP continues [1]. One generally accepted hypothesis is that the imbalance of muscle strength within the quadriceps group may result in mechanical changes in the knee joint that cause PFP. However, there is no direct scientific evidence linking the imbalance of muscle strength to PFP. In addition, a recent study in a rabbit model showed that a partial imbalance caused by weakness of the vastus medialis (VM) did not affect patellofemoral joint pressure [3].

However, in order to study the relationship between quadriceps muscle imbalance and patellofemoral joint pressures systematically, the forces of the individual quadriceps muscles must be controlled independently. Therefore, the purpose of this study was to investigate changes in patellofemoral joint (PFJ) contact distribution when stimulating the different muscles of the quadriceps group to various degrees to simulate systematic muscle weakness experimentally. Based on previous research [3], we hypothesized that patellofemoral joint pressures will not be affected by strength imbalances of the quadriceps muscle group.

METHODS

All experiments were performed on skeletally mature New Zealand white rabbits (n=5). The force in each muscle could be controlled individually by electrical stimulation of the individual nerves of the quadriceps muscles using home-built cuff-type electrodes that were implanted surgically [4]: vastus lateralis (VL), VM, and rectus femoris (RF, vastus intermedius stimulation was combined with RF). Patellofemoral pressure distributions and muscle forces were measured while stimulating the entire quadriceps muscle group simultaneously, stimulating each muscle individually, or stimulating two or three muscles using all possible combinations, producing the same quadriceps forces with different contributions of the individual muscles. All experimental procedures were approved by the Animal Ethics Review Committee of the University of Calgary.

Rabbit knees were held in place by bone pins inserted into the pelvis and femur. A tibial restraining bar was used to hold the knee joint at the target angle and measure the resultant knee extensor force. PFJ pressure distribution was measured by inserting Fuji pressure sensitive films into the patellofemoral joint [3]. Using films of different sensitivity, the joint contact areas, peak pressures, contact area shapes, and average pressures could be calculated using a custom-written analysis program (Matlab).

Patellofemoral joint contact distributions were then compared for corresponding knee angles and knee extensor forces (±5%), but different combinations of individual muscle forces.

RESULTS AND DISCUSSION

Joint contact areas, peak pressures, and average pressures increased with increasing knee extensor muscle forces.

Pressure distributions in force-matched trials varied considerably (Table 1). Typically, average pressures were smaller when all muscles were stimulated simultaneously compared to when only selected muscles were used to produce knee extension.

	ALL	VL+VM	VL+RF	VM+RF
AP[MPa]	7.3	10.6	11.5	9.3
CA[mm^2]	5.0	6.6	7.1	6.6
Contact shape				

Table 1. Representative results from one animal. For the contact pressure distributions, left and right side of the images correspond to the lateral and medial side of the knee, while up and down in the images correspond to proximal and distal, respectively. (AP: average pressure, CA: contact area)

Contact areas and pressure distributions seemed most affected by the loss of VM (VL+RF condition) when compared to stimulating all muscles of the quadriceps group simultaneously, showing the opposite to the results found previously that VM weakness does not affect patellofemoral joint contact distribution to a significant degree [3].

CONCLUSIONS

Patellofemoral joint contact distribution depends greatly on the combination of muscle forces contributing to the resultant knee extensor force. VM weakness appears to affect PFJ contact pressure distribution the most.

EFFECT OF ARTICULAR GEOMETRY ON PATELLOFEMORAL JOINT FUNCTION

INTRODUCTION

The articular geometry of the patellofemoral joint varies widely among people and changes in geometry are thought to affect joint function. Most studies on the shape-function relationship have used 2D measures [1], which are subjective and do not adequately characterize complex 3D geometries. Furthermore, previous work has largely been observational with confounding variables, such as muscle property differences, obscuring the effect of geometry on joint function. Statistical shape modelling offers an objective framework to characterize geometry using modes of variation in shape. Our objective was to directly examine the effect of variations in articular geometry on the contact mechanics of the patellofemoral joint during gait.

METHODS

MR images were segmented for the right knee of 14 healthy participants (6F, 24.1±4.4 years, 74.8±10.6 kg) to create surface models for the femur, tibia, and patella bone and cartilage. Meshes were aligned in their automatically generated anatomical coordinate systems [2] and node correspondence was established [3]. Principal component (PC) analysis was applied to create a statistical shape model that captured variation in whole joint geometry, but not alignment. New knee models were then created based on ±1, 2, and 3 standard deviations of the PC scores for the first six modes of variation. Each new geometry was used to create a multibody knee model that included six degrees of freedom patellofemoral and tibiofemoral joints and 14 ligaments represented by bundles of nonlinear elastic springs [4].

These knee models were then integrated into a lower extremity musculoskeletal model which used an elastic foundation model to calculate cartilage contact pressure. Dynamic simulations were performed for each new knee model using the same inverse kinematics from a healthy 23 year old female walking overground. For the knee, the measured flexion angle was tracked while the COMAK simulation routine [4] was used to concurrently predict the patellofemoral and remaining tibiofemoral degrees of freedom, muscle and ligament forces, and cartilage contact pressures. The effect of the geometrical variations on the resulting kinematics, ligament forces, and cartilage contact pressure patterns was then examined during initial stance.

RESULTS AND DISCUSSION

The first six modes of variation, which explained 70% of the variation in geometry, were examined. Each had specific effects on joint function. Mode 2, which captured changes in the lateral trochlear inclination (increase of 9° from -3 to +3 SD) and trochlear groove depth of the femur, substantially affected contact pressure patterns (Fig 1). The maximum pressure was greater for low scores for this mode, which corresponds to a shallower trochlear groove (30% decrease in max pressure from -3 to +3 SD). The contact pressure distribution also changed with this geometrical feature; the pressure was concentrated on the lateral border of the patellofemoral joint for a shallower groove and more distributed between medial and lateral sides for a deeper groove. Additionally, at the instant of peak patellofemoral force, more force was required in the medial patellofemoral ligament to prevent lateral translation of the patella for the shallower than for the deeper trochlear groove.

Increased lateral cartilage stress has been proposed as a mechanism for patellofemoral pain (PFP) and those with PFP often have shallow trochlear grooves. While the shape model was constructed from asymptomatic participants, the observed effects may provide insight into this mechanism.

CONCLUSIONS

Subtle differences in articular geometry resulted in altered patellofemoral joint function during gait. This highlights the importance of subject-specific geometries when modelling knee joint contact and statistical shape modelling may provide a method for rapidly generating subject-specific geometries using a morphable knee model. Additionally, this type of modelling may be useful in studying the role of morphology in pathologies such as patellofemoral pain.

REGIONAL MODULATION OF VASTI MUSCLE ACTIVITY IN RESPONSE TO ACUTE PAIN PERSISTS AFRER PAIN RESOLUTION

INTRODUCTION

Current pain-adaptation theories propose changes in motor strategies as a purposeful adaptation to reduce the stress on painful tissues [1]. As regions within the quadriceps muscle have potential to produce forces in different directions [2], changes in muscle activation may occur non-uniformly and depend on the location of the noxious stimulation.

The objective of this study was to investigate regional redistribution of EMG activation within the vasti muscles in response to noxious stimulation applied to different locations in muscular and non-muscular tissues around the knee. The persistence of altered motor strategies after pain resolution was also investigated.

METHODS

Fourteen participants performed an isometric knee extension task consisting of 5 contraction at 10% of the maximal voluntary contraction performed at baseline, during pain induced by a single bolus injection of hypertonic saline solution in four locations (FP: medial infrapatellar pad; VMD: distal vastus medialis [VM]; VMP: proximal VM; VL: vastus lateralis) and after pain recovery. Contractions were performed when the participants reported a pain level of at least 3/10 and again when pain recovered to 0/10. Surface EMG signals from VM and VL were collected using high-density surface EMG (electrode grids of 13x5 electrodes spaced 8mm), placed across each muscle [3]. The distribution of muscle activation was calculated as the average rectified value (ARV; 13x5 values for each muscle) of each channel of the grid during the hold phase of the ramp. For each condition, muscle activation was calculated as the average of the 5 highest channels of each grid. To characterize spatial variations of the EMG distribution in the pain and after-pain conditions, normalized change scores (NCS) relative to baseline were calculated as 100*(TRIAL-BAS)/BAS, where TRIAL is the ARV distribution during the pain or after-pain condition and BAS is the ARV distribution at baseline (Fig.1). The barycenter of the 5 channels with the lowest NCS was calculated and considered representative of localized inhibition. Friedman and paired Wilcoxon tests were run to test the effect of injection site on muscle activation, separately for VM/VL, during/after pain. Two-way ANOVAs were run to test the effect of location and pain condition on the position of the channels with lowest NCS for VM and VL separately; post-hoc testing was run by testing which conditions were significantly different from 7 (i.e.: the midpoint of the grid).

RESULTS AND DISCUSSION

VM muscle activation decreased by ~10% when VMD was injected (Friedman: P<0.05; Wilcoxon: P<0.01). No significant changes were observed when the other sites were injected or after pain. ANOVA identified a main effect of injection site on the location of the channels that showed large decrease of EMG activity in VM (P<0.05, Fig.1). Preferential inhibition of the distal region of VM was observed when VMD or VL were injected (both P<0.001), and after pain resolution (VMD: P<0.001, VLD and VMP: P<0.05). A main effect of pain/after-pain existed for VL (P<0.05). Preferential inhibition of distal VL was observed after resolution of pain when VL (P<0.001), VMP (P<0.01) and VMD (P<0.01) were injected. Spatial changes in the location of the activation within the vasti appear to persist after pain resolution.

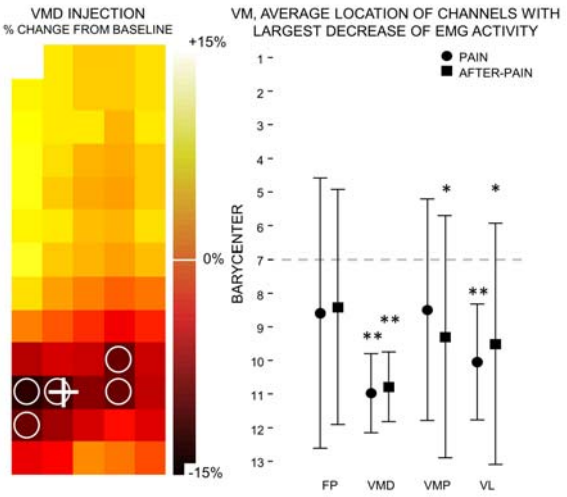

Figure 1: Left: normalized change scores map during VMD pain, channels with largest decrease in EMG activity (circles) and barycenter (cross). Right: Average location of the channels with largest EMG decrease in VM.

CONCLUSIONS

Modulation of vasti activation in response to acute muscle pain is non-uniform. Preferential inhibition of the distal VM can be observed during pain and after pain resolution. Preferential inhibition of the distal VL was observed after pain resolution only. This concurs with the hypothesis of specific reduction of tissue loading in the presence of a noxious stimulus, and implies that recovery of pain does not motivate recovery of motor strategy.

INTRODUCTION

Knee ligament injury is an increasingly problem in clinical orthopedics, due to the popularization of sports practices. There is still controversy among specialists about the choice of the graft source to be used in the reconstruction of the anterior cruciate ligament (ACL), either the patellar or the semitendinosus tendons [1]. The possibility to assess mechanical characteristics of the tendons preoperatively, *in vivo* and noninvasively, could be a significant advance for clinical decision.

The ultrasound elastographic technique based on the supersonic shear wave imaging (SSI) [2] has been applied in recent years to study the shear modulus (μ) of pathological and healthy patellar tendons [3]. However, for the semitendinosus tendon (ST), to date, no studies using SSI were found.

The aim of this study was to compare the shear modulus (μ) of the semitendinosus and patellar tendons using SSI elastography in two knee angles, 0 and 80 degrees of flexion.

METHODS

A group of 18 healthy male volunteers, (28.4 ± 2.2 years, 180.2 ± 8.1 cm, 88.4 ± 11.4 Kg) read and signed the free and informed consent (Research Ethics Committee of the University Hospital, nº. 1.674.064). The AIXPLORER V.9 (Supersonic Shearwave Imaging, Aix-en-Provence, France) was used with a linear transducer operating at a frequency of 4-15MHz, preset MSK tendon option, 0-800 kPa scale. The left knee was positioned at two angles in the sagittal plane, 0º (K0 full extension) and 80 degrees of flexion (K80). For the PT and ST (Figure 1) imaging acquisition, the subject laid supine and prone, respectively, and the transducer was positioned longitudinally to the direction of the tendon fibers. Elastographic images were collected after 10 s after stabilizing the color map. A second image was acquired for reliability calculation. Image processing was performed with a custom Matlab (MathWorks, Natick, MA, USA) routine, which reads the matrix data and calculated the mean and standard deviation (SD) values of the selected ROI. These values were divided by three to obtain the μ values as the data exported by the equipment referred to the Young modulus (E) approximation ($E \approx 3\ \mu$). Two indexes were calculated between tendons. A relaxed index, calculated as $IR=\mu_{ST\text{-}K80}/\mu_{TP\text{-}K0}$ and a tensioned one as $IT=\mu_{ST\text{-}K0}/\mu_{PT\text{-}K80}$, referring the positions where both tendons were relaxed and tensioned, respectively.

The intraclass correlation coefficient (ICC) was calculated between the consecutive two images, for each knee position and tendon, for measurements reliability assessment. The comparison between the IT and IR indexes was performed using the t-test for dependent measures. It was adopted a significance level of 5% ($p \leq 0.05$)

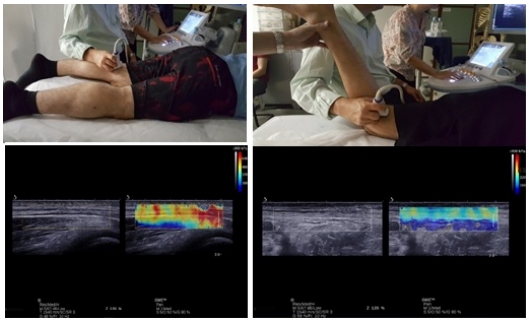

Figure 1: SSI image acquisition for ST tendon with the knee extended (K0) and flexed (K80).

RESULTS AND DISCUSSION

CCI ranged from 0.823 to 0.998. The average shear moduli for ST were $\mu_{ST\text{-}K0} = 197.62 \pm 31.93$ kPa and $\mu_{ST\text{-}K80} = 77.76 \pm 30.08$ kPa and for TP were $\mu_{TP\text{-}K0} = 23.45 \pm 5.89$ kPa and $\mu_{TP\text{-}K80} = 113.92 \pm 57.23$ kPa. The ST shear modulus were higher than the TP, for both knee angles, with a considerable variation among the subjects.

The relative shear modulus indexes were IR= 3.63 ± 1.50 and IT=2.00 ± 0.96 ($p < 0.05$). The proposed indexes showed that in the relaxed condition the ST shear modulus is approximately three and a half times greater than PT. This difference reduces approximately twofold when both were in some tensile state.

The so-called guide waves that are generated and can be summed to the shear waves in the the cable-like structures like tendons is a technical issue that has been addressed; a limitation that prevents the comparison of data among subjects. The indexes proposed in this study highlights the importance to work with relative or normalized data.

CONCLUSIONS

In this work, we presented a non-invasive and harmless evaluation of the semitendinosus and patellar tendons shear moduli (μ) with SSI elastography, proposing indexes that may be potentially useful for clinical analysis of the most used grafts in ACL reconstruction.

FEMOROACETABULAR IMPINGEMENT PATIENTS EXHIBIT ALTERED PEAK JOINT ANGLES DURING THE GAIT CYCLE

INTRODUCTION

Cam-type femoroacetabular impingement (FAI), which is characterized by an aspherical femoral head, is purported to be the most common form of hip pathoanatomy, and has been implicated as a major cause of hip osteoarthritis (OA) [1]. The aspherical femoral head is thought to induce aberrant joint kinematics, which in-turn lead to cartilage lesions and delamination of cartilage from subchondral bone at the junction between cartilage and the acetabular labrum. However, the evidence linking cam morphology with deleterious hip articulation is surprisingly contradictory.

The reason for the lack of consensus could arise from the methods used to measure hip joint kinematics. Previous studies of FAI patients used markers adhered to the skin surface to track bone motion and calculate kinematics. Our lab previously measured soft tissue artifact in the hip using high-speed dual fluoroscopy (DF) [3], an x-ray technique with accuracy and bias < 1 mm and < 1° [4]. We found that skin markers significantly underestimate range of motion and joint angles, with the largest errors in the transverse plane (mean ROM error 20° during hip rotations) [3].

Our long-term goals are to elucidate the pathomechanics of cam FAI and to quantify the ability of treatment to improve hip dysfunction. Toward this goal, the purpose of this study was to use high-speed DF to compare joint angles in cam FAI patients to young, asymptomatic adults during walking.

METHODS

Participants provided informed consent prior to participation in this Institutional Review Board approved study. FAI patients (N=6, 4 male, aged 28 (SD 7) years, BMI 24 (SD 2) kg/m^2) were diagnosed with FAI through a positive impingement clinical exam and alpha angle (>55°) by a board certified orthopaedic surgeon (SKA). FAI patients were compared to asymptomatic young adults with normal hip anatomy from our previous study (N=11, 6 male, aged 23 (SD 2) years, BMI 21 (SD 2) kg/m^2) [3].

All subjects were imaged with high-speed dual fluoroscopy (100 Hz) during a static standing trial and during level walking on a dual-belt treadmill at their self-selected speed [3]. Bony landmark positions over time were found using model-based tracking [5]. Body segment orientation and hip joint angles were calculated according to ISB recommendations [6]. Angles were time normalized to the gait cycle from foot contact to the next ipsilateral foot contact of the imaged hip. To account for variable subject anatomy, angles while walking were offset by their value during the static activity.

Range of motion and peak joint angles (maximum and minimum) of each group were compared using a two-sample t-test with significance set at P<0.05.

RESULTS AND DISCUSSION

Qualitatively, hip joint angles appeared similar between cam FAI patients and asymptomatic subjects during the time-normalized gait cycle (Figure 1). Range of motion did not differ between the groups in any of the three anatomical planes. Peak extension angle was smaller in cam FAI patients compared to asymptomatic subjects (mean minimum flexion -12.2° vs. -17.0°, respectively, P=0.04). Peak abduction trended toward significance for cam FAI patients relative to asymptomatic subjects (maximum abduction 5.4° vs. 2.6°, respectively, P=0.06).

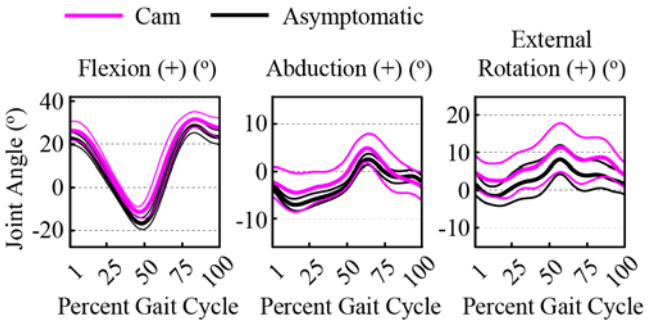

Figure 1: Joint angles over the time-normalized gait cycle. Data plotted as mean (thick lines) ± 95% CI (thin lines).

To our knowledge this is the first study to measure dynamic hip joint angles in FAI hips using high-speed DF. Altered peak joint angles for cam FAI patients relative to asymptomatic subjects are consistent with reflective skin marker studies; however, unlike previous studies we did not observe limitations in range of motion.

CONCLUSIONS

While qualitatively similar, cam FAI patients exhibited altered peak joint angles during walking relative to asymptomatic subjects. This suggests patients compensate, but it appears that reduced range of motion is not a defining characteristic of cam FAI. It will be necessary to confirm our findings in a larger sample size.

DEEP HIP MUSCLE ACTIVATION IS ALTERED DURING SQUATTING IN SYMPTOMATIC FEMOROACETABULAR IMPINGEMENT

INTRODUCTION

Femoroacetabular impingement (FAI), a structural abnormality of the hip joint, is a significant cause of hip pain and reduced function in younger active adults [1]. Evidence to support FAI as a principal determinant for the future development of hip osteoarthritis is mounting [2]. Yet, current treatments are suboptimal, likely in part due to the absence of experimental data regarding the physical impairments associated with symptomatic FAI. Hip muscle function in this condition has not been well defined. Initial evidence shows altered coordination of deep hip muscle activity in symptomatic FAI during walking [3], despite the generally pain-free nature of this task in FAI, as the hip joint does not move towards the impingement position (deep hip flexion, combined with hip adduction and internal rotation). Hip muscle activity during squatting, a task towards the impingement position, has not been investigated but may provide further insight into the neuromuscular adaptations of this patient population. This exploratory study aimed to investigate activation patterns of the hip muscles during a deep squat in individuals with and without symptomatic FAI.

METHODS

Fifteen individuals with symptomatic FAI (clinical examination and imaging) and 14 age- and sex-comparable controls without morphological FAI on magnetic resonance imaging underwent testing. Intramuscular fine-wire and surface electrodes recorded electromyographic (EMG) activity of selected deep and superficial hip muscles during the squatting task. The tri-phase squat included: (i) descent from a standing position to the end of self-chosen available range; (ii) a 3-second hold; and (iii) ascent to the upright standing position. Participants were instructed to use their preferred strategy to squat as deeply as possible at a self-selected controlled pace. Individual muscle EMG patterns were normalised to the mean of the peaks of 5 repetitions, and were statistically compared between groups using a wavelet-based linear mixed effects model based on the technique of wavelet functional ANOVA (wfANOVA) [4] ($p<0.05$).

RESULTS AND DISCUSSION

The FAI and control groups were comparable for age (25±5 vs. 27±5 yrs, respectively), sex (males: 73% vs. 71%), BMI (24.4±2.5 vs. 23.2±1.9 kg/m^2), and leg tested (dominant: 67% vs. 64%). Participants with FAI reported an average pain score of 2 on an 11-point numerical rating scale after completing the squatting task (range 0-8). There were no between-group differences in leg-length normalised squat depth ($p=0.12$) or ascent speed ($p=0.11$), however, descent speed was significantly slower in the FAI group ($p=0.05$).

During squat descent, FAI patients exhibited greater EMG activity of deep hip external rotator and extensor muscles (gluteus medius (GM), piriformis (PI, Figure 1), obturator internus (OI) and quadratus femoris (QF)) than controls. These muscles have mechanical actions that oppose impingement and are likely to have an active role in hip joint stabilization. Greater activation may relate to the slower decent speed of FAI patients, and/or be a strategy to stabilize the joint and reduce provocation as the hip approaches deep flexion and impingement.

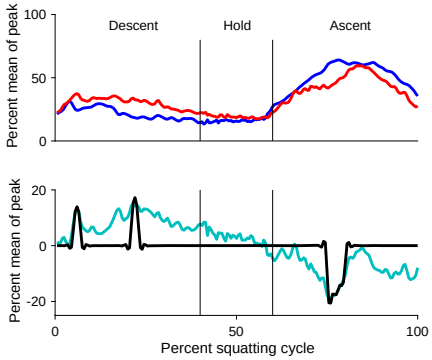

Figure 1 Ensemble average (± 1.96*SEM) EMG patterns from PI for control (blue) and FAI (red) participants over a squatting cycle (top). Average between-group difference (FAI-control; green), significant contrasts (black)(bottom).

During squat ascent, FAI patients exhibited lower EMG activity of deep hip external rotator and extensor muscles (GM, PI and OI) than controls. Gluteus maximus amplitude was also lower than controls during the initial 14% of ascent as FAI patients moved out of deep hip flexion. Lower activation of these agonists may relate to pain inhibition.

The different squatting strategies exhibited by FAI patients may be favorable for symptoms and function in the short-term. However, there could be long-term consequences if this leads to increased or abnormal joint loading.

CONCLUSIONS

Deep hip muscle activation is altered during squatting in symptomatic FAI. Future studies should examine patients prospectively and post-operatively to establish whether treatments targeted at these features would be potentially beneficial.

GLUTEAL TENDINOPATHY & HIP OSTEOARTHRITIS: DIFFERENT PATHOLOGIES, DIFFERENT HIP BIOMECHANCS

[1]**Kim Allison**, [1]Michelle Hall, [2]Paul Hodges, [1]Tim V. Wrigley, [2]Bill Vicenzino, [1]Yong-Hao Pua, [1]Ben Metcalf, [2]Alison Grimaldi and [1]Kim Bennell

INTRODUCTION

Gluteal tendinopathy (GT) is a recalcitrant cause of lateral hip pain most frequently experienced by individuals aged 40 – 70 years [1]. The condition is associated with high levels of pain and disability, which are comparable to those associated with hip osteoarthritis (OA) [1], a condition also experienced in this age group. Unlike hip OA, where evidence-based guidelines exist for exercise and gait retraining in conservative management, little evidence exists to guide management of GT. Common to both GT and hip OA are evidence of hip abductor weakness [2, 3] and altered walking biomechanics [2, 4]. Recently, a cross-sectional study identified no difference in walking speed or step length between those with hip OA and GT [5], indicating that hip pain rather than differences in pathology may drive dysfunction. While this appears to support using similar conservative management strategies in both GT and OA, it is imperative to better understand hip biomechanics in both conditions. This study aimed to compare the external hip adduction moment (HAM) and hip kinematics during walking in individuals with symptomatic unilateral GT and unilateral, symptomatic hip OA.

METHODS

Sixty individuals with unilateral, symptomatic, MRI-confirmed GT (14 males) and 69 individuals with unilateral, symptomatic hip OA (K-L Grade ≥ 2) (30 males) underwent three-dimensional gait analysis during barefoot walking. Using Vicon Nexus 1.8.5, kinematic and kinetic data were calculated, and moments normalized to body weight x height (BW.Ht(%)). The primary kinetic outcome was the external HAM, to reflect an internal abductor moment developed by the hip abductor muscles (implicated in GT pathology and known to be weak in hip OA and GT). The maximum HAM for each trial was determined for 0-50% (first peak) and 50-100% (second peak) of stance phase and minimum value between peaks (mid stance HAM). Values from the six trials were averaged. HAM values were compared between groups using an ANCOVA with walking speed as a covariate. Hip kinematic variables at the three HAM time points were similarly averaged and compared.

RESULTS AND DISCUSSION

The present study is, to our knowledge, the first to compare three-dimensional gait biomechanics between those with GT and hip OA. The OA group was significantly older (61 ± 8 vs 54 ± 9 years) and heavier (79.5 ± 5.6 vs 73.8 ± 13.4 kg). No differences were identified between groups in walking speed or step length ($p>0.05$), consistent with previous work [4]. Between-group differences were identified in all biomechanical variables (**Table 1**), with and without age, sex and weight included as covariates (based on between-group differences).

Table 1. Group biomechanical data, mean (SD).

	GT	Hip OA	*P* value
External hip adduction moment (HAM), Nm/BW.Ht(%)			
1st peak	5.7 (1.3)	4.6 (1.4)	**<0.001***
Mid stance HAM	3.5 (0.8)	3.0 (1.2)	**0.01***
2nd peak	5.0 (1.0)	4.0 (1.5)	**<0.001***
Hip adduction angle, degrees			
At 1st peak HAM	8.0 (4.2)	3.2 (5.3)	**<0.001***
At Mid stance HAM	5.6 (3.4)	2.0 (4.6)	**<0.001***
At 2nd peak HAM	4.7 (3.7)	1.4 (4.6)	**<0.001***
Hip flexion angle, degrees			
At 1st peak HAM	20.3 (6.6)	23.9 (8.7)	**0.02***
At Mid stance HAM	2.6 (6.6)	10.3 (8.8)	**<0.001***
2nd peak HAM	-9.0 (8.2)	3.4 (10.2)	**<0.001***
Hip internal rotation angle, degrees			
At 1st peak HAM	2.7 (7.4)	-3.0 (9.0)	**<0.001***
At Mid stance HAM	2.3 (7.0)	-1.3 (9.4)	**0.01***
At 2nd peak HAM	1.3 (6.9)	1.0 (8.2)	0.83

* $p<0.05$

Individuals with GT exhibited a 14-18% greater HAM throughout the stance phase of walking than those with hip OA. This is consistent with previous data that demonstrate a 9-33% greater HAM in those with GT than healthy controls [4]. This implies greater force-generating demand on the hip abductor muscles (and thus tendon loads) in GT, with direct potential relevance for GT pathology. Further, differences in implied hip abductor muscle loading suggest different mechanisms (and targets for treatment) may be associated with hip abductor weakness in those with hip OA and GT.

Between-group differences in hip kinematics in all planes were identified between groups, of 3.4 – 12.5 degrees. In particular, the hips of the GT group were more adducted, and the hip OA group more flexed, which is likely to be detectable with visual inspection by experienced clinicians in clinical practice. This suggests that different approaches to gait modification (frontal vs. sagittal plane) are likely to be indicated for individuals with GT and hip OA.

CONCLUSIONS

Hip kinematics and kinetics differ between individuals with unilateral, symptomatic GT and unilateral, symptomatic hip OA. This provides justification to test individualization of conservative treatments to disease-specific impairments.

ESTIMATING CARTILAGE STRESS DISTRIBUTION IN PATIENTS WITH FEMOROACETABULAR IMPINGEMENT USING SUBJECT-SPECIFIC FINITE ELEMENT MODELS

INTRODUCTION

Femoroacetabular impingement (FAI) is a growing health concern that affects 10-25% of the general population [5]. FAI is characterised by abnormal hip joint bone geometry that leads to mechanical impingement of the bones and soft tissues causing hip pain. FAI is also believed to be a leading cause for early osteoarthritis [6]. As such, it is vital to have a clear understanding about cartilage stress distribution in patients with FAI in order to develop an effective surgical technique that can correct this abnormality [8]. The aim of this study is to use subject-specific finite element (FE) models to analyze changes in cartilage stress distribution patterns in patients with FAI.

METHODS

A recent study by Anderson et al. demonstrated that subject-specific geometry is a crucial factor in the accuracy of FE analysis of cartilage contact stresses in the hip [1]. We have used MRI scans from two subjects who have FAI as well as one normal subject. Inclusion criteria for FAI subjects were 1) aged 18-35; 2) symptoms of hip pain; 3) radiographic evidence of FAI. Subject-specific FE models of these subjects were developed using a set of software tools developed for the Musculoskeletal Atlas Project (MAP), a Python based open source framework [10]. We used a generic template mesh generated from Visible Human Data, which was then customized to patients' MR scans using Free Form Deformation algorithm [3] available in the MAP Client. First, bone and cartilage surfaces were segmented from the MR image using the opens source software ITK-SNAP [9]. Then the template mesh was morphed to match the segmented points, generating subject-specific FE models of the acetabulum, proximal femur and acetabular and femoral cartilage layers.

FE analysis was performed using FEBio, an open source FE software tool [7]. Tied contact was used to describe bone-to-cartilage interface and cartilage-to-cartilage interface was modeled using sliding contact. We used a homogenous, isotropic nearly incompressible, neo-Hookean hyperelastic material with shear modulus G=13.6 MPa and bulk modulus K=1,359MPa (ν=0.495) [4]. Bones were treated as rigid bodies. Loading conditions were obtained from a previous study by Bergman et al [2]. We used the peak hip contact force during level walking, which was scaled according to the body mass. Maximum cartilage octahedral shear stress was measured and compared for the normal and FAI cases.

RESULTS AND DISCUSSION

The subject-specific FE models were generated with less then 1.1mm average RMS error between the model and segmented data points (Figure 1). The cartilage contact stress of the healthy subject was spread throughout the whole cartilage. However, FAI subjects showed stress concentrations, especially on the anterosuperior quadrant of the acetabular cartilage (Figure 2). The peak stress in the FAI patients was ~33.5% greater than the pain-free control subject. In these few patients geometrical abnormalities in FAI subjects appear to cause stress concentrations in the cartilage.,.

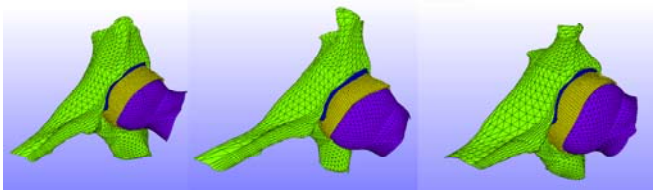

Figure 1: Subject-specific geometries of the left hip joint obtained from MAP-Client software (frontal view).

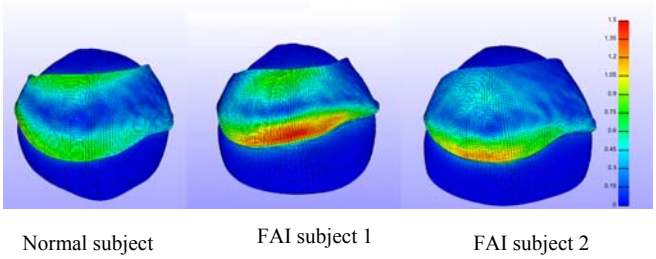

Figure 2: Subject-specific cartilage stress distribution of normal and FAI subjects (superior view)

CONCLUSIONS

We have presented results from subject-specific FE analysis of FAI patients and shown that cartilage stress distribution and peak stress magnitude of FAI patients differs to a normal healthy subject. These preliminary findings indicate the important role that bone geometry plays in the distribution of cartilage stress in FAI. Further analysis with more subjects is required to support these findings.

INTRODUCTION

Cerebral Palsy (CP) is a neuromusculoskeletal disorder associated with a non-progressive neurological insult. Paradoxically, the biomechanics of CP are often progressive, worsening with age. This observation has led researchers to focus on the musculoskeletal system as an avenue for understanding CP biomechanics. Among this research, we [1] have reported muscle volume deficits as a feature observed in CP, with soleus muscle often affected.
While volume deficits are an indirect indicator of strength impairment, an understanding of muscle architecture is necessary to connect structural deficits to functional impairments such as reduced strength, impaired gait, and fatigue in CP. The purpose of this study was to use diffusion tensor imaging (DTI) to investigate the muscle fibre architecture of the soleus muscles in adolescents with CP, focusing on pennation angle, fibre length, and physiological cross-sectional area (PCSA).

METHODS

Images were acquired from five CP subjects (2 female, 3 male, height 1.51±0.03m, mass 41.8±8.34kg, age 12.4±0.5y) from knee to ankle. Scanning was conducted on a 3T Siemens Skyra scanner using an echo planar imaging DTI sequence (slice thickness: 5mm, resolution: 1.64×1.64 mm, TE: 74ms, TR: 4400ms, 20+1 directions, B0: 400mm/s^2) and a 3D T1 VIBE Dixon sequence acquired in the sagittal plane (resolution: 0.8×0.8×0.8mm^3, TE: 5.22 ms, TR: 10.4ms). T1 images were resampled to a slice thickness of 4mm. Two datasets from a previous pilot study of typically developed (TD) individuals (1 female, 1 male, height 1.58±0.11m, mass 56.5±12.02kg, age 28±3y) were used as a comparator dataset. The soleus muscle was segmented from T1 vibe images using ITK snap (V 3.4.0). DTI post-processing and analysis was conducted with DSI studio software. Additional analysis was performed with custom code written in Matlab.

RESULTS AND DISCUSSION

Soleus muscles in subjects with CP had smaller pennation angles than TD subjects (Fig. 1) in both axial (Θ_{xy}) and sagittal planes (Θ_{yz}). Angular deviations in the coronal plane (Θ_{xz}) were not apparent between CP and TD subjects. Normalized muscle volumes were higher for TD than for CP subjects (Table 1). Surprisingly, the fibre length/muscle length ratio (L_f/L_m) and the PCSA/mass ratio were higher for CP than for TD subjects (Table 1).

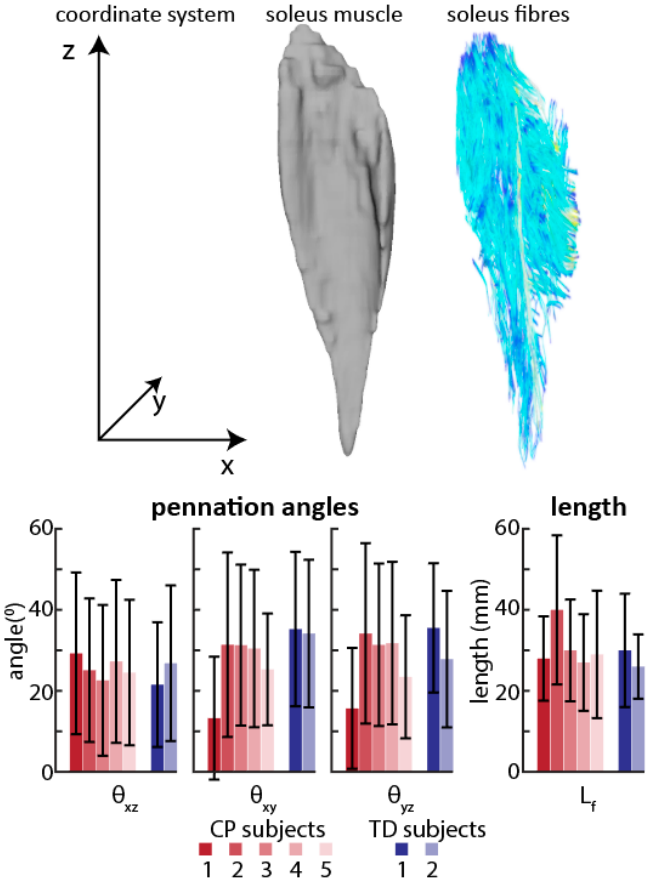

Figure 1: Illustration of soleus muscle model, fibres from DTI, and results. Pennation angles were determined in the coronal (xz), axial (xy), and sagittal (yz) planes. Muscle fibre lengths were determined from DTI post-processing.

CONCLUSIONS

In this study, we used DTI to determine soleus muscle architecture in adolescents with cerebral palsy. Although subjects with CP had reduced muscle volumes, normalized muscle volumes, and PCSAs, their normalized PCSAs were higher than for TD subjects, indicating a potential adaptation to high forces required by CP gait or an excess of non-contractile tissue within the muscle. This study is ongoing and work currently underway includes collection of these data in age-matched typically developing adolescents.

Corresponding author email: giorgio.davico@griffithuni.edu.au

INTRODUCTION

Cerebral palsy (CP) is a non-progressive disorder of the neuromuscular system caused by damage to the brain during early development. Children with CP, as opposed to their typically developing (TD) peers, exhibit gait dysfunctions mainly due to abnormal motor control and altered muscle growth which eventually lead to bone deformities [1].

Musculoskeletal (MSK) modelling can be used to determine muscle force contributions to gait which are required to quantify joint loading [2] and evaluate MSK disorders. To resolve muscle force contribution static optimisation is commonly used; however, this technique may not be appropriate to study a pathological gait characterized by aberrant muscle activations and high levels of co-contraction, such as CP.

We recently assessed the gait of monozygotic twins, one typically developed and the other with CP. The aim of this study was to compare the ability of a commonly used static optimisation technique and an EMG-driven approach (CEINMS) to determine muscle force contributions and contact forces at the knee joint during gait. We hypothesized that (1) muscle force contributions would be similar between the twins when using static optimisation but larger in the CP twin when adopting the EMG-driven approach and (2) joint contact forces would differ accordingly.

METHODS

Two twin brothers (13 yo), one typically developed (height = 169.0 cm, mass = 59 kg) and one with CP (height = 171.8 cm, mass = 59 kg) were recruited as part of a larger study approved by the Griffith University Human Research Ethics Committee. Wireless EMG electrode pairs were placed on the Gastrocnemii, Soleus, Tibialis Anterior, Semimembranosus, Biceps Femoris, Sartorius, Tensor Fasciae Latae, Gracilis, Vastus Medialis and Lateralis and Rectus Femoris muscles. Contextually, 42 reflective markers were attached to the trunk, pelvis and lower limbs in accordance with [3]. Participants were asked to walk on a treadmill at three different speeds, once a self-selected preferred walking speed was determined.

Collected data were processed using different software: Vicon Nexus (v 2.3) to label and reconstruct marker trajectories, MOtoNMS to process EMG signals and define the maximal muscle activation, OpenSim (v 3.3) to scale a MSK model (Gait 2392) and run inverse kinematics, inverse dynamics, muscle analysis and static optimisation simulations and CEINMS [4] to perform the EMG-driven analysis. Prior to the CEINMS simulations musculotendon and activation parameters were calibrated [5]. Summed muscle force contributions to the knee joint moment, calculated via CEINMS and static optimization, were used as inputs to compute joint contact forces (JCFs) at the knee.

RESULTS AND DISCUSSION

Reported results are for one gait cycle of a walking trial at preferred walking speed. Despite little to no differences in gait from a visual inspection, inverse kinematics showed an increased ankle plantarflexion and knee flexion during mid-stance in the twin with CP with associated increased ankle plantarflexion and knee extension moments compared to his twin brother.

EMG-driven muscle simulations showed an initial large contribution of the knee extensors followed by an increased flexors force production in stance in the twin with CP. In comparison, static optimisation results revealed for both twins an overall reduced force production by both the knee flexors and extensors (Figure 1). As expected, the two approaches showed larger discrepancies in summed muscle force magnitude when describing the CP condition.

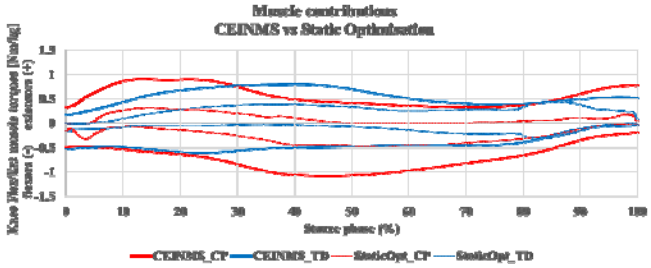

Figure 1: Knee flexor (negative) and extensor (positive) muscle contributions to knee joint moment in a child with CP (red) and his TD brother (blue) estimated using static optimisation (thin dotted line) and CEINMS (solid line).

Preliminary results on joint contact forces calculated using muscle forces from static optimisation revealed inter-subject differences in JCF magnitude. Additionally, the CP twin developed higher forces earlier compared to his TD brother. However, the maximal peak force was comparable. We expect CEINMS to further emphasize these differences.

CONCLUSIONS

Our results showed that static optimisation may underestimate the summed force contribution of the knee extensor and flexor muscles which in turn may cause the corresponding joint contact forces to be underestimated. Moreover, the present study demonstrated the ability of CEINMS to account for additional muscle co-contraction in both healthy and pathologic gait, as highlighted by the muscle activation patterns of selected muscles.

SUBJECT-SPECIFIC GAIT CHARACTERISTICS ARE ALTERED IN CHILDREN AND ADOLESCENTS WITH RECURRENT PATELLAR DISLOCATION

[1] **Martina Barzan**, [2]Luca Modenese, [3]Sheanna Maine, [3]Patricia O'Gorman, [1]David G Lloyd and [1,3]Chris P Carty

INTRODUCTION

Patellar dislocation (PD) is a relatively common injury in the skeletally immature population, with an estimated incidence rate of 43-77 per 100,000 individuals in children [1] and adolescents [2]. Furthermore, children and adolescents experience recurrent patellar instability after acute first-time dislocation at a recurrence rate of 38.4% -91% [3], after both conservative and surgical treatments.

Nowadays, static measures from magnetic resonance imaging (MRI) are used to gain insights into the anatomy of the patellofemoral joint (PFJ) and assess the risk of PD. However, these measures are static and therefore unable to provide understanding of the PD mechanism during dynamic tasks. Gait analysis can complement MRI findings and help understand the interaction of segments and joints of the lower extremity. Recent studies on a mixed population of adolescents and adults with patellar instability [4,5] revealed gait patterns deficits, such as lower knee extension moment. Nevertheless, these studies used link segment models with a simplistic knee hinge, which cannot provide subject-specific insights on PFJ (dys)function. Conversely, subject-specific computational models of the musculoskeletal system, with individualized tibiofemoral joint (TFJ) and PFJ mechanisms [6,7] based on each individual's anatomy, can capture the complex functional relationship between multiple risk factors for PD and account for the substantial inter-subject variability that is typical of the paediatric population suffering from PD.

The aim of this study was to investigate the gait characteristics of children and adolescents suffering from recurrent PD by using subject-specific computational models.

METHODS

Four patients (age: 11.7±2.1, mass: 56.3±12.2 kg, height: 1.60±0.08 m) who presented with recurrent PD and 4 age-matched typically developing participants (age: 11.0±2.5, mass: 35.0±9.1 kg, height: 1.52±0.19 m) underwent MRI and 3D gait analysis. MRI acquisitions consisted of full lower limb (1.5T, modified 3D PD SPACE) and knee (3.0T, T2WI 3D TSE) scans. A ten-camera Vicon camera system (Vicon Motion Systems Ltd, UK) and 4 AMTI force plates (Watertown, USA) recorded kinematics and kinetics during 6 walking trials. For each participant, 3D lower limb bones, knee ligamentous structures (patellar tendon, ACL, PCL and MCL) and articular knee cartilage were reconstructed using Mimics 19.0 (Materialise, Leuven).

The passive motion of the TFJ and PFJ was modelled as a 5 rigid links parallel mechanism and a hinge joint, respectively, with surface contact conditions and ligament length constancy [6]. MRI-measured geometrical parameters were adjusted by using two optimization algorithms [7]. The TFJ and PFJ kinematics results were then incorporated into a subject-specific full lower limb OpenSim skeletal model created in NMSBuilder, with individualized body segment geometry and inertial parameters determined using different bone and soft tissues densities. TFJ and PFJ kinematics and kinetics during gait were computed using OpenSim.

RESULTS AND DISCUSSION

Control participants had low variability, whereas PD patients had large variation with some having greater deviation from controls (least stable patients) (Fig1). During loading response and mid-stance, where the patella is least stable, PD patients walked with an externally rotated patella (Fig1C) and a more superior position of the patella (Fig1D) with respect to controls. As external rotation of the patella increased in PD patients, there was a concomitant increase in lateral patella displacement (r=-0.99). Additionally, patients with a more lateralized patella exhibited low peak knee extension moment during loading response and mid-stance (Fig1B), a possible compensation to lower quadriceps contraction and risk of PD.

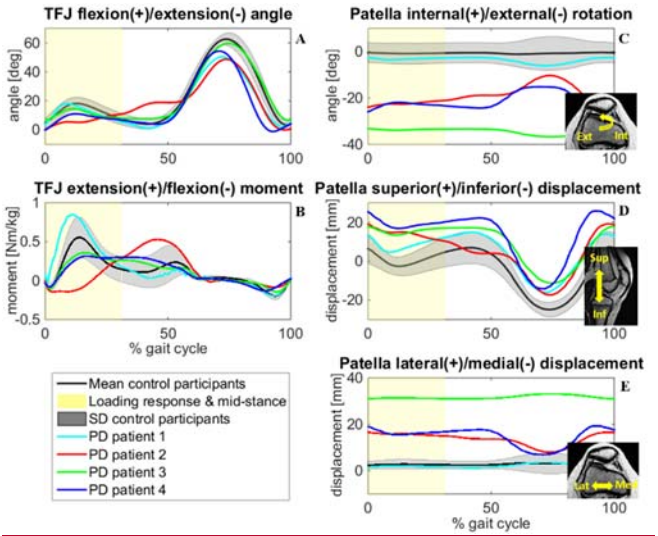

Figure 1: TFJ, PFJ kinematics and knee moments for PD patients and control participants during gait.

CONCLUSIONS

Subject-specific models of PD patients can capture the pose of the patella relative to the femur during gait. These results may be used to determine the likelihood of PD and to personalize surgical planning in the treatment of PD patients.

SIMULATING MUSCLE SPASTICITY DURING GAIT BASED ON PASSIVE SPASTICITY ASSESSMENT

[1]**Antoine Falisse**, [1]Lynn Bar-On, [1]Kaat Desloovere, [1]Ilse Jonkers and [1]Friedl De Groote
[1]KU Leuven, Belgium
Corresponding author email: antoine.falisse@kuleuven.be

INTRODUCTION

Muscle spasticity is a common neural control impairment in children with cerebral palsy (CP) which may undermine their walking ability. It is generally defined as a velocity-dependent increase in tonic stretch reflexes [1], causing resistance to passive stretches. A neuro-musculoskeletal model was recently developed to simulate muscle spasticity in the hamstrings during passive stretches through a linear muscle velocity feedback [2]. This model could capture the salient features of the spastic response (i.e., a rise in muscle activity) but could not explain the sustained muscle activity observed following passive stretches.

In this study, the aim is threefold. First, we extend the aforementioned model by describing muscle spasticity as a combination of muscle velocity and length feedback to explain the muscle activity during and following the stretches. Second, we calibrate the model to simulate muscle spasticity in the hamstrings, rectus femoris, and gastrocnemii during passive stretches at different velocities. Third, we use the calibrated model to evaluate muscle spasticity during gait.

METHODS

EMG, marker trajectories, and reaction forces were collected from two children with CP during passive stretches of spastic muscles (hamstrings, rectus femoris, and gastrocnemii) at different velocities [3] and during gait motions. The gait2392 OpenSim musculoskeletal model [4] was used and scaled to the subjects' anthropometry. Subject-specific muscle-tendon parameters were subsequently estimated [5]. The Hill-type muscle model of the spastic muscles was then extended with a model of muscle length (1) and velocity feedback (2):

$$\tau_{l,m}\dot{u}_{l,m} = \begin{cases} -u_{l,m}, & if\ l_m \leq T_{l,m} \\ -u_{l,m} + g_{l,m}l_m, & else \end{cases} \quad (1)$$

$$\tau_{v,m}\dot{u}_{v,m} = \begin{cases} -u_{v,m}, & if\ v_m \leq T_{v,m} \\ -u_{v,m} + g_{v,m}v_m, & else \end{cases} \quad (2)$$

where l_m and v_m are the length and velocity of muscle m respectively, $u_{l,m}$ and $u_{v,m}$ are the muscle excitation from the length and velocity feedback respectively, $\tau_{l,m}$ and $\tau_{v,m}$ are the time delays of the length and velocity feedback respectively, $g_{l,m}$ and $g_{v,m}$ are the gains of the length and velocity feedback respectively, and $T_{l,m}$ and $T_{v,m}$ are the thresholds of the length and velocity feedback respectively.

For each spastic muscle, the feedback gains were estimated by minimizing the difference between EMG and simulated muscle excitation from passive stretches at different velocities. In passive motions, the muscle excitation is assumed to be generated by feedback only and in our model results from combined length and velocity feedback. EMG-driven simulations of knee moments during gait were finally performed using the calibrated models and the spastic contribution of the spastic muscles was extracted and compared to EMG.

RESULTS AND DISCUSSION

The proposed spasticity model reproduced the EMG salient features for all spastic muscles during and following passive stretches at different velocities (e.g., see Fig. 1, left). In gait simulations, the model generated a velocity-driven spastic contribution from the hamstrings during the swing phase which fell within the EMG envelope (e.g., see Fig. 1, right). The model did not generate any spastic contributions from the rectus femoris and gastrocnemii although spastic responses were observed in passive motions.

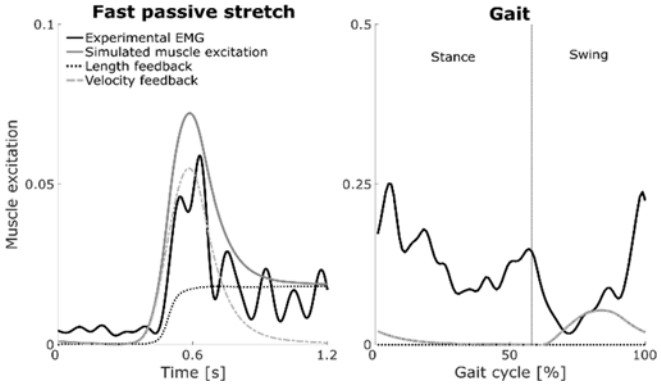

Fig. 1: Muscle excitation of the semimembranosus (hamstrings) during fast passive stretch (left) and gait (right)

First, we found that length feedback can explain the sustained muscle activity following passive stretches. Second, our results suggest that, under the assumption of similar feedback mechanisms during passive and gait motions, only the hamstrings have a spastic contribution during gait for the studied subjects. In future work, we will investigate the validity of this assumption and how feedback modulation during gait, due to loading and upright posture for instance, may influence the effect of spasticity on the gait pattern.

CONCLUSIONS

We modeled muscle spasticity as a combination of muscle length and velocity feedback and reproduced EMG from passive motions for different muscles. Our model suggests a velocity-driven spastic contribution from the hamstrings during the swing phase of gait but no contribution from the other muscles for the studied subjects.

MULTISEGMENT KINEMATIC ANALYSIS OF THE ASYMPTOMATIC FLEXIBLE FLAT FOOT IN CHILDREN WITH THE RIZZOLI FOOT MODEL

[1] **Paolo Caravaggi**, [1] Alberto Leardini, [1] Maurizio Ortolani ,[2] Chiarella Sforza, [3] Nicola Portinaro, [3] Artemisia Panou

INTRODUCTION

Flat foot (FF) is a complex deformity characterized by eversion of the subtalar joint, plantarflexion of the talus and of the calcaneus, dorsiflexion of the navicular, and supination of the forefoot. However, the most evident morphological features are heel in valgus and flattening of the medial longitudinal arch (MLA) in weight bearing. The incidence of FF changes with age: about 37 - 60% in 2-6 years children, and only 4 - 9% in 8-13 years children. Clinical evaluation of FF is usually performed via Jack and tiptoe standing tests, while objective functional analysis of FF is seldom performed. Only a few studies have reported multi-segment kinematics of FF in children [1], and no information are currently available on midfoot motion during gait.

The aim of this study was to determine the kinematic differences between normally developed (ND) feet and asymptomatic FF in children, using the Rizzoli Foot Model. Quantifying the typical kinematic alterations present in FF, including the midfoot joints, may help selecting the most suitable timing for treatments, including surgery.

METHODS

20 children with bilateral asymptomatic FF (13 M and 7 F; age 13.3 ± 0.8 years) and 10 ND age-matched children (5 M and 5 F; age 13.1 ± 0.8 years) were recruited. According to the clinical protocol of the hosting Institution, participants who had hindfoot frontal-plane inclination larger than 16° were included in the FF group. Only asymptomatic FF were evaluated in this study, and children practicing sports at a competitive level were also excluded to limit the occurrence of foot overuse problems in the FF population.

Radiological indicators of FF condition such as the calcaneal pitch, lateral talo-firstmetatarsal angle, and talo-navicular coverage, were measured from weight bearing lateral X-rays. Valgus of the calcaneus was measured with a goniometer.

The subjects' feet and shanks were instrumented with 18 reflective markers according to the Rizzoli Foot Model [2, 3]. Markers trajectories were recorded by a 6-camera motion system (Bonita B10, Vicon, UK). A static acquisition in double-leg standing, and three full gait cycles at comfortable walking speed were recorded for the left and right limb of each subject. Intersegmental rotations in the three anatomical planes were calculated for the following joints: shank and foot (Sh-Fo); shank and calcaneus (Sh-Ca); calcaneus and midfoot (Ca-Mi); midfoot and metatarsus (Mi-Me), and calcaneus and metatarsus (Ca-Me). MLA deformation and hallux-to-metatarsus sagittal- and frontal-plane rotations were also calculated [3]. Mann-Whitney test was used to assess statistical differences between FF and ND in clinical parameters, and in static and dynamic gait-analysis parameters.

RESULTS AND DISCUSSION

All clinical parameters in the FF group were consistent with a diagnosis of flexible plano-valgus foot. In the left and right foot, respectively, valgus of the calcaneus was 22.7 ± 4.7 deg and 24.5 ± 4.1 deg, and calcaneal pitch was 17.1± 6.3 deg and 17.2 ± 6.0 deg.

In double-leg standing, the FF group presented the following differences with respect to ND: the calcaneus resulted more plantarflexed and everted to the shank ($p < 0.05$; Figure 1); the midfoot resulted more dorsiflexed, everted and abducted to the calcaneus ($p < 0.05$), and the metatarsus resulted more dorsiflexed to the calcaneus. In general, temporal profiles of intersegmental rotations during the gait cycle in the FF group presented an offset consistent with the differences observed in the corresponding static posture. Maximum MLA deformation during stance was significantly larger in the FF group in both left and right foot ([ND, left] = 185 ± 28 deg; [FF, left] = 214 ± 17 deg; $p< 0.001$).

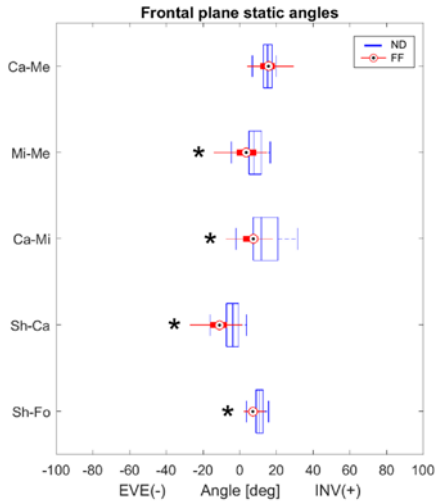

Figure 1: Boxplot of the frontal-plane intersegmental static postures [deg] in the ND and FF groups for five foot joints. For each joint, * indicate statistically significant differences between the two groups ($p<0.05$).

CONCLUSIONS

Motion analysis is seldom used for the functional evaluation of the extent of FF deformity. According to the results of this study, FF in children is characterized by several alterations in clinical and kinematic parameters with respect to normally developed feet. This information may help evaluate more objectively and non-invasively the severity of flat foot deformity and also support the assessment of the efficacy of relevant treatments.

QUANTIFYING REHABILITATION EFFICACY IN CHRONIC STROKE REQUIRES A MULTI-MODAL APPROACH: COMBINING BIOMECHANICS, NEUROPHYSIOLOGY AND CLINICAL MEASURES

Penelope A McNulty
Neuroscience Research Australia and University of New South Wales
penelopemcnulty@gmail.com

INTRODUCTION

Motor impairment is the most common outcome after stroke. The largest and most rapid gains in function occur in the first month post-stroke when patients have the greatest exposure to therapy and different therapy modalities. It is often stated that no further improvement can occur in the chronic period, ie >3 months post-stroke, and that any gains are not true improvement but a restitution of the recovery made in the acute and sub-acute post-stroke period and lost over time.

The apparent absence of improvement in chronic stroke may reflect sample selection, assessment tool selection, a lack of any rehabilitation, insufficient rehabilitation intensity, or data analysis methods. Ongoing unmet needs were reported for 84% community-dwelling stroke survivors in Australia, of which 82% were associated with movement ability [1]. Yet many well-conducted randomised controlled trials (RCTs) demonstrate significant improvements in motor ability in chronic stroke (see [2]). This analysis of data from a series of studies including an RCT comparing Wii-based Movement Therapy (WMT) and dose-matched modified-Constraint-induced Movement Therapy (mCIMT) [3], was designed to explore differences in rehabilitation outcomes using a range of measurement modalities.

METHODS

Patients completed dose-matched 14-day rehabilitation protocols with 10 formal 1-hour therapy sessions on consecutive weekdays, augmented by progressively increasing home practice and a behavioural patient-centred protocol. Motor function was measured using a suite of tools immediately pre- and post-therapy. Clinical tools included the Wolf Motor Function Test, upper-limb motor Fugl-Meyer Assessment, Motor Activity Log Quality of Movement scale, and active and passive range-of-motion at 7 upper-limb joints. Neurophysiological and biomechanical tools included wireless telemetry during therapy sessions at early- (day 2) and late- (day 12-14) therapy to assess limb motion and electromyography (EMG).

RESULTS AND DISCUSSION

All patients, regardless of age (18-83 years), time post-stroke (2 months to 21 years), or level of motor impairment (a flicker of movement in a single digit to minor impairments) improved with therapy. WMT was as effective as mCIMT on every measure of upper-limb motor ability, but with better lifestyle outcomes at 6 months, and higher patient preference, acceptance and persistence [3]. Hence WMT and mCIMT data can be combined to examine assessment tools.

While all patients demonstrated significant clinical test improvements and reported substantial functionally-relevant benefits in everyday life, no one clinical assessment was suitable across the spectrum of residual voluntary motor capacity post-stroke. Averaged data from any one tool over- or under-estimated the magnitude of improvement due to individual patients' capacity for improvement, and assessment tool floor and ceiling effects. However, the cross-over study that followed the RCT (n=12) demonstrated a continued trajectory of improvement over a 17-month period in chronic stroke pm every measure.

Analyses of biomechanical and neurophysiological changes emphasised the absence of any one pattern of improvement after stroke. Patients with similar clinical test outcomes demonstrated either increased or decreased EMG, both of which represent improved motor control for individual patients. Contrary to our hypothesis, there was no association between the level of residual voluntary motor capacity and the direction of the change in EMG with therapy. Averaged data often produced non-significant outcomes, despite obvious clinical improvement.

No coherent pattern of change in active or passive range-of-motion was evident with therapy, whereas increased joint excursion, and faster acceleration and deceleration were significant at late- therapy. No correlations were found between changes in range-of-motion and: joint kinematics (excursion, velocity, acceleration and deceleration), therapy performance, and Wolf Motor Function or Fugl-Meyer scores. This was the first study to investigate kinematics *during* therapy and to consider movement deceleration which represents better motor control at the end of movements. Such braking is important to avoid patients hitting their hand or themselves while moving objects. Kinematic data also revealed a larger repertoire of movements with better motor control by late-therapy.

CONCLUSIONS

There is no one pattern of improvement in stroke and no single clinical test that has sufficient sensitivity across the spectrum of post-stroke impairment. Kinematic and neurophysiological assessments provide greater resolution and more detail, but data cannot simply be averaged to describe the stroke population. Patient experience of therapy outcomes was best reflected in Motor Activity Log scores. Motor improvement is possible in chronic stroke, but careful selection of assessment and analysis methods is critical.

KNEE MUSCLE ACTIVATION STRATEGY IN GIRLS WITH GENERALIZED JOINT HYPERMOBILITY

[1,2]**Bente R Jensen**, [1]Jesper Sandfeld, [1]Pia S Melcher, [2]Katrine L Johansen, [1]Peter Hendriksen, [2,3]Birgit Juul-Kristensen
[1]University of Copenhagen, Denmark

INTRODUCTION

Generalized joint hypermobility (GJH) is a condition where the individual's joint has an exaggerated ability to exceed beyond normal range of motion. The reported prevalence of GJH in children varies between 8-30%, depending on the cut-off criteria used to define GJH. GJH is an advantage for performance in e.g. dancing and gymnastics.

However, GJH increase the risk of future knee joint symptoms and injuries and is anticipated to be a risk factor for development of osteoarthritis. Our knowledge regarding muscle activation strategy in GJH is limited. Recent studies reported larger postural sway, reduced activation of the hamstring muscles and faster rate of early force development in GJH [1, 2].

The aim was to study muscle activation pattern, with special focus on medial-lateral activation strategy, in girls with knee GJH.

METHODS

Sixteen girls with GJH (14.3 years and average Beighton score 6.8) and 11 healthy girls (14.0 years and average Beighton score 1.7) (NGJH) were recruited for the study. Both groups were engaged in sport and performed approximately 4 hours of physical activity per week.

The girls performed maximal and submaximal (20%MVC for 30 s) isometric knee flexions with their dominant leg in sitting position and with the thigh horizontal. Knee angles were 90°, 110°and 130°. In addition, maximal knee extension contractions were performed at 90° knee angle. Contractions were separated by 1-2 min rest to avoid fatigue. Three repetitions were performed in each position.

Surface EMG was recorded (1000 Hz) from knee extensor (mm. vastus lateralis and medialis) and knee flexor muscles (mm. biceps femoris, semitendinosus, gastrocnemius lateralis and medialis). EMG recorded during maximum contractions was used for normalization.

Medial-lateral co-activation ratio was calculated as medial muscle activation divided by lateral muscle activation (average medial EMG_{RMS} x average lateral EMG_{RMS}^{-1} x 100 (%)).

RESULTS AND DISCUSSION

Medial-lateral co-activation ratios were higher for GJH than for NGJH. Thus, grand average medial-lateral co-activation ratio was 144% for GJH and 128% for NGJH ($p=0.015$) with quadriceps and hamstring muscles included in the ratio and 150% for GJH and 134% for NGJH ($p=0.019$) with quadriceps, hamstring and gastrocnemius muscles included in the ratio. Higher values of medial-lateral activation ratio in GJH than in NGJH was consistent across all knee angles. Muscle strength did not differ between GJH and NGJH.

Compressive knee forces are assumed to play a key role for the development of knee osteoarthritis and the most common site of knee osteoarthritis is medial. It has recently been reported that increased co-contraction of medial knee muscles is associated with progression of medial knee osteoarthritis. Thus, a positive correlation was found between medial relative to lateral co-contraction with loss of medial cartilage volume and further that lateral muscle co-contraction correlated inversely with cartilage loss [3].

CONCLUSIONS

Markedly asymmetric activation of the knee muscles towards higher medial muscle activation in GJH than NGJH, indicating higher levels of medial joint compression in GJH was found. Based on these findings it seems likely that the GJH specific muscle activation strategy plays a role in the increased risk of future joint symptoms in persons with GJH.

EVALUATION AND MONITORING OF MOTOR CONTROL OF THE LUMBO-PELVIC MOVEMENT IN PATIENTS WITH CHRONIC NONSPECIFIC LOW BACK PAIN

[1] **Sharon Tsang**, [1] Grace Szeto, [2] Eva Chun, [2] Caroline Wong, [2]Angelina Yeung, [2] Edwin Wu and [3] Raymond Lee

INTRODUCTION

Impaired movement kinematics in the lumbar spine and hip joint in terms of the regional mobility and the ratio between these two regions had been reported previously in individuals with low back pain (LBP) [1]. However, it remains controversial whether regional mobility is sensitive to differentiate the alteration of movement control of the lumbo-pelvic region between symptomatic and healthy individuals. Emerging evidence is now available in the research of chronic neck pain, suggesting that selected variables of the movement profile namely the mean and peak velocity, and time to peak velocity in percentage of movement cycle are sensitive and specific outcome measures in differentiating patients with neck pain from asymptomatic individuals [2]. This study aimed to examine the relevant variables of the movement profile in order to better comprehend the manifestation and recovery of the movement pattern of the lumbo-pelvic region in people with chronic LBP.

METHODS

Three-dimensional kinematics of the lumbar spine and bilateral hips were acquired during forward bending in standing using the motion capture system (Vicon), in adult individuals who suffered from chronic non-specific low back pain (n=5; 2M) and age- and gender-matched healthy individuals (n=5). Full body model of the Plug-in gait was used to acquire the kinematics of the spine and periphery when participants performed the forward bending task. Participants were instructed to perform the forward bending task for 7 cycles consecutively at their self-preferred speed. The variables related to the movement profile include the 1) angular mobility, 2) velocity (peak and mean value) of the lumbar spine and hip joints; and 3) the time to peak velocity (expressed in percentage of the respective phase) during the flexion phase and extension phase (i.e. recovery phase) of the bending task. These variables were compared between two groups. In addition, a reassessment using the same testing protocol was conducted for participants in LBP group after the completion of a 6-week exercise programme that emphasizes on re-education and practice of movement control using fitball under the supervision of physiotherapist.

RESULTS AND DISCUSSION

Figure 1 shows the trajectory of the movement velocity of the lumbar spine of a participant in the LBP group during the flexion phase and extension phase of the bending, before and after the 6-week exercise programme. Table 1 shows the mean (standard deviation, SD) of the kinematic variables for comparison between healthy and LBP group; before and after exercise programme in LBP group of participants. ANOVA was used to analyze the performance of the participants.

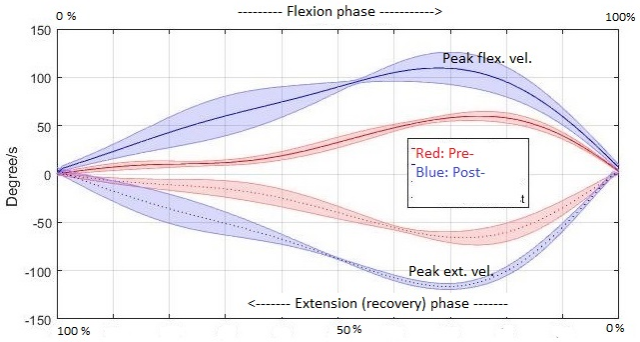

Figure 1: Trajectory of the velocity profile of a participant in LBP group, before and after the exercise programme.

Table 1. Movement profile with mean (SD).

Variable	Healthy (n=5)	Low back pain (n=5)	
		Pre-	Post-
Flexion phase (s)	1.2 (0.2)	1.4 (0.4)	0.7 (0.2)
Extension phase (s)	1.3 (0.2)	1.7 (0.2)	0.8 (0.1)
Lumbar flexion mobility (°)	53.6 (4.7)	42.2 (13.4)	48.6 (17.9)
Hip flexion mobility (°)	76.3 (2.5)	56.3 (17.3)	68.1 (14.6)

* significant difference between healthy and LBP group as baseline; # indicates significant difference for pre-(baseline) and post-treatment comparisons in LBP group.

CONCLUSIONS

The results of this pilot study suggest the potential application of value of peak and mean velocity of the lumbar spine and hip joint as the movement profile variables to evaluate the performance and monitor the recovery progress of the lumbo-pelvic movement in people with chronic non-specific LBP.

MOTOR CORTEX REPRESENTATION OF DEEP NECK FLEXOR MUSCLES DIFFERS BETWEEN INDIVIDUALS WITH AND WITHOUT NECK PAIN

INTRODUCTION

Deep neck flexor (DNF) muscles have fundamental role in maintenance of the stability and posture of the neck. Previous studies have shown that people with neck pain present changes in motor control, such as, delayed feedforward activation during arm movements [1]. Similar changes in deep lumbar muscle activation have been observed in low back pain (LBP). Additionally, differences in location of the representation of back muscles at the motor cortex [4] and convergence between the representations of separate muscles [3] has been found in conjunction with the temporal differences. Whether similar motor cortex changes are present in other musculoskeletal pain conditions, including neck pain has received limited attention. This study aimed to compare the representation of superficial and deep neck flexor muscles at the motor cortex in people with and without chronic neck pain.

METHODS

Ten pain-free controls and ten participants with neck back pain (NP) for more than 3 months and moderate disability (Neck Disability Index: >20%) were recruited. Electromyographic activity of DNF was recorded with custom bipolar electrodes inserted via the nose to the posterior oropharyngeal wall at level of C2-C3. Surface electrodes were placed over inferior third of the sternocleidomastoid (SCM) muscle.

Cortical organization (parameters of the map of representation of neck muscles at the motor cortex) was investigated using transcranial magnetic stimulation (TMS). A 7 cm diameter figure-of-eight coil with the handle orientation parallel to sagittal plane at 100% output intensity was used to deliver stimulus over the scalp. To determine the area of representation, the stimuli started 8-12 cm lateral to the vertex in the inter-aural line (previous studies [2] have shown this site generates greatest responsive of neck flexor muscles to TMS stimulation). The borders of the map were determined delivering pulses one centimeter away in four directions (anterior, posterior, medial and lateral) until less than three motor evoked potentials (MEP) were discernible. During the mapping, five stimuli were delivered (5-s interval) in each location.

The maps were normalized to the MEP with the largest amplitude. Map features assessed were: centre of gravity (CoG) and volume. The area overlap of the representations of DNF and SCM was calculated between groups.

RESULTS AND DISCUSSION

The representation of DNF for the pain-free control group is shown in Fig. 1, the area of maximal activity was found 7 cm lateral from the vertex and 2 cm anterior from the inter-aural line. Consistent with previous research[2], the peak of activity for SCM was found 5 cm lateral from the vertex in line with inter-aural line. Similar map volumes were find for both muscles (DNF: 12.5 $\pm$ 5.4, SCM: 9.5 $\pm$ 4.7; p=0.211). The location of CoG for DNF and SCM was statistically different (DNF: 6.1 $\pm$ 2.3, SCM: 4.0 $\pm$ 2.1; p=0.05). Previous studies of back muscles in LBP have described smaller volume and different location of CoG of the cortical representations, when compared with pain-free participants. In this study no difference was shown between groups for map volume (SCM: pain-free: 9.5$\pm$4.5, NP: 5.4$\pm$3.8, p=0.06; DNF: pain-free: 12.5$\pm$5.1, NP:9.7$\pm$3.8, p=0.24) or CoG (SCM: pain-free: 4.0$\pm$2.1, NP: 4.9$\pm$1.9, p=0.34; DNF: pain-free: 6.1$\pm$2.3, NP: 6.1$\pm$2.4, p=0.97). However, in contrast to greater convergence between maps for separate muscles observed in LBP [3], we observed a significantly lower area of overlap between the maps of DNF and SCM for the NP than pain free controls (Pain-free: 20, NP: 11 number of sites overleaped, p=0.04).

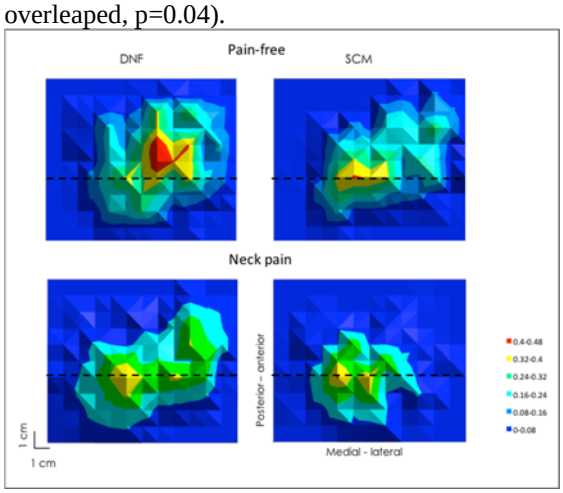

Figure 1: Mapped representation of deep neck flexor and sternocleidomastoid muscles. Top panel shows pain-free control group and lower panel neck pain participants.

CONCLUSIONS

The study showed that it is possible to map the representation of DNF muscle at the motor cortex and this muscle has a different location to the superficial neck flexor muscles (SCM). Also, when NP participants were assessed the representation of deep and superficial neck flexors overlapped less than in pain-free participants, suggesting a different organization of the motor cortex. This difference may be related to a different strategy of coordination between muscles in NP.

INTRODUCTION

Direct repair immediately after flexor injury is the standard in clinical practice. However, flexor tendon reconstruction is the primary surgical procedure for restoring tendon function if the direct repair fails because of severe adhesions or repaired tendon ruptures, which occurs in an estimated 10% to 30% of cases. In this study, we developed a novel intrasynovial allograft tendon revitalized with autologous bone marrow stromal cells (BMSCs) to stimulate tendon healing and regeneration. Further, we synovialized the allograft tendon with carbodiimide derivatized autologous synovial fluid (cd-SYN) to improve tendon gliding ability. We hypothesized that this revitalized, synovialized allograft would improve the functional outcomes for flexor tendon reconstruction compared with clinically conventional autograft tendons. To test our hypothesis, canine flexor tendons were used with a clinically relevant tendon repair failure model..

METHODS

In total, 16 dogs were used in the study. A failed flexor digitorum profundus (FDP) repair with scar digit model was created in the second and fifth digits. Following tendon repair failure, bone marrow was harvested and autologous BMSCs were used for allograft seeding (Fig 1). Six weeks afterward, a single-stage reconstruction was performed on the second and fifth digits randomly assigned for either using the peroneus longus tendons harvested from hind limb or revitalized and synovialized FDP tendon allograft. The allograft tendon was seeded with BMSCs (5 X 10^5 cells/slit) (Fig 1). Then the tendon was treated with cd-SYN of the following formula: 46% native synovial fluid, 10% gelatin, 1% 1-ethyl-3-([3-dimethylaminopropyl] carbodiimide hydrochloride), and 1% N-hydroxysuccinimide in 0.1 M of 2-[N-morpholino]ethanesulfonic acid buffer.

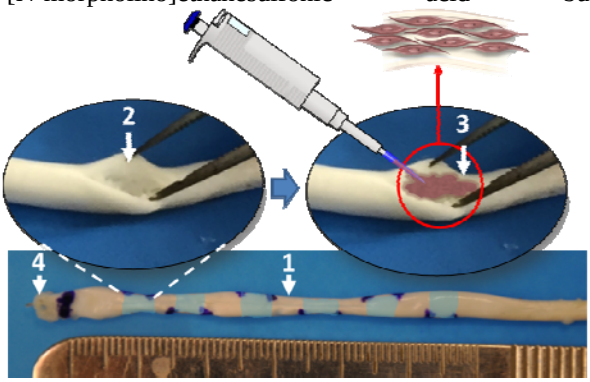

Figure 1: Allograft cell seeding

Following 6 weeks of tendon reconstruction, the digits in each group were mechanically assessed, including the work of flexion for functional evaluation, tendon friction for gliding ability, and tensile strength at repair sites for conjunction healing capacity. Adhesion formation was also evaluated during graft dissection. Two samples in each group were qualitatively examined for histologic characteristics and cell viability.

All quantitative data are presented as mean and standard deviation (SD) and analyzed with repeated-measures of analysis of variance

RESULTS AND DISCUSSION

The allograft group showed significantly lower nWOF than the autograft control group (P<.05). Under a 2-Newton force applied to the FDP tendon, the total ROM of the 3 joints (MCP, PIP, and DIP) was significantly greater in allograft group (mean [SD], 103.2 [12.6]) than the autograft group (71.1 [11.4]) (P<.001). The adhesion score of the allograft group was significantly lower than that of the autograft group (P<.001). No significant difference was found regarding gliding resistance between allograft and autograft, but both of the treated groups showed significantly greater gliding resistance than the intact tendons (P<.001). The strength to failure and stiffness of the distal attachment and proximal repair in the allograft group were significantly less than the autograft group (P<.05).

In histologic observations, abundant adhesions were observed on the surface of autograft tendon (Figure 1D-8F). However, the treated allografts had a smooth layer of paratenon covering the tendon surface without evident adhesion to the surrounding tissues, and the transplanted BMSCs within the allograft slits were observed at 6 weeks after surgery (Figure 1G,H,I). (Figure 2).

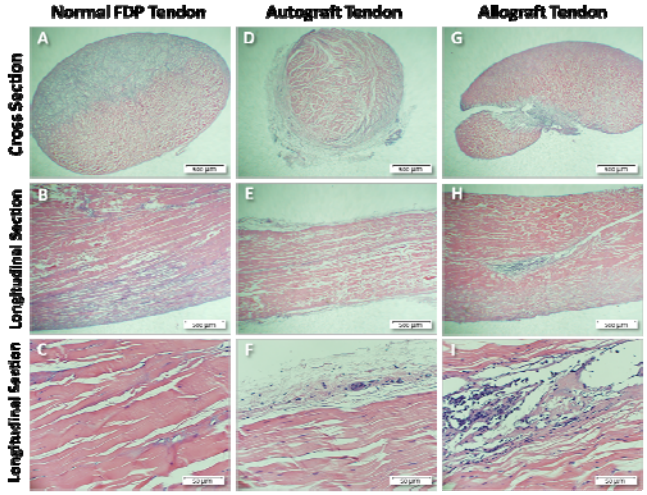

Figure 2: Histology

CONCLUSIONS

Cellular lubricant-based modification of allograft tendons improved digit function and reduced the adhesions, but decreased healing strength compared with autograft for flexor tendon reconstruction.

IMPLANTABLE PASSIVE MECHANISMS FOR DIFFERENTIALLY DISTRIBUTING MOVEMENT ACROSS MULTIPLE TENDONS IN TENDON-TRANSFER SURGERY

[1] **Ravi Balasubramanian**, [2]Francisco Valero-Cuevas

INTRODUCTION

The tendon-transfer surgery for high median-ulnar nerve palsy seeks to restore finger flexion capability by directly suturing the flexor tendons of all four fingers to the wrist extensor muscle (see Figure 1a). While such a surgical procedure is simple, there is an important drawback: the suture couples the flexion of all the fingers. This leads to inconvenient/inappropriate finger movements that compromise tasks such as the grasping of objects. Specifically, the fingers cannot adapt naturally in a staggered manner to the object's shape as the donor muscle contracts. This forces patients to make compensatory wrist and forearm rotations, or use excessive muscle force to close the fingers and establish contact. Overall, the coupled finger movement resulting from the surgery leads to poor grasping capability.

This paper explores the development of implantable miniature passive mechanisms for tendon-transfer surgeries where multiple tendons are sutured to one muscle. These mechanisms, such as pulleys and links inserted between biological tendons, enable "differential action" between the tendons even when driven by one muscle (see Figure 1b). Specifically, the mechanism will distribute the movement provided by the muscle across multiple output tendons while each joint driven by the tendon naturally adapts to external constraints. Importantly, these mechanisms do not require power or control signals, and only mechanically transmit the force and movement from the patient's muscle to the tendons and joints. When applied to the tendon-transfer surgery for high median ulnar nerve palsy, the differential mechanism would enable the fingers to adapt to the object shape naturally even while driven by a single muscle. The mechanism adds an additional passive degree of freedom (rotation of the mechanism itself) to the muscle-tendons-finger biomechanical system, when compared with using the direct suture. This concept is inspired by the use of such mechanisms in the design of "underactuated" robotic hands, where a single motor drives multiple degrees of freedom through these differential mechanisms. This has been shown to improve robotic grasping capability. The challenge in this project is to design these passive mechanisms so that they may be surgically implanted within the human forearm for long-term function.

METHODS

Different embodiments of the passive differential mechanisms are being explored, including the moving pulley and the moving seesaw mechanism. Human cadaver experiments with the pulley embodiment were conducted [1]. In the experiment, the *Flexor Digitorum Profundus* tendons were wrapped around pulley. The pulleys are then driven by a motor in the pulling direction of the *Extensor Carpi Radialis Longus* muscle. The actuation force at which the fingers establish full contact with a stemmed ball was measured.

RESULTS AND DISCUSSION

Figure 1c compares the actuation force required to close the cadaver fingers with the suture-based procedure or the implant-based procedure [1].

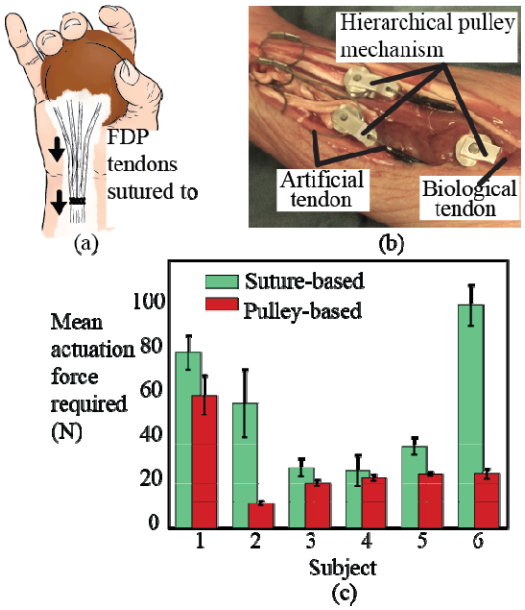

Figure 1: (a) The current suture-based tendon transfer surgery. (b) Human cadaver experiment showing the tendon-transfer surgery using the pulley-based differential mechanism. (c) Force required to close cadaver fingers following the suture-based surgery and the pulley-based surgery [1].

CONCLUSIONS

This paper presents a novel surgical technique for advancing reconstructive tendon-transfer surgeries where multiple tendons are directly sutured to one muscle. By using implanted differential mechanisms between the muscle and the tendons, the human cadaver experiments show that the fingers can adapt better to object at lower actuation forces.

INTRODUCTION

The extensor mechanism (EM) of the finger is a complex anatomical structure which transmits the forces of the extrinsic and intrinsic hand muscles to the finger joints. The EM has been incorporated into biomechanical models of the finger and is usually represented as a 3D-network of extensible or non-extensible strings placed on finger bones at given joint angles.

However, such 3D-models contain many unknown parameters that should be determined. It seems that most studies in this field have only focused on EM modelling but not on its parametrization and validation.

The purpose of this study was to create a numeric model of the long finger EM that includes main tendons and ligaments as well as to perform a parametric identification of the model to match the force distribution in the simulated EM with the experimental data.

METHODS

The EM was modeled as a network of elastic bands. Each EM component, or band, was discretized by the chain of the points, connected by elastic elements. Hence, the EM position was represented by the array of the point coordinates. Each two sequential points, discretizing an EM band, were connected by a spring with a linear elasticity model. The forces of four muscles (dorsal ulnar interosseous, extensor digitorum, dorsal radial interosseous and lumbrical) were applied to the model. The principle of Minimum Potential Energy was used to find the equilibrium state, in which the EM internal forces balance the muscle forces.

The distribution of the internal forces among the simulated tendons in the model were characterized by a vector $\mathbf{C}^{**}$. A model parametrization was performed to make $\mathbf{C}^{**}$ fit the experimental values $\mathbf{C}$, oberved by Chao [1] for the extended posture. The lengths of two intercrossing bands, extensor lateral and interosseous medial band (1 and 2 in Figure. 1) were chosen as the identified parameters. Nelder-Mead algorithm (`fminsearch` function in Matlab R2012b, MathWorks, Natwick, MA) was used to minimize the root-mean-square error between $\mathbf{C}^{**}$ and $\mathbf{C}$.

As the EM is deformable, the internal force distribution among the simulated bands can vary when the muscle forces change. To quantify this variation, the model sensitivity was calculated as the partial derivative of $\mathbf{C}^{**}$ with respect to the muscle forces.

RESULTS AND DISCUSSION

The lengths of extensor lateral band and interosseous medial band, that minimizes the RMSE between $\mathbf{C}^{**}$ and $\mathbf{C}$ were found. Their values were 38.0 mm and 32.7 mm, the RMSE was 0.11.

The parametrized model was used to simulate three postures: full extension (Figure 1a), mid-flexion (Figure 1b), and full flexion (Figure 1c). The scaled-up retention apparatus during full extension (Figure 1d) and full flexion (Figure 1e) is also shown.

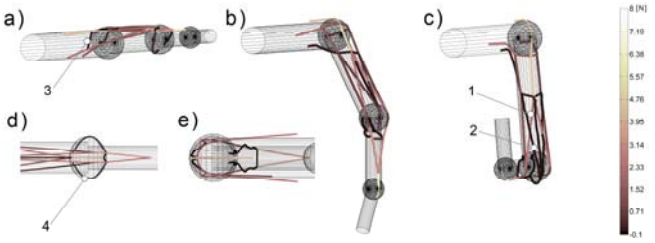

Figure 1: The extensor mechanism simulation for three finger postures.

The changes of the EM configuration are seen from the figure, e.g. the distal shift of the extensor hood and the relaxation of the retinacular ligament could be observed (3 and 4 in Figure 1). The changes of the simulated EM configuration are consistent with the experimental data, reported in [2].

The sensitivity analysis has shown that the force distribution among the simulated tendons are most sensitive to lumbrical muscle force variation. This finding confirms the importance of balance of muscle forces applied to the EM.

CONCLUSIONS

In this study, a biomechanical model of the EM was proposed to simulate the changes in the EM configuration with posture in order to better understand force transmission in the bands. The parametrization of the model was firstly performed to fit the distribution of the forces among the tendons to experimental data. Finally, we calculated the sensitivity of the parametrized model to the variation of the muscle force values.

MUSCLE FORCE OPTIMIZATION IN PIANO PLAYING – A BIOMECHANICAL ANALYSIS

[1] **Michael C K Mak**, [1]Leung-Kim Hung
[1]The Chinese University of Hong Kong
Corresponding author email: michaelck_mak@hotmail.com

INTRODUCTION

Piano playing at the performance level places a high demand on forearm and intrinsic muscles. In piano literature, technically advanced pieces require intensive muscular contractions over an extended period of time. This can lead to fatigue and may result in playing related musculoskeletal disorders of the hands. As fatigue is related to the total muscle force exerted, one should aim to minimize the total muscle force required to produce a note and optimize the use of the stronger extrinsic digit flexor muscles during key-strike. We hypothesize that tendon and thus muscle forces differ between varying finger postures during key strike from relatively flexed to extended. The aim of this study is to find the finger posture that results in the optimization of muscle forces.

METHODS

Nine key strike positions of the index finger were established, from relatively extended to flexed joint positions. Five amateur pianists with no hand prior hand injuries or symptoms were recruited. They were asked to perform a simulated keystrike on a wooden block with the right index finger, with extension of the interphalangeal joints. Then without moving the finger away from the key, they were asked to adopt the most flexed key strike posture in a continuous motion. This was recorded with an optical motion analysis system (Vicon, UK). Nine finger positions at equal intervals within this motion were derived for each subject and the mean joint angles for each position obtained.

The fingertip force P was estimated to be 8.9N, which was derived from Harding's study [1]. All the tendons involved in force production of the finger consisted of the long flexors and extensors and the intrinsic tendons. Dimensions of the metacarpal and phalanges were taken from the cadaveric study by An [2].

Instantaneous moment arms of all the tendons contributing to finger force production were calculated for different joint angles by differentiating the tendon excursion, derived from the models of Landsmeer, with respect to the joint angle [2].

The tendon forces were then obtained by solving joint equilibrium equations [1]:

DIPJ: $\text{FDP-LU})(d_b)\text{-TE}(d_a)\text{-}P(L_1\sin\theta_0) = 0$

PIPJ: $(\text{FDS})(d_f)+(\text{FDP-LU})(d_c)\text{-ES}(d_g)\text{-RB}(d_d)\text{-UB}(d_e)\text{-}P[L_1\sin\theta_0+L_2\sin(\theta_0+\theta_1)] = 0$

MCPJ: $\text{FDS}(d_i)+(\text{FDP-LU})(d_h)+\text{LU}(d_k)+\text{RI}(d_j)+\text{UI}(d_l)\text{-}P[L_1\sin\theta_0+L_2\sin(\theta_0+\theta_1)+L_3\sin(\theta_0+\theta_1+\theta_2)] = 0$

Where P is the fingertip force and $L_{1\text{-}3}$ are the lengths of the distal, middle, and proximal phalanges respectively.

Two optimization criteria were applied separately, yielding two sets of solutions. They were minimization of total muscle stress, in which total muscle stress (equal to force divided by PCSA); and maximization of the sum of the FDS and FDP tendon forces.

RESULTS AND DISCUSSION

When the total muscle stress was minimized, the position with the least tendon force exerted is the most extended position. There is an increase in FDS and FDP tendon force with more extended positions, with the highest in position 1 (Table 1).

When the tendon forces of FDP and FDS were maximized, their forces increase as the finger is more extended and are highest in position 1. The FDP force in the fully extended position is 6.3 times that of the maximally flexed position. The FDS force is also higher in extended positions.

The results of this study show that an extended finger position results in less overall muscle stress, and confers an optimal use of the long forearm muscles.

With a more flexed finger position, the extensor muscle (TE and ES) and intrinsic muscle forces (radial interosseous (RI), ulnar interosseous (UI) and lumbrical (LU)) tend to increase, and the flexor tendon forces tend to decrease in both optimization models.

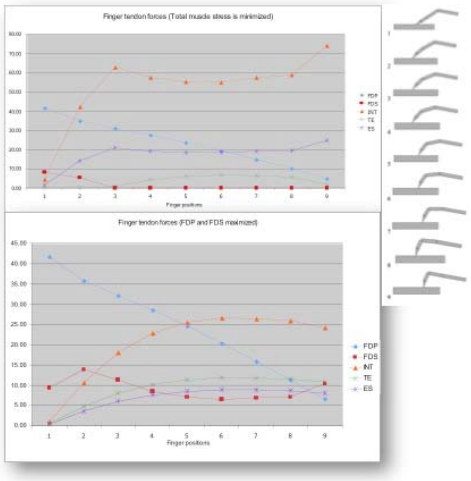

Figure 1: Tendon forces under the two optimization criteria.

CONCLUSIONS

This study therefore supports the adoption of a more extended finger position in piano playing. This would likely reduce fatigue by minimizing the total muscle stress through maximizing the use of the strong extrinsic flexors. This conclusion needs to be confirmed by *in-situ* measurement of the actual muscle forces and finger motions during piano playing, using non-invasive techniques.

THE BIOMECHANICAL EFFECT OF DORSAL RADIAL LIGAMENT RECONSTRUCTION IN THUMB INSTABILITY PATIENTS

INTRODUCTION

Patient with an instable trapeziometarcarpal (TMC) joint often experience debilitating pain, while showing nog signs of cartilage deformation. It is suggested that a shorting of the dorsoradial ligament (DRL) improves thumb stability and reduces pain.

Previous research has shown that dynamic computed tomography (CT) can be used to directly quantify movements of individual (meta)carpal bones. Therefore, the aim of this study is to quantify the effects of DRL reconstruction on thumb kinematics and joint contact patterns using dynamic CT. These kinematics were compared with age-and-sex-matched healthy volunteers.

METHODS

Five patients, with pain and laxity at the TMC joint, but without radiographic signs of osteoarthritis, were recruited. Dynamic CT scans were made during active thumb abduction-adduction, flexion-extension and two functional grip tasks using a radiolucent jig. Scans of the patients were acquired before and 3-6 months after DRL reconstruction.

The healthy, age-and-sex-matched, volunteers underwent the same scanning protocol.

Motion of each bone in the articular chain of the thumb was quantified. In addition, we mapped changes in the contact patterns between the articular facets during the entire motion cycle.

RESULTS AND DISCUSSION

During active thumb motion, there is movement in both the TMC and trapezioscaphoid (STT) joints. In all patients, dorsal subluxation of the first metacarpal (MC1) could be clearly demonstrated and quantified. Furthermore, the dynamic contact patterns suggest point loading of TMC cartilage during dorsal subluxation. After DRL reconstruction, subluxation of MC1 and cartilage point loading were reduced in all patients. Post-surgery changes in contact area were largest during lateral key pinch (Figure 1). Furthermore, surgery at the TMC joint also influences STT kinematics and contact area.

The healthy volunteers showed less dorsal displacement of the MC1 and greater joint congruency during several tasks.

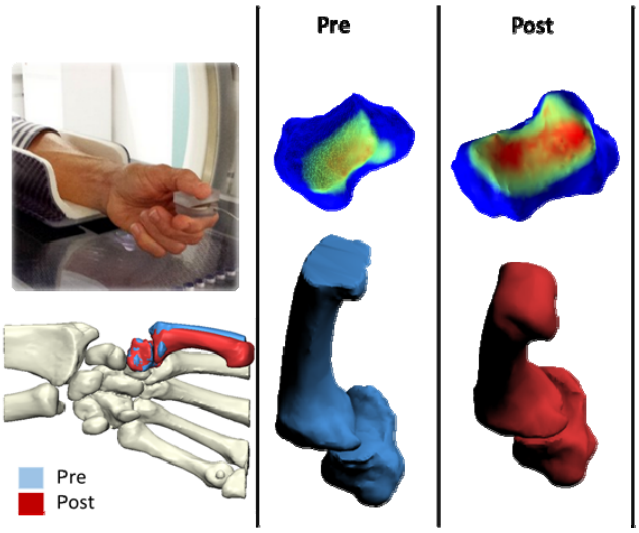

Figure 1: Dorsal translation and articular contact area of the 1st metacarpal during lateral key-pinch. Pre- vs. Post-surgery.

CONCLUSIONS

Patients with TMC instability show greater dorsal displacement of MC1 and increased point loading compared to healthy volunteers.

DRL reconstruction decreases subluxation of MC1 and point loading of the TMC cartilage. However, we demonstrated that DRL reconstruction also influences the STT joint. Hence, surgery at the TMC joint could lead to, potential decremental, compensatory movements at the more proximal joints or *vice versa*.

INTRODUCTION

Successful long jump performance requires high approach run velocity and an efficient redirection of center of mass (CoM) motion into a parabolic flight curve during the take-off step [1]. Recently, the best Paralympic athlete with a unilateral below the knee amputation (BKA) achieved jumping distances comparable to the best non-amputee athletes, while taking off from his affected leg using a running specific prosthesis.

The purpose of the present study was to identify potential biomechanical differences between the maximum sprinting and take-off step biomechanics between the best long jumper with BKA (LJwBKA) and a subject sample of non-amputee athletes, including the current Olympic champion (nonAMPS).

METHODS

The LJwBKA (personal record (PR): 8.45 m) and the non-amputee long jumpers (n = 7; PR: 6.81 – 8.52 m) were analyzed using 3D motion capturing (250 Hz, Vicon, Oxford, UK) and ground reaction force (GRF) measurements (1000 Hz, Kistler AG, Winterthur, Switzerland). Rigid body modelling techniques (ALSKA, Institute of Mechatronics, Chemnitz, Germany) were applied in order to calculate 3D joint angles, moments, power and work in addition to CoM mechanics. The prosthesis was modelled as 2 rigid bodies connected at a joint at the point of highest curvature at the prosthetic blade.

RESULTS AND DISCUSSION

The LJwBKA achieved a maximum jump distance of 7.96 m compared to 6.51-7.92 m for the nonAMPS. Maximum running speed was slower for the LJwBKA compared to the best nonAMPS jumper (9.98 vs. 10.64 m/s; nonAMPS: 9.64-10.64 m/s). The LJwBKA showed a 9.2% lower average vertical force application to the ground in the affected compared to the non-affected side, indicating an impaired ability to apply high vertical forces during short contact times. Based on the work of Weyand et al., this is indicative of a reduced ability to achieve high maximal running speeds [2].

During the take-off step, the LJwBKA demonstrated a different motor solution compared to nonAMPS, with a much greater reliance on energy exchange at the prosthesis compared to the knee and hip joints (Figure 1). The LJwBKA was able to create a high vertical GRF impulse (0.48 BWs; nonAMPS: 0.30-0.52 BWs), while creating a lower net horizontal GRF braking impulse (-0.07 BWs; nonAMPS: -0.09 - -0.17 BWs). All of the CoM energy stored in elastic elements and absorbed by eccentric muscle fascicle work during the first part of the take-off step was regained during the second part of the take-off step, while nonAMPS regained between 35% and 77% of their CoM energy.

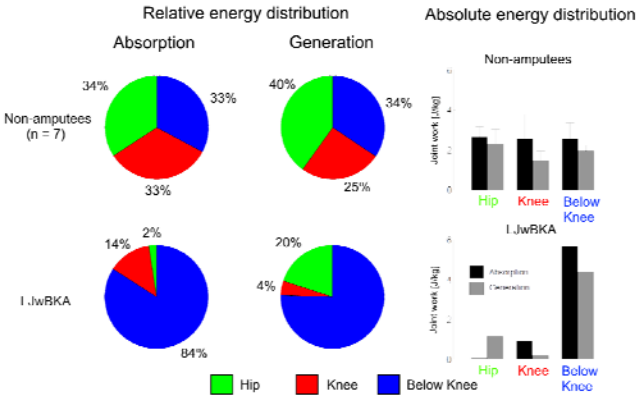

Figure 1: Joint energy distribution within the lower extremities of the LJwBKA and nonAMPS. Below the knee refers to ankle and metatarsal phalangeal joint in nonAMPS and to the prosthesis in the LJwBKA.

The estimated amount of positive work originating from the return of energy previously stored in elastic materials (tendon and ligaments; prosthesis in LJwBKA) was 12% (0.50 J/kg) higher for the LJwBKA compared to the best nonAMPS athlete and 37% (1.27 J/kg) higher compared to the nonAMPS mean value. Elastic energy return is considered beneficial in movement tasks requiring maximum power output as it is not related to contraction velocity like power developed by muscle fibers. These results indicate that the LJwBKA utilizes a different, more efficient take-off technique than nonAMPS.

CONCLUSIONS

The results of the present study indicate a performance disadvantage of the LJwBKA during the run-up and a performance advantage during the take-off. Based on these findings, future technical regulations regarding inclusion of Paralympic athletes in the Olympics should consider both the biomechanics of the main movement and preceding parts of the event. In addition, rules committees need to take into account the comparability of biologically and technologically generated motor control solutions.

STEP FREQUENCY AND STEP LENGTH OF 100-M SPRINT IN PARALYMPIC T42 SPRINTERS

INTRODUCTION

Current Paralympic classifications for track events in athletics are generally based on level of amputation and/or similar levels of disabilities. Consequently, the T42 class is competed by athletes with unilateral or bilateral transfemoral amputations, or functional impairments. Although these morphological differences among athletes might induce sprint mechanics during a 100-m sprint, little is known about how the differences in disability levels affect running mechanics in the T42 class. Therefore, the aim of this study was to investigate the differences in the spatiotemporal parameters of a 100-m sprint among sprinters with unilateral or bilateral transfemoral amputations, or functional impairments in men and women.

METHODS

We analyzed 74 races of 18 female sprinters with unilateral or bilateral transfemoral amputations, or functional impairments from publicly available Internet broadcasts. These races included several Paralympics, the IPC Athletics World Championships, and other national- and international-level competitions from 2008 to 2016.

Each performance at every competition was considered individually. Based on the classification system created by the International Paralympic Committee, we only included the Women's T42 class (defined as unilateral or bilateral transfemoral amputees and athletes with other impairments that are comparable to a unilateral above knee amputation). Individual races were excluded from the analysis if the athlete did not complete the race or if the athlete's body was not visible throughout the race. We only included sprinters who satisfied the A-qualification standards of 100-m sprint in Women T42 class as 18.95 s. In the present study, we separated the whole population into three groups based on different amputation levels as sprinters with unilateral (UTF) and bilateral transfemoral amputees (BTF), and sprinters who have functional impairments without amputations (FI). Consequently, we collected data from 57, 8, and 9 data from 14 UTF, 2 BTF and 2 FI, respectively.

For each sprinter's race, the average step frequency and step length were calculated using the number of steps in conjunction with the official race time [1,2]. One-way ANOVA and a Bonferoni multiple comparison test was performed to compare spatiotemporal parameters among three groups.

RESULTS AND DISCUSSION

Figure 1 shows the averaged step frequency-step length plot for all individuals in the three. There was no significant main effect of amputation levels on the official race time among 3 groups.

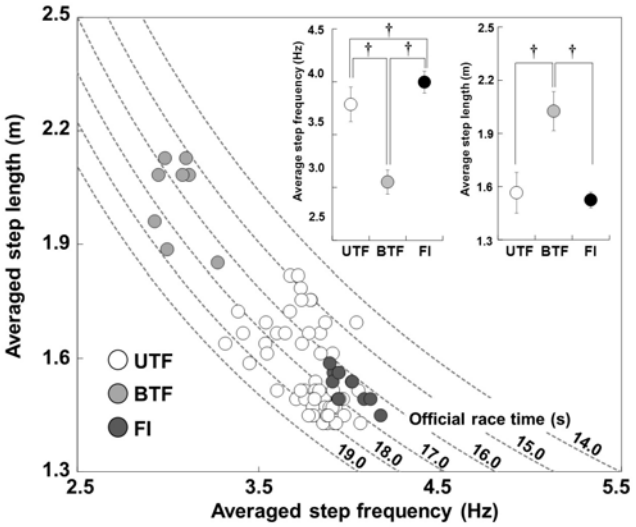

Figure 1: Relationships between averaged step frequency and step length among three groups. Dotted lines denote the official race times. Upper right panels show comparisons of average step frequency and step length among 3 groups. A dagger (†) indicate significant differences between the two relevant groups at $p < 0.01$.

However, the averaged step frequency was the lowest in BTF, followed by UTF and FI. According to a previous study, while running, the prosthetic knee joint in a transfemoral amputee fully extends early during swing and remains straightened until the late stance [3]. The overextended knee increases the moment of inertia of the leg around the flexion-extension axis of hip joint, which affects swing leg kinematics [3]. As a result, the time it takes prosthetic knee users to reposition the swing leg for the next step increases, which has the direct effect of reducing step frequency in BTF and UTF [2,3]. Further, we found that the averaged step length in BTF was significantly longer than UTF and FI, while there were no significant differences in the step length between UTF and FI. These results indicate that BTF and FI would adopt step length-reliant and step frequency-reliant strategies to perform 100-m sprint, while UTF may use an intermediate strategy.

CONCLUSIONS

These results suggest that spatiotemporal parameters of a 100-m sprint would not be the same among different amputation levels, even in the same Paralympic classification.

LUMBAR SPINE REACTION FORCES IN SEATED PARA-SPORT: CROSS-COUNTRY SIT-SKIING

[1] **Marie Lund Ohlsson**, [2,3]Jonas Danvind and [4]L Joakim Holmberg

INTRODUCTION

For wheel-chair users shoulder injuries [1] and lower back injuries [2] are common. Lower back kyphosis of the spine, increases the anterior shear force in the lower back [3] and increases the risk of shoulder injuries [4].

Cross-country sit-skiing (CCSS) is an endurance sport where the athlete is seated in a sledge mounted on a pair of skis and propel themselves by poling with a pair of sticks. This sport creates more equal loading on the muscles around the shoulder than wheel-chair rolling [5] which is positive in an injury perspective for the gleno-humeral joint [1].

Athletes in CCSS with reduced trunk muscle control often sits in a sledge with their knees higher than their hips (KH) and a backrest. This position is hypothesized to be associated with spinal kyphosis and hence an increased risk of injuries. Therefore we have created a new sitting position with knees lower than hips (KL) with the trunk restrained on a frontal support.

The aim of this study was to compute the L4/L5 joint reactions and compare the results between the positions KH and KL.

METHODS

Five female abled-bodied cross-country skiing athletes (62.6 ± 8.1kg, 1.67 ± 0.05m) performed one exercise test session in each sitting position; The sessions included a sub-maximal incremental test, including 4-6 exercise levels of 3 min (exercise intensity nr 4, 37W, reflected race-pace) and a maximal time-trial (MAX) of 3 min on a commercial skiing ergometer (ThoraxTrainer A/S, Denmark).

Full-body kinematics (Qualisys AB, Sweden) and pole forces (Biovision, Germany) were measured in 200 Hz. These data served as input to inverse dynamic simulations in The AnyBody Modelling system (AMS 6.0, Anybody Technology A/S, Denmark). For each participant and sitting position, simulations were made for exercise intensity 37W and MAX over four poling cycles using a 5th order polynomial muscle recruitment criteria. Compression forces and anterior shear forces between L4 and L5 were computed and normalized to each participant's standing joint reactions. Data were compared pair-wise between the two sitting positions.

Statistical significance ($p \leq 0.05$) were marked with asterisk (*). Tendency of difference ($0.05 \leq p < 0.10$) were marked (ǂ).

RESULTS AND DISCUSSION

Performance was higher in position KH (KL: 0.77±0.08 W/kg, KH: 1.00±0.14 W/kg, $p < 0.01$). No difference were observed in cycle length or cycle time. Kinematics results showed that KL had less spine flexion and range of motion in flexion. KH showed higher mean pole force in 37W and tendency of higher peak pole force in MAX.

In standing, L4/L5 compression and anterior shear forces were 354 ± 45N and 32 ± 11N respectively. The normalized L4/L5 reaction forces (fig. 1) were larger in KH, especially during MAX intensity due to higher power. For equal power output, 37W, the mean anterior shear force was larger in KH and the mean compression force showed tendency of larger in KH (p=0.077).

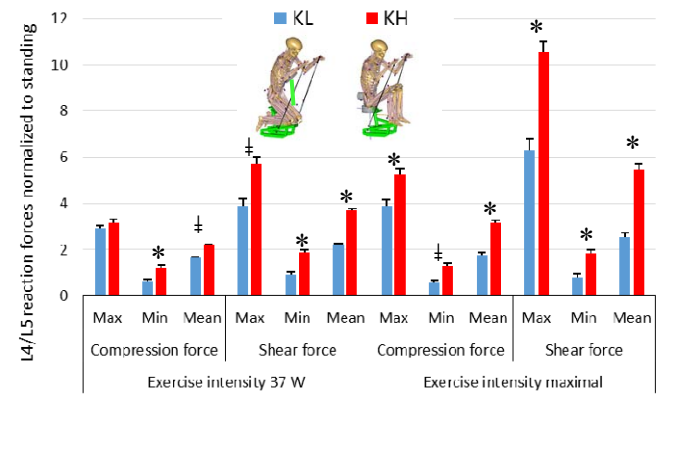

Figure 1: Normalized joint reaction forces, compression and anterior shear forces, between vertebrae L4/L5 for the two sitting positions KH and KL with trunk restraint. Min – minimal force, Maximal force and Mean – mean force over the four poling cycles.

CONCLUSIONS

Based on inverse-dynamics musculo-skeletal simulations of 5 abled-bodied athletes, the sitting position KL with frontal restraint reduced the compression and shear force between the L4/L5 vertebrae but impeded performance. This study shows the difficulty of comparing performance and safety in the same piece of equipment.

EFFECT OF FATIGUE ON PROPRIOCEPTION AND EXTERNAL ROTATOR ECCENTRIC REACTION IN THROWERS WITH OR WITHOUT PAIN

INTRODUCTION

Shoulder overload injuries are a major problem in throwing sports [1]. Throwing is characterised by a forceful internal rotation and after ball release the internal rotation is braked by eccentric action of the external rotators. External rotator strength has previously been related to increased risk of shoulder injury [2]. Also proprioception is considered important for functional stability of the shoulder, and previously proprioceptive measures like threshold to detection of movement or reproduction of position have been used to evaluate shoulder function in athletes [3]. The objective of this preliminary study was a) to examine the potential differences in shoulder proprioception and external rotator activation between athletes with and without shoulder pain, and b) to investigate how fatigue influences shoulder proprioception, using a novel, and more dynamic, method of measuring detection of movement in the shoulder.

METHODS

24 female elite level European team handball athletes (aged 18-26 yrs) volunteered to participate. 10 players were participating in training and games despite pain, and 14 players without symptoms served as control group. First, maximal isometric internal rotation strength (MVIC) was measured in a supine position with the shoulder and elbow in 90° abduction and flexion, respectively, using a handheld dynamometer. Subsequently, the subjects were seated upright with the upper arm supported in 90° abduction in the scapula plane, the elbow in 90° flexion and the forearm vertical. From the back side of a firmly attached wrist band, a cable was directed around a pulley to an electromagnet with a load attached. The subject would hold the load above the ground by a slight internal rotation of the shoulder joint to a vertical position of the forearm, and as such be in a position similar to a throwing position. At a random interval 1-3 second after lifting the load off the ground, the load was released and the shoulder would internally rotate. The subjects were instructed to, as quickly as possible, decelerate the internal rotation, thereby resembling the situation after ball release in throwing. An accelerometer was attached to the wrist to record the movements. After integration of the acceleration data, the time from release to the start of deceleration (reaction time, RT) was determined as the time to peak velocity. This outcome parameter is proposed to rely on the proprioceptive ability to detect onset of movement, however in a more dynamic –and functional-manner, compared to other measures of thresholds to detection of movement. The time from the start of the deceleration to the end of internal rotation, i.e. the instant of zero velocity was defined as deceleration time (DT). DT may rely on the ability to forcefully activate the external rotators. The total stop time was the sum of RT and DT, and by further integration of the velocity curve the total distance moved was obtained, and these parameters comprised both RT and DT as an overall measure of shoulder stability. After thorough practice, 5 test trials were performed. The tests were performed with a load corresponding to 30 % MVIC.
Data was collected before and after a functional fatiguing protocol consisting of alternating 5 maximal throws with 5 submaximal throws for a total of 60 throws. Level of fatigue was rated using a 10-point Borg-scale. A two-way repeated measures ANOVA was used to examine differences between groups and effect of fatigue.

RESULTS AND DISCUSSION

Level of fatigue increased from 2.2 to 6.2 ($p>0.001$) on the 10-point Borg scale for both groups combined, but no difference in fatigue development between groups were found. Also no difference in MVIC between groups was found. Significantly slower RT was observed in the group with pain (pain group: 101 ms (SD: 8.7) vs. control group: 93 ms (SD: 9.5), $p=0.03$, effect size: 0.83), which may indicate that the ability to detect the sudden perturbation was diminished in this group. However, the observed difference did not change with fatigue, indicating that proprioception is not affected by fatigue, as also shown in other studies (e.g. [2]). No differences between groups were found in the other outcome parameters, which may indicate that the ability to activate the external rotators is not influenced by pain, or that lack of external rotator activation was not the problem in this small sample of athletes. No effect of fatigue was detected in any parameter, but a numeric, yet non-significant, increase in DT after fatigue corresponding to 10% was observed for the group with pain compared to the control group (7 ms (SD:17) vs. 1 ms (SD:6), respectively, $p=0.22$). This may be further explored in a larger study.

CONCLUSIONS

This new approach to testing shoulder stability during conditions more close to functional throwing conditions was able to distinguish athletes throwing with pain from non-symptomatic control subjects, showing a slower reaction time, but no effect of fatigue. The present study cannot determine whether this observed difference is a result of pain or a factor contributing to a poorer stability, potentially resulting in pain. The potential of this test may be further explored in a larger prospective study.

EFFECT OF DIRECTION OF UNEXPECTED PERTURBATION ON GAIT CHARACTERISTIC AND DYNAMIC STABILITY DURING TREADMILL WALKING IN YOUNG ADULTS

[1, 2] **Forough Madehkhaksar**, [2]Kim Sczuka, [2]Jochen Klenk, [2]Clemens Becker and [1, 2]Michael Schwenk

INTRODUCTION

Most of the falls occur after a loss of balance while walking and after an unexpected perturbation such as a slip or trip [1]. Therefore, understanding of how humans control and maintain stability during perturbed walking can help to reduce the likelihood of falls. To our knowledge, there have been no studies to compare dynamic stability and gait parameters during perturbed walking in different directions, despite the high ecological validity of this research question.

This study aimed to examine the effect of unexpected perturbations applied from different directions on gait and dynamic stability during treadmill walking.

METHODS

10 healthy young participants (age: 22-36 yrs; 7 females) walked on a perturbation treadmill (Balance Tutor) at fixed speed of 1.11 $m.s^{-1}$ and were subjected to unexpected perturbations in left, right, forward, and backward directions. First, subjects completed 5 min of normal walking without perturbation, to become familiar with the treadmill. The last min of normal walking trial was used for data analysis (Normal). Then, 4 trials of 1 min treadmill walking were recorded. During each trial, a single perturbation towards a specific direction was presented.

Kinematic data was recorded at 200 Hz with 8-camera motion capture system (Vicon Motion System, Oxford, UK). A total of 35 reflective markers were placed at specific anatomical locations in accordance with the Plug-In-Gait marker set. Time frame of interest was 15 sec including 5 sec before and 10 sec after perturbation. Gait parameters including step length, step width, and cadence as well as margin of stability in anterior posterior (MoS-AP) and in medio-lateral (MoS-ML) directions were measured at the instant of the heel strike. All parameters were measured with custom MATLAB programs.

Statistical analysis was performed using SAS software. One way repeated measures ANOVA including a post hoc Bonferroni test was used to analyze measurements.

RESULTS AND DISCUSSION

Results show that gait characteristic and dynamic stability were affected depending on the direction of the presented perturbations (Table 1).

Stride length during sideward perturbations was significantly shorter than Normal ($p<0.001$); also stride length during left perturbation was significantly shorter than backward ($p<0.001$). Step width during left perturbation was significantly larger than Normal ($p<0.001$) and forward perturbation ($p<0.05$). Cadence during sideward perturbations was higher than Normal ($p<0.001$).

Shorter step lengths, which bring the center of mass (COM) closer to the moving base of support (BOS), enhance stability [2]. Our findings are line with previous studies that showed decreases in stride length as well as increases in step width and cadence with increasing perturbation intensity [3]. Our study shows that subjects exhibited the strategy of decreased stride length and increased step width and cadence particularly during sideward perturbations.

MoS-AP during sideward perturbations was significantly lower than Normal ($p<0.001$). In contrast, MoS-ML during left perturbation was significantly higher than Normal ($p<0.05$). Also, MoS-AP during forward perturbation was significantly lower than Normal ($p<0.05$). MoS-AP accounts for the relationship between the BOS boundaries and COM motion. In previous studies, MoS-AP significantly decreased in response to perturbation [4]. While, MoS-ML increased in response to applied perturbation implies a decreased in risk of falling [4]. Results suggest that lateral dynamic stability was controlled by taking wider steps to maintain stable walking, as found previously [3, 4].

CONCLUSIONS

The results show that the increase in cadence and step width as well as decrease in stride length are strategies to increase MoS, and thus to decrease the probability of falling in the presence of perturbations in young adults. According to this observation, sideward perturbations seem to be more challenging than forward and backward perturbations. Further studies need to evaluate whether similar balance control strategies exist in older adults. In this context, this study can be useful for designing advance balance and gait evaluation under dynamic conditions and for introducing novel assessment protocols for estimating fall risk.

UNPREDICTABLE SLIP AND TRIP TRAINING INVOKES BOTH REACTIVE AND PROACTIVE LEARNING

INTRODUCTION

Falls are a major problem for older people. Perturbation training is a relatively new approach with preliminary data suggesting that one training session can reduce falls by up to 50% [1] Furthermore, systematic review evidence suggests that following exposure to repeated perturbations in the laboratory, older people quickly adapt their gait and reactive responses to avoid falling [2]. The predictability of repeated perturbations has led to proactive adaptations within the session including slower gait and a more forward leaning posture, which may confound the study of reactive learning.

Here we present data from a new training system incorporating the possibility of both trips and slips in various walkway locations. Gait adaptions were minimized by fixing cadence and step length to maximise perturbation impact. This paper aims to determine if both proactive and reactive learning can be invoked by unpredictable training regimes.

METHODS

Ten healthy young adults (5 female and 5 male) aged 20 to 40 years participated. The training system comprised an 11-m walkway of moveable decking tiles. Slips of up to 70cm were induced by movable plate on hidden low friction rails. Trips were induced by spring loaded 14-cm height tripping panels, released from the decking tiles using a wireless controller during mid swing phase. Participants received a total of 12 slips (S1 to S12) and 12 trips (T1 to T12) trials with 6 unperturbed walk trials randomly presented throughout. Perturbations were given in three conditions sets of 8 trials: (1) right leg fixed location, (2) left leg fixed location and (3) random leg, random locations.

An 8-camera VICON system at 100 Hz was used to collect kinematic data. Thirty four 14-mm markers were attached to the whole body according to a modified Plug-in-Gait model (Nexus 1.8.3). Centre of mass (COM) and margin of stability (MOS) were calculated from the 3D markers using custom software developed in MATLAB (R2010a).

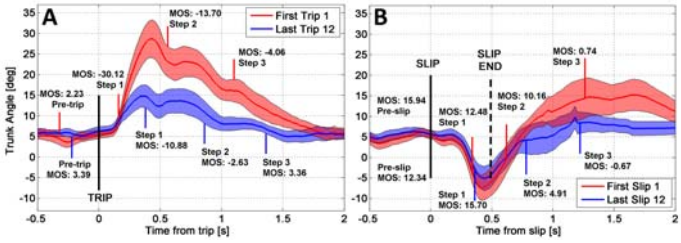

Figure 1: Trunk angles and MOS during approach, trips (A) or slips (B) and recovery during the first and last trials

RESULTS AND DISCUSSION

Slips induced backward followed by forward trunk leaning caused by acceleration followed by deceleration of the slipping plate [Fig 1A]. Trips induced forward leaning only [Fig 1B]. No changes in cadence or walking speed were observed. Participants therefore had to react differently to slips and trips to avoid falling. This enabled us to examine the reactive (feedback) learning while minimizing the proactive (feedforward) learning.

Trips: No participants recorded a fall. Across the 12 trips, mean MOS at the first recovery step improved (-30cm at T1 and -11cm at T12, p=0.03) and the maximum trunk angle following the trip decreased [Fig 2B] (p=0.02). This indicates the participants learnt to take more effective recovery steps. Reactive learning included increases in COM height (p = 0.005) and toe height (p=0.005) during obstacle clearance. The higher COM may be induced by more push-off indicated by increased plantar-flexion of the stance ankle during obstacle clearance (1.2º at T1 and -13.8º at T12, p=0.02). During unperturbed walks a proactive increase in toe clearance (+3.0cm) was also detected, but this was less than the increase in toe height during recovery (+12.8cm).

Slips: One participant recorded a fall on their first slip (S1). Across the 12 slips, mean MOS at the first recovery step remained positive (+10cm at S1 and +18cm at S12, p>0.05). This demonstrates most participants maintained their balance in recovery. Reactive learning included reduced slipping speed (135cms^{-1} at S1 and 83cms^{-1} at S12, p=0.003) and increased COM height during the slip (p = 0.008). Participants learned to minimise the slip by reducing the mean "COM-BOS (base of support) angle" between the COM and the heel of the foot during slip (p = 0.02), which accounted for 64% of the change in slip speed (r=0.80). Increased dorsi-flexion of the slipping leg ankle at slip termination (-1.8º at S1 and 8.8º at S12, p=0.01) also suggests the BOS was more beneath the COM. A proactive change in the "approach angle" at the first contact with the sliding plate was also detected (p=0.09) but this only accounted for 15% of the reduced slip speed (r=0.30).

CONCLUSIONS

The slips and trips induced opposing balance loss and required participants to react immediately simulating real life fall scenarios. The unpredictable training invoked both proactive (increased toe clearance and decreased approach angle) and reactive (increased COM height and dorsi-flexion of the sliding ankle) learning in a single session. Therefore, this may provide a powerful tool to prevent falls.

MECHANICAL CONSEQUENCES OF STEPPING ON AN UNANTICIPATED BUMP WHILE WALKING

[1,2] **Osman Darici**, [2]Hakan Temeltas [1]Art Kuo
[1]University of Calgary, [2]Istanbul Technical University
Corresponding author email: odarici@umich.edu

INTRODUCTION

Human walking can be perturbed substantially by small but unanticipated height irregularities of the ground surface. The reaction to an obstacle is planned about two footfalls ahead [1], and appears to greatly reduce the disturbance from a bump in the surface. However, the adjustments that take place are not understood, nor are the effects if the bump is unanticipated. Simple walking models help to explain the mechanics of walking, in terms of timing and amount of work performed by the two legs during the step-to-step transition. These models suggest that the timing is particularly critical for bumpy terrain. Therefore, in an experiment we measured the work and timing performed by humans traversing a single, small bump, when it is anticipated and unanticipated.

A bump is expected to have several consequences. Its height and therefore potential energy difference should slow down a person for at least the step on the bump. If average speed is to be recovered, the body must be accelerated, which would require more mechanical work than level walking. A simple model shows that trailing leg push-off should normally occur just before the leading leg collision to reduce energy losses [2], but an unanticipated bump would be expected to disrupt that timing with a relatively earlier heelstrike collision, and ultimately more total work to traverse and recover from the bump. In contrast, anticipation should provide opportunity to plan for and reduce the timing disruption. We therefore expect an unanticipated bump to entail more overall mechanical work, with earlier relative timing of collision, compared to an anticipated bump. We therefore conducted an experiment to examine how humans compensate for a small bump in the road.

METHODS

Healthy human subjects (N=8) walked on a treadmill while their walking was occasionally disturbed by small bumps affecting a single step at a time (Figure. 1). The bumps consisted of 2.5 cm thick foam (rigid, closed-cell polystyrene), which were manually placed onto the treadmill either Anticipated (with full vision available) about one step ahead, or Unanticipated due to visual obstruction of the bump by basketball dribbling glasses and headphones to reduce audible cues. Two relevant steps were examined: the step starting with the heelstrike just Before the bump, and the next step starting On the bump. We quantified mechanical work performed on the center of mass (COM work rate) by each leg, summarized by total positive work for each step (Figure 1). Relative timing was quantified by the time by which positive Push-off work by trailing leg preceded negative Collision work by the other, based on the instances when 50% of the corresponding leg work was performed.

RESULTS AND DISCUSSION

We found that subjects performed more work with poorer timing when stepping on the Unanticipated bump (Figure 1).

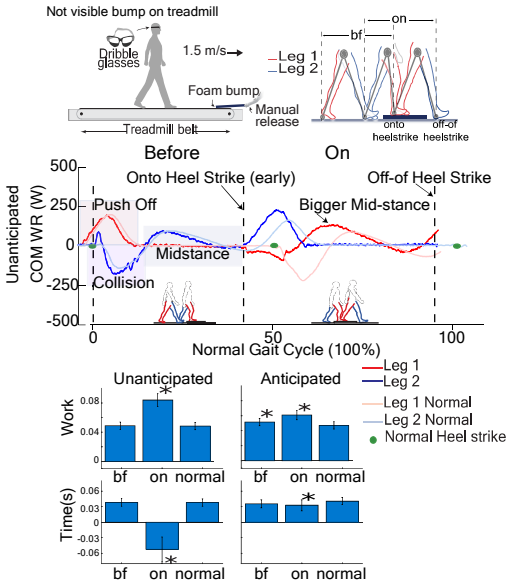

Figure 1: Experiment stepping onto an Anticipated or Unanticipated foam bump. Traces of COM (center-of-mass) work rate vs. time for Before and On bump steps; and bar graphs of positive COM work and of push-off-to-collison time lag (*p<0.05).

Positive COM work was greatest in the unanticipated On step, 74.1% ($p < 0.05$) greater than normal. In normal level walking, Push-off precedes Collision by about 37 ms, but actually occurred about 52 ms later (shown as negative timing, Figure 1) in the on-bump Collision ($p<0.05$). In contrast, the Anticipated bump resulted in less positive work, only 28.5% ($p < 0.05$) greater for On step compared to normal level walking. Anticipation also yielded timing more similar to normal, about 32 ms. Some of the compensation occurred prior to the bump, with about 9.3% more positive work ($p < 0.05$) during Before step, with overall work of both steps far less than Unanticipated case. Work rates traces show that compensations mostly occurred in the middle stance phase after collision.

CONCLUSIONS

Traversing an unanticipated bump requires more mechanical work than normal, and disrupts the timing of the push-off. Anticipation leads less mechanical work and better timing.

CONTRIBUTIONS TO LATERAL WALKING BALANCE FROM TRUNK ROTATION AND FOOT PLACEMENT

Xiao-Yu Fu and Arthur D Kuo
University of Michigan and University of Calgary
Corresponding author email: xiaoyu.fu@ucalgary.ca

INTRODUCTION

Humans use a combination of step placement and other movements to balance during walking. Lateral balance appears to be particularly unstable, countered by active control of lateral foot placement [1], particularly for lateral perturbations toward the swing leg [2]. However, dynamic modeling [1] and standing balance experiments [3] suggest that rotation of the trunk and limbs (arms and swing leg) about the body center of mass can generate reactions that affect lateral balance as well. We propose that humans use trunk and limb rotations for balance, less prominently than foot placement but nonetheless significantly. Moreover, the magnitude of such rotations should increase under conditions that limit freedom of foot placement. We therefore performed an experiment to test whether and how humans employ body rotation to counter externally applied lateral perturbations.

METHODS

We used a force-feedback cable system to apply brief lateral perturbations at waist level to healthy human subjects walking on a treadmill (Fig. 1). We measured perturbation responses in terms of trunk and limb rotation as well as foot placement. The cable system allowed for relatively free lateral motion, except when superimposing a lateral pull at varying points during the stride. Subjects (n = 10) were asked to walk at 1.25 m/s on an instrumented split-belt treadmill, with cables attached via a harness designed to allow for unimpeded arm swing.

We used momentary perturbations throughout each subject's gait cycle to test for phase dependence. Perturbations (100 – 250 N, 0.2 sec duration) were randomly applied to the left or right at 10 equally spaced time points during the subject's gait cycle, as detected from ground reaction forces. Perturbation and timing were randomized, with 6 - 10 normal strides between perturbations. We then used inverse dynamics and other calculations to estimate the lateral force induced on the body center of mass by rotation of the trunk, and compared it against lateral foot placement at different phases of the gait cycle. We focused on perturbations toward the stance leg, which must be countered either with a cross-over foot placement, or with a trunk reaction.

RESULTS AND DISCUSSION

Subjects performed either foot placement or trunk reaction for balance, dependent on perturbation timing. They produced trunk-induced lateral force for early-stance perturbations, along with relatively little lateral foot displacement adjustments (Figure 1). In contrast, cross-over steps were produced in response to mid-stance perturbations, but with very little trunk action. These differences may be due to the stance leg acting as a physical obstacle to the swing leg crossing over, in early stance. Later in stance, the swing leg has a clearer path to crossing over. Trunk rotation appears to be used to greater extent when cross-over is impeded, as was the case for early-stance perturbations.

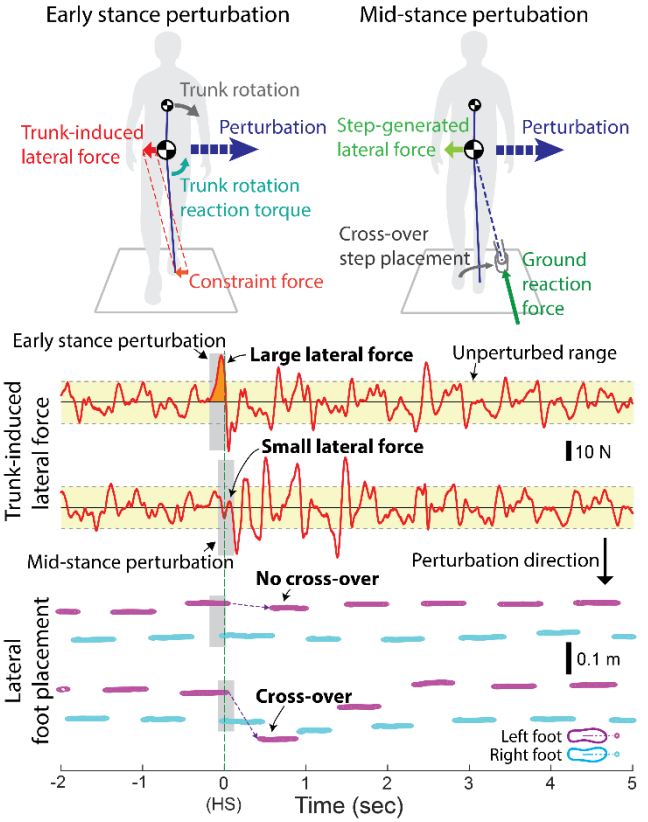

Figure 1: (Top) Inverted pendulum model of the body during perturbations towards the right stance leg, at early stance (left) or at mid-stance (right). (Bottom) Representative data from one subject shows greater trunk-induced lateral force in response to early stance perturbations, coupled with a lack of the cross-over step placement seen after mid-stance perturbations.

CONCLUSIONS

Upper body motion is used to control lateral balance during walking. Although lateral foot placement remains the dominant mechanism to correct against perturbations, multiple limb actions may be selected and coordinated as well, particularly when foot placement is constrained.

ANTICIPATORY SPEED CHANGES FOR OPTIMAL HUMAN WALKING ON UNEVEN TERRAIN

Osman Darici[1,2], [2]Hakan Temeltas, [1]Art Kuo
[1]University of Calgary, [2]Istanbul Technical University
Corresponding author email: odarici@umich.edu

INTRODUCTION

Humans often negotiate uneven terrain, visually anticipating bumps and then planning and executing compensatory actions. On level terrain, the energetically optimal motion entails steady speed and stride parameters [1], but stepping up a sidewalk curb might entail intentional speed adjustments both prior to and after the step up. The type and governing factors for such adjustments are unknown. However, optimality might still apply to uneven terrain just as it does on level terrain.

A step up a curb disturbs walking speed. The upward motion generally implies a loss of forward speed, which could be compensated for through other, intentional speed adjustments. as compensation. In steady walking, a major contribution to energetic cost is from the work performed to redirect the body center of mass velocity in the transition from one pendulum-like stance leg to the next [2]. We hypothesize that such work also applies to non-steady gait and stepping up and down curbs. Minimization of these step-to-step transition costs might explain and predict the speed adjustments appropriate for transient perturbations. We therefore computed optimal speed trajectories for the model, and tested them with human subjects walking up and down curbs and bumps.

METHODS

We simulated a simple walking model with a point mass for the pelvis and rigid, pendulum-like legs taking fixed step lengths (Figure. 1). Energy losses come only from collisions similar to a "rimless wheel" [2], and are restored by impulsive push-off from the trailing leg just prior to leading leg heel strike collision. We modeled the perturbations such as a step up as small, vertical height discrepancies. Optimization was performed to determine the push-off sequence, in terms of positive push-off work, to most economically negotiate the terrain unevenness. For a single step up a curb, the optimal strategy is to speed up over several steps prior to the step up, losing speed on the upward step, and then gradually speeding up again to return to nominal speed. Each type of perturbation yields a different optimal speed trajectory.

In the experiment, healthy young adult subjects (N = 12) walked on a walkway with four possible perturbations (Fig. 1). These included a step up, a step down, and two combinations thereof. A floor surface of slightly greater height (7.5 cm) was devised from rigid foam blocks, arranged to simulate a sidewalk curb or bump. Subjects were instructed to traverse the walkway with approximately the same self-selected speed regardless of perturbation. We measured step-by-step walking speed with inertial measurement units on the feet, and compared speed deviations with the model (Figure 1).

RESULTS AND DISCUSSION

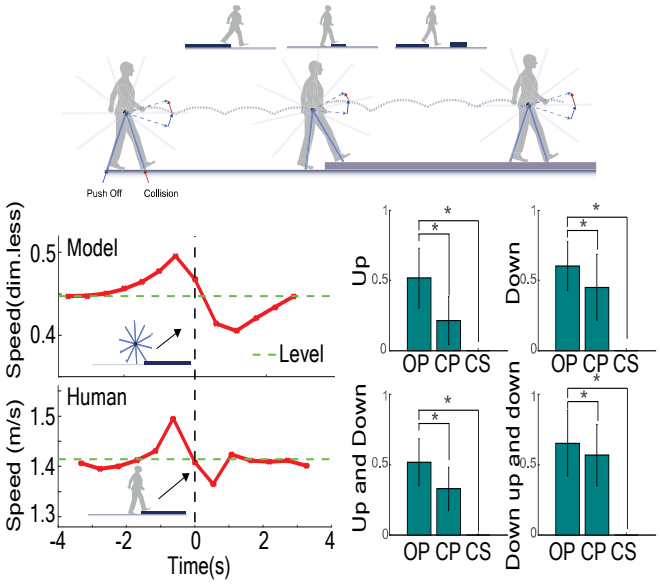

Figure 1: Experiment included walking up a curb and other conditions. Average speed trajectories for Model and Human both exhibited speeding up, then slowing down on and briefly after the curb, and then restoring nominal speed. Predictions were assessed with correlation coefficients against human; positive values indicate predictability for Optimal Push-off (OP) model, Constant Push-off (CP) suboptimal model, and Constant Speed (CS) control (*p<0.05).

Human subjects adjusted gait speed significantly and repeatably. For the step up a curb, humans sped up in advance of losing speed on the curb, then regained speed similar to the model (Figure 1). Moreover, the speed trajectories for the other perturbations; Step Down, Up-and-Down, and Down-then-Up-and-Down were also quite similar to prediction (positive correlations, not shown). The work for redirecting the body center-of-mass between steps therefore appears to govern the speed adjustments humans make for uneven terrain.

CONCLUSIONS

Humans adjust their speed dynamically to economically traverse small bumps and curbs. Adjustments occur for several steps prior to and after a perturbation, as predicted by a simple dynamic walking model minimizing mechanical work for step-to-step transitions.

INERTIAL SENSORS BASED INVERSE KINEMATICS: ACCURACY ASSESSMENT ON A ROBOT APPLICATION

INTRODUCTION

Musculoskeletal models are increasingly used within kinematics and dynamics studies of human locomotion, to estimate various non measurable quantities, such as muscle and joint contact forces. These models are typically driven by kinematics data from stereophotogrammetric motion capture systems, which are certainly the most accurate, but are usually also expensive, bulky and require a dedicated laboratory with trained personnel. An increasing number of studies are therefore investigating the use of wearable Inertial Measurement Units (IMUs) to assess human kinematics, both for clinical and outdoor applications [1]. Some studies also assessed their use to drive musculoskeletal models [2]. Nonetheless, the widespread use of IMUs is still limited by the fact that their orientation estimates are generally affected by errors, due to both intrinsical (i.e. parameters calibration sensitivity) and environmental causes (electromagnetic disturbances), which need to be dealt with through appropriate procedures [3].
This study presents an IMU-based model-constrained Inverse Kinematics (IK) tool designed to overcome this limitation so as to accurately estimate joint angles on multiple Degrees of Freedom (DoF) kinematic chains.

METHODS

In order to isolate IMU-related sources of errors from IMU-independent ones, such as soft-tissues artefact and bone alignment, the accuracy assessment of the proposed IMU-based IK tool was conducted on a robotic arm. A 6-DoF UR-10 (Universal Robots A/S, Denmark) was used to perform the experiments.
Four Cometa WaveTrack IMUs (Cometa Systems, Italy) were positioned on the four links around the three most proximal joints of the robot (i.e. shoulder-pan, shoulder-lift and elbow joints). The desired trajectory was defined by manually moving the robot links. The robot was then programmed to repeat it consecutively for four times. One trial was recorded at 50 percent of the robot maximum speed (i.e. 60 deg/s for the shoulder and 90 deg/s for the elbow). Data were synchronously collected, using a common trigger signal, from the robot's encoders (125 Hz) and from IMUs (286 Hz).

A model of the UR-10 was implemented in OpenSim [4] porting the URDF model available as part of the ROS-Industrial package [http://wiki.ros.org/universal_robot]. Virtual IMUs were placed on model links accordingly to the placement procedure followed in the experimental setup.
Joint angles were then computed using the developed IMU-based IK tool. This tool estimates the model pose at each time frame minimizing the sum of the squared differences, expressed as the absolute angle around the Euler axis, between the orientation of the experimental and the virtual IMUs, the latter rigidly attached to model links. The main innovation and benefit of the developed approach is the use of model constraints to reduce the space of the possible solutions, i.e. model poses, so increasing the overall accuracy of the results.
Results obtained from the IMU-based IK were compared to the experimental joint angles measured from the robot encoders in terms of Pearson correlation coefficient, Root Main Square (RMS) error and maximum absolute error.

RESULTS AND DISCUSSION

The proposed IMU-based IK estimates showed (Figure 1) an almost perfect agreement with the experimental joint angles measured from robot encoders for all the observed joints ($r > 0.999$). Evaluated over the full trial, the highest RMS error was recorded at the shoulder-pan joint, equal to 0.89 deg. The highest absolute error, 1.93 deg, was recorded at the same joint.

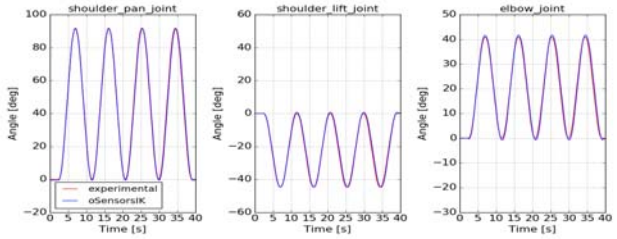

Figure 1: Robot joint angles: experimental from robot's encoders (red) and IMU-based IK estimates (blue).

CONCLUSIONS

The aim of the proposed study was to assess the performances of the developed IMU-based IK tool on the controlled test-case of a multi-DoF robot arm movement. The obtained results are very promising, showing that the presented approach could help to overcome the limitation of IMU technology for motion analysis applications, enabling their usage with musculoskeletal model in both clinical and outdoor scenarios.

MEASURING TEMPORAL PARAMETERS OF TREADMILL WALKING USING A SHANK MOUNTED GYROSCOPE

INTRODUCTION

The measurement of temporal events during walking is fundamental to assessment of many features of walking. In more recent years inertial measurement units (IMU) have become popular for the assessment these features. IMU systems allow measurement to be performed outside the confines of a gait laboratory with relatively little expense.

Previous work has shown that the timing of initial (IC) and final (FC) ground contact times can be estimated from angular velocity measurements of the shank obtained using a gyroscope [1,2]. The pattern of angular velocity about the mediolateral axis is distinctive with a peak around mid-swing and sharp troughs before and after this peak. A number of different methods to filter and extract the times for IC and FC from the troughs in the gyroscope signal have been described. While the timing of ICs have generally been accepted to occur at the minima of the gyroscope velocity following mid-swing [1,2], more recently the relationship between the timing of FCs and the minima in the gyroscopes velocity preceding mid-swing have been questioned [3].

The purpose of this work was to investigate relationship between the timing of IC and FC, and the angular velocity of the shank measured by both a motion capture system, and a shank mounted gyroscope, for the purpose of determining IC and FC from a single gyroscope angular velocity measurement

METHODS

Ten healthy young adults (5M, 5F; 20-29 years; 57-97kg; 1.63-1.93m) were recruited for this study.
Subjects walked on a treadmill to assess their comfortable walking speed (0.96-1.28m/s). Treadmill walking trials were subsequently performed in random order at comfortable, slow (comfortable -20%), and fast speeds (comfortable +20%) for 3 minutes, over 2 sessions. A total of 60 walking trials were recorded. Reflective markers were used to track the orientation of the right shank, as well as the position of the heel in space for each subject. Marker positions were tracked using a 12-camera motion capture system (60 Hz) using Cortex (Motion Analysis Corp., Santa Rosa CA, USA) software. Only motion in the sagittal plane was considered for this analysis. An IMU (W2, Memsense Rapid City, SD USA - 100Hz) was attached laterally to the mid-shank. Only the gyroscope signal corresponding to angular velocity around the mediolateral axis was used for analysis.

Shank angle in the sagittal plane was calculated using Visual 3D software (C-motion, MD, USA). Shank angle, heel marker position and gyroscope angular velocity signals were processed using Matlab R2015b (Mathworks, Natick, MA, USA). IC and FC times were determined from heel marker velocity using the method described by Zeni et al. [4].

RESULTS AND DISCUSSION

The results for a representative subject walking at a comfortable speed are shown in figure 1.

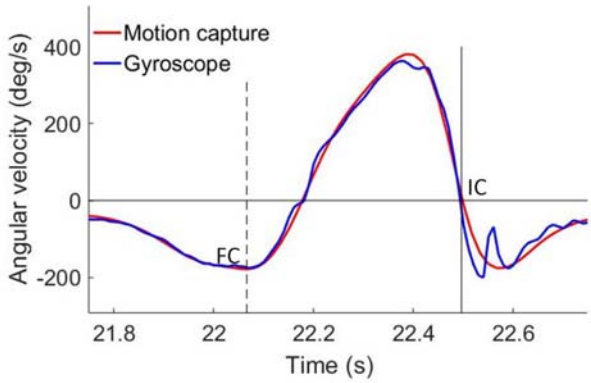

Figure 1: Sagittal plane shank angular velocity for a representative subject at comfortable walking speed.

These data show that IC coincides most closely with the time of zero angular velocity following mid-swing, whereas the timing of FC coincides with the minima in angular velocity of the shank immediately preceding mid-swing. This supports the results described by Aminian et al. [1], who found a systematic error of 10ms delay in the determination of IC using gyroscopes. The concept that IC occurs at or around the time of zero angular velocity has biomechanical validity, as it is the instant when the shank switches from pivoting forward about the hip and knee, to pivoting about the heel.

CONCLUSIONS

These results show that the timing of IC and FC while walking on a treadmill can be determined with a high level of accuracy using a gyroscope. While the method that performed best for these subjects differs from methods previously described, further testing with healthy subjects as well as older, and impaired subjects, is required before previous methods can be discounted. Whether this method can be applied to overground walking also requires future investigation.

COMPARISON OF TWO DIFFERENT PRESSURE DISTRIBUTION INSOLE SYSTEM

Klaus Peikenkamp, Velid Atalay
University of Applied Sciences Münster
Corresponding author email: peikenkamp@fh-muenster.de

INTRODUCTION

When performing a study with pressure distribution insoles own measured data are often compared with those published in literature even if different measuring systems are used. Sometimes the literature provide some reference data [1] or
norm values which are then used to classify the own data. This study deals with difficulties, which may occur when comparing data from different pressure distribution insole systems.

METHODS

Two different well-established insole systems (S1, S2) were compared during different movements of daily activity for a certain number n of subjects: (i) counter movement jump (CMJ) on a force platform FP (Type: 9287C, Kistler, Switzerland, n=50), (ii) walking (n=15), and (iii) descending stairs (n=11). Directly before data acquisition both insoles system were calibrated. Each subject performed six CMJ with each insole system on the force platform so that force and pressure data could be c synchronously. 27±1 steps were performed during treadmill walking at 4.0±0.1 km/h. Descending velocity of the stairs was 85 steps/min and the middle five steps were analyzed. Measuring frequency of the FP was 1000Hz and that of both insole system was 200Hz. For the CMJ trials the jump height h was calculated by the flight time t for both force platform and S1, S2 with

$$h = \frac{gt^2}{8}$$

For each of the foot regions forefoot (fore_f), midfoot (mid_f), and rearfoot (rear_f) of the right foot. two parameters are extracted from the pressure data: (i) p_max, defined by the maximum pressure value occurring during the movement, and (ii) p_ave, here for every time step the values of all sensors within the corresponding region are averaged. p_ave is then defined by the maximum of these mean values during the movement.
Because of partly missing normal distribution, Wilcoxon test was used to check for significant differences ($p<.05$).

RESULTS AND DISCUSSION

Jump height differs significantly between the three measuring systems (Table 1), but these differences are small and therefore not relevant in daily practice. S1 provide significantly lower values for both p_max and p_ave compared to S2, except p_ave during walking. For S1 both p_max and p_ave are significantly lower at the mid_f compared to fore_f and rear_f, whereby the differences between the last mentioned regions are less than 3 N/cm². This effect can also be observed for S2 with respect to p_ave whereas p_max at rear_f is significantly lower compared to fore_f. Thus, during walking S1 and S2 do not differ only with respect to absolute values but also in the load ratio between fore_f and rear_f. For both insole systems, the analyzed pressure values are similar or smaller for descending stairs compared to walking at 4 km/h. The relative differences of p_max between S1 and S2 are larger for descending the stairs compared to walking. For S2 both p_max and p_ave reveal their maximum at fore_f and the minimum at rear_f. This tendency cannot be observed for p_max in S1. So also for descending stairs, the insole systems show different characteristics when comparing mid_f to rear_f.

CONCLUSIONS

The number of measurements executed after the latest calibration might affect the measurement outcome of pressure distribution insoles, so that both systems were calibrated directly before the measurements. However, the partial large differences in the analyzed parameters indicate that researchers must be very careful when comparing own pressure distribution insole data with those in the literature, especially when different insole systems are used. The differences depend not only on different sensors used in different systems but also on varying spatial resolutions. Our results show that especially comparing maximum pressure values seems to be critical. When comparing parameters averaged over several sensors as it was performed in this study by p_ave, the absolute differences between the systems still remain. However, at least the general load characteristics seems to be better comparable. Finally, both analyzed insole systems seems to calculate accurately the height during jumping performances so that the use of a force platform is not compulsory for this purpose.
On the congress several additional parameters are presented to compare both insole systems.

CORRECTING JOINT KINEMATIC PREDICTIONS FROM INERTIAL SENSORS USING A CAPACITIVE STRETCH SENSOR

[1] **Massoud Alipour**, [1]Ted Yeung and [1,2]Thor Besier
[1]Auckland Bioengineering Institute, University of Auckland, Auckland, New Zealand

INTRODUCTION

Kinematic measurement is an integral part of biomechanics and the current gold standard is to use optical motion capture to track segmental positions and orientations. However, optical motion capture is limited to small capture volumes, and requires significant time and cost. One method to overcome these limitations is to use inertial measurement units (IMUs) to measure the linear accelerations and angular velocities of the body segments. Typical IMU-based motion measurement systems integrate acceleration and angular velocity data, resulting in numerical drift. Although data fusion algorithms have improved in recent years, reducing the error from drift, these methods are not immune to drift problems over longer time periods (i.e. > 20mins).

This paper presents a new approach that combines IMU data with a capacitive stretch sensor to perform drift correction. We tested our approach using a simplified model of the elbow joint and illustrate how the addition of a stretch sensor can improve the estimation of a simple flexion-extension joint motion over an 80 min epoch.

METHODS

Our sensor integration set up involved coupling two six-axis IMUs (LSM6DS3) with a capacitive stretch sensor (StretchSense,NZ) connected to an Arduino microcontroller. The Arduino board was programmed to collect synchronous data from all three sensors. The IMUs and stretch sensor were attached to a wooden rig with a one-degree of freedom hinge joint, to represent a human elbow joint (Figure 1). We ensured the stretch sensor was pre-stretched at full extension. Using the onboard data fusion filter provided by the IMU manufacturer [1] we calculated 3D Euler angles between the two segments of interest. The stretch sensor was calibrated to known joint angles and linear interpolation was performed to derive 2D joint angles at different amounts of stretch. This setup enabled us to calculate flexion-extension kinematics in real-time using either the IMUs or the capacitive stretch sensor. Finally, we calculated a 'combined' flexion angle, which took 3D data from the IMU data and updated the flexion value with the mean value from the stretch sensor.

Synchronous IMU and stretch sensor data were collected for a period of 2 hours with the arm rig in a position of ~110 degrees (measured using a protractor). We calculated joint angles using IMU-data, Stretch sensor-data and a combination of both IMU and Stretch sensor.

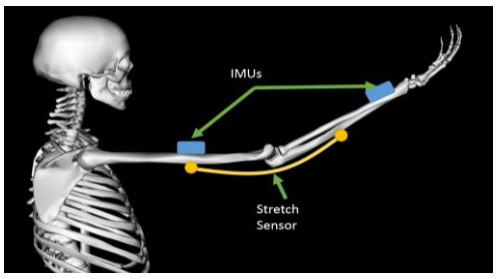

Figure 1: Experimental setup of combined sensors.

RESULTS AND DISCUSSION

The flexion-extension angle calculated from IMU data began to deviate from 110 degrees after ~16 mins of data capture. By 80 mins the angle calculation had drifted by ~4 degrees (Figure 2). The angle measured from the capacitive stretch sensor was noisy but stable across the entire 2 hour epoch, thus supporting its' use as a drift-correction sensor. As expected then, the angles from combined IMU and capacitance stretch sensor was stable across the entire 2 hour epoch and had similar noise to the IMU data.

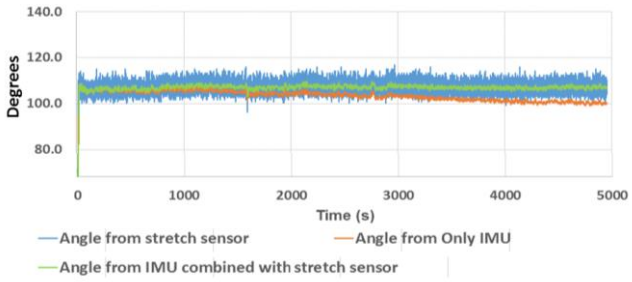

Figure 2: Joint angles calculated from a capacitive stretch sensor (blue), two IMUs (red), and a combination of IMUs and stretch sensor (green).

In this proof of concept study, we show that a combination of stretch sensor and IMUs can provide a robust sensor set to capture joint kinematics with little drift. Having the additional stretch sensor information enabled us to correct the IMU angles in the yaw direction, where standard methods combining acceleration and gyroscope data cannot. Although we did not test our approach to measure off-axis motion in a more complicated joint, we anticipate that the full 3D kinematics would be more robust using this sensor combination. Using a stretch sensor instead of compass heading to reduce drift also has the advantage of reducing potential noise from the surrounding environment, such as motors and metal artifact. This becomes useful to explore the use of wearable sensors to track joint kinematics of patients using assistive devices or exoskeletons.

Using this purpose-built sensor set we aim to extend our approach to develop an accurate, subject-specific, predictive model of upper limb kinematics..

DEVELOPMENT OF A GROUND REACTION FORCE (GRF) SENSOR ROBUST TO REPETITIVE IMPACT FORCE

[1] **Junghoon Park**, [1] Sangjoon J. Kim, [2] Youngjin Kim and [1] Jung Kim
[1]Korea Advanced Institute of Science and Technology (KAIST)
[2]Incheon National University
Corresponding author email: Jungkim@kaist.ac.kr

INTRODUCTION

Investigating vertical ground reaction force (vGRF) and anterior-posterior GRF (A-P GRF) is important for evaluating the performance of athletes and identifying injuries in sports biomechanics. In order to measure GRF, a number of GRF measurement systems that implement force sensitive resistor (FSR) sensors, which are piezo-resistive type force sensors, have been introduced [1]. However, the capacity and repeatability of FSR sensors are relatively low making it difficult to accurately measure GRF during extreme movements, such as running, jumping and etc. [2]. In this study, we developed an optical type force sensor adequate of measuring GRF during running and developed a wearable two axes GRF measurement system to monitor vGRF and A-P GRF during running at 10 km/h.

METHODS

If the running speed of an athlete becomes faster, GRF loading can be assumed as continuous impacts because the force level becomes higher and the duration of loading becomes shorter. Therefore, the force sensors used to measure GRF during running should be robust against impact. We first developed a small multi-axial force sensor (31x 27x10 mm) with high capacity and repeatability. In order to investigate the robustness of the developed force sensor on impact, the proposed sensor was compared with 1) a high performance force /torque sensor (Mini45, ATI, Canada) as a reference sensor and 2) a FSR sensor (A401, Tekscan, USA). They were impacted 100 times in the normal direction and data was sampled at 10 kHz using cRIO (CRIO-9102, National Instrument, USA). After verifying the characteristics of the proposed force sensor, we attached eight developed force sensors to a pair of shoes to measure vGRF and A-P GRF during running at 10 km/h. We compared the GRF data of the developed system with a force plate (Instrumented treadmill, Bertec, USA).

RESULTS AND DISCUSSION

Figure 1 (a) is the results of the impact test. The FSR data and the data acquired using the proposed force sensor are normalized by the data acquired using Mini45. The force measured by FSR decreased 31% while the force measured by the developed force sensor decreased 9% after 100th impacts. This shows that FSR may be unreliable for the measurement of repetitive impact on the heel during running. In addition, the hysteresis error of FSR increased by 492% and increased 280% for the proposed force sensor after 100th impact as shown in figure 1 (b). The increase in hysteresis means that errors in the force measurement can occur when a load at a frequency greater than 1 Hz is applied. From this test, it seems that the developed force sensor may be much more robust than FSR under impact. In other words, the proposed force sensor is more suitable to measure GRF during running.

For the running test, the peak value of the vertical GRF was at average 2.32 BW and 0.24 A-P GRF when measured by the developed system. The normalized root mean square errors (NRMSEs) between peak vGRF measured by the force plate and the developed system was 8.47% and NRMSEs between peak A-P GRF measured by them was 7.91%. The accuracy to measure GRF was greater than 90% for peak vGRF and A-P GRF. In order to reduce the NRMSE errors, the number of the sensor should increase in the system or the area covered by the force sensors should be expanded.

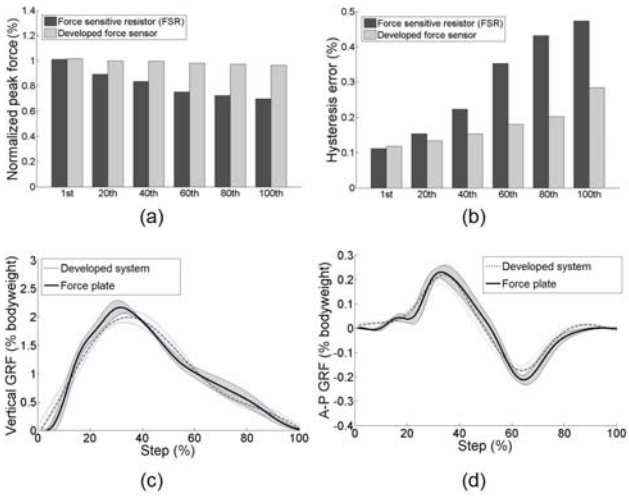

Figure 1: (a) Normalized peak force and (b) hysteresis error of force sensitive resistor (FSR) and the developed force sensor during impacts. (c) Vertical ground reaction force (vGRF) and (d) anterior-posterior GRF (A-P GRF) measured by the developed system.

CONCLUSIONS

We developed a force sensor that was more impact resistant than FSR. This means that the use of the proposed force sensor could be more suitable for GRF measurement during extreme movements such as running. We developed a GRF measuring system and compared GRF data of the developed system with a commercial force plate. There were some errors on measuring GRF during running, but it could be solved by installing additional sensors to the system.

MULTI-DIRECTIONAL NECK INJURY CRITERIA: APLLICATION TO NECK BRACE EVALUATION

INTRODUCTION

Within the automotive industry, neck injury criteria are typically addressed per impact direction, (frontal, lateral or rear impact). In case of motorcycle accident, neck injury often has a catastrophic outcome if not fatal. To protect motorcyclists' necks, a number of neck braces are available on the market. Although the level of protection of these systems are not well known, the reason being that there exists no evaluation standard in the field. The present study suggests the development of model based multi-directional neck injury criteria followed by a numerical approach of the question by coupling the neck brace FE model to a full validated head-neck model attached to the THUMS 3 human body model. A very first injury risk assessment under various impact loading conditions is conducted based on neck injury criteria expressed in terms of neck loading efforts.

METHODS

The first step consists of a detailed setup of the different FE models, i.e. the head-neck model and the neck brace model. An existing detailed head-neck FE model (Meyer et al. 2008) already validated under front, lateral oblique and rear impact was further validated under vertical loading based on data published by Nightingale et al 1997. Moreover, a special dedicated coordinate system was added to each vertebra in order to compute forces and moments in 6 DOF. A number of volunteer tests and PMHS tests reported in the literature were simulated and permitted an original neck model validation in terms of forces and moments. Finally, for the assessment of neck injury under complex loading, maximum forces and moments reported in the literature were considered in order to establish injury curves for a number of key parameters. For the modelling of the protective system, an existing validated full-face motorcycle helmet FE model was considered and a novel neck brace FE model was developed. The CAD file of LEATT neck brace available on the market was considered for meshing. In this study the neck brace is supposed to be rigid, a hypothesis motivated by the fact that an optimal alternative load path away from the neck and into the upper torso should be created during impact without any neck brace deformation. Finally the helmet-neck brace-head-neck models are coupled to THUMS-V3 human body FE model as illustrated in figure 1

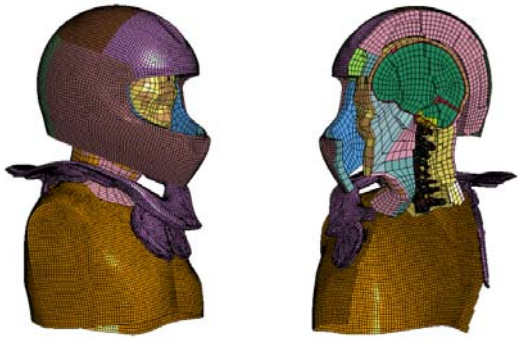

Figure 1: Illustration of the neck FE model coupled to the head and the helmet-neck brace protection system

Subsequently, motorcyclist's impacts are simulated with the above coupled models in order to assess neck injury risk for different impact conditions. Considered initial velocities are 6.5, 7.5 and 8.5 m/s, and for each impact velocity three body angles relatively to the horizontal are considered, i.e. 80, 90 and 100°. In order to evaluate the efficacy of the neck brace, the above mentionned nine simulations are conducted without the neck brace. Simulation results are expressed in terms of neck parameters Fx, Fz, My as well as Nij and are compared to available thresholds reported in the literature.

RESULTS AND DISCUSSION

In order to define an injury risk curve for the mechanical parameter (Fx, F-x, My, M-y, Fz) a synthesis of the literature review is reported in terms of histograms. **Error! Reference source not found.** includes the threshold used by regulations such as EuroNCAP, JNCAP, IIHS as well as thresholds reported in the literature and based on experimental data. This analysis permitted it to define an injury risk curve for each of the five key parameters as reported in table 1. The injury risk curve are defined by the binary logistic regression under the SPSS software. Coming to the simulation of impacts, the computed parameters transmitted to the neck are significantly over the threshold suggested for AIS1 neck injury. However, the results clearly demonstrate that these parameters are reduced by 10 to 25% with the neck brace. For AIS3 injury risk expressed by Nij, the results show that the neck brace reduces the injury risk from approximately 80% to 70% at 6.5 m/s, 80% to 75% at 7.5 m/s and no discernible reduction of risk at 8.5 m/s. More noteworthy, for the 100° body impact angle the injury risk drops from 70% to 40%. As a whole it can be concluded that neck brace reduces neck loading and neck injury risk, even if the neck loading remains very critical at impact speed of 6.5 m/s and over.

CONCLUSIONS

A detailed neck model is validated under five impact directions in terms of kinematics and neck loading efforts. Further this neck model provides multi-directional injury criteria for complex neck loading situations. Further a full FE model of "helmet-neck brace-head-neck-body" is considered for neck brace evaluation under motorcyclist's head on impacts. Results report an objective evaluation of neck brace efficacy compared to a motorcyclist who would not wear such a protection system.

INTRODUCTION

Cervical spine muscles play an important role in maintaining head-neck balance and in preventing intervertebral joint lesions [1]. Abnormal muscle behavior may be an explanatory factor of neck pain and cervical spine disorders [2]. Furthermore, the developmental mechanisms of surgical complications, particularly adjacent segment disease and postoperative junctional kyphosis, are not yet fully understood. Abnormal spine loading and muscular dysfunction could be an issue. Quantifying the spinal muscle force distribution and the corresponding intervertebral joint load in different configurations could provide valuable information for a biomechanical and clinical evaluation of the patient. However, multiple muscle systems are difficult to model because of the redundancy problem [3]. The aim of the present study is therefore to propose a subject-specific biomechanical control model for active cervical spine muscle force estimation.

METHODS

The proprioception-based regulation model originally developed for the lumbar spine [4] was enhanced and adapted to the cervical spine. The model assumes that spinal muscles protect the spine (and the spinal cord) under an external load *NetFM* by maintaining the resulting intervertebral joint load *JL* below the physiological limits *TH*. From a free body diagram, equation (1) can be deduced:

$$F_M + JL = NetFM \quad (1)$$

The muscle forces F_M and the corresponding intervertebral joint forces JL are calculated using a closed-loop control. A regulation function Y with amplification coefficient α is evaluated at each iteration:

$$Y_i = \alpha.(JL_i/TH_i)^3 \quad (2)$$

Based on muscle geometric data, extracted from MRI and biplanar X-ray data, and a literature-based antagonism law, a muscle activation pattern was obtained, yielding the muscle forces regulating the external load *NetFM*. Equation (1) can then be updated. The iterative process ends as soon as *JL* drops below *TH* or a stable minimum is reached.

The model was evaluated based on the comparison with literature data in four configurations (flexion, extension, left bending and left twist). The effect of the uncertainty on the muscle orientation was assessed in a Monte-Carlo analysis. The influence of the main model parameters was quantified in a full factorial analysis. The feasibility of building this subject-specific model was illustrated with a case study of one volunteer (male, 26 years, 65 kg) in the upright posture. The external forces were derived from the available imaging data using barycentremetry.

RESULTS AND DISCUSSION

The model predictions, although independent from EMG recordings, appeared consistent with the literature.

The intervertebral joint loads respected the physiological thresholds in all configurations, except for postero-anterior shear forces in left twist and extension and compression forces in extension, as was also noted in the literature. Moreover, the model behavior was found robust against the uncertainty on the muscle orientation, with a maximum coefficient of variation (CV) of 10%. Also, the muscle force distribution seemed to vary with the *TH* values, meaning that the activation strategy depends on the joint status.

Figure 1 shows the subject-specific muscle force pattern for one volunteer at the C5-C6 intervertebral level.

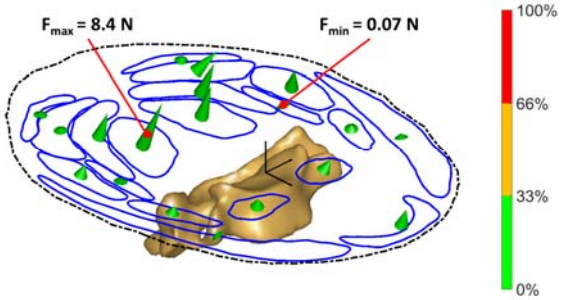

Figure 1: The predicted muscle forces for one subject. The cone length is proportional to the force magnitude and its color refers to the ratio between the exerted force and the force at maximal contraction.

It has to be acknowledged that the current model has its limitations. The forces generated by the passive elements, i.e. the ligaments, the external envelope and the muscle fascia, are not considered. Also, the muscle antagonism activity was simplified and based on literature.

CONCLUSIONS

This study proposes a robust control model, predicting a physiologically feasible activation pattern independently from EMG data. This should offer a relevant and efficient tool for the biomechanical and clinical study of the cervical spine, which might improve the understanding of cervical spine disorders.

VARIABILITY OF CERVICAL KINEMATICS ANALYZED BY A FINITE HELICAL AXIS APPROACH

INTRODUCTION

Although the description of motion in terms of Euler-Cardan or helical angles may be kinematically complete, the clinical interpretation of the results may be difficult. The respective predefined axes mostly do not reflect the actual rotary axes of the joint. Furthermore, variations in the localization of the axes reduce the reproducibility of the results and may lead to an over or underestimation of angle values, called "crosstalk effect" [1] . For this reason, the Euler angles often require a predefined anatomical coordinate system according to the joint they describe and the three angles are sequence dependent. Among different parameters used for the analysis of joint movements, such as range of motion, angular velocity and jerkiness, Woltring [2] introduced the use of instantaneous helical axis (IHA). Most studies exploring the IHA tend to produce good qualitative results, but quantitative results are often lacking. Graphical representations of the IHA have been used in many different studies and adds to an easier interpretation.

A new approach using the finite helical axis (FHA) was introduced by our research groups [3]. Two "new" parameters were used to evaluate the features of the cervical kinematics. One is called Convex Hull (CH) and it is the area through which all the axis pass at a specific section plane. One can then search and identify the section plane in which this area has the minimum value, finding the minimum CHA (cm^2) that characterizes that movement and the partly related Path-length describing the perimeter of the CH. The other "tool" that was introduced is the Mean Angle (MA) that is the mean value of the distribution of the angles between the mean FHA_0 and each of the instantaneous FHA_i .

The aim of this study is to investigate the differences in the qualitative features of the cervical movements between healthy and pathological subjects, using the CH, MA and PL.

METHODS

An electromagnetic tracking device (Polhemus Liberty, USA) was used to register three active cervical movements in healthy controls (C) and neck-pain patients (NP) and data were analyzed using a custom made Matlab routine. A total of 1747 registrations were analyzed. Three subgroups of acute neck pain, migraine and non-specific neck pain subjects were distinguished. Differences between and within groups were analyzed using the independent Mann-Whitney U test for non-parametric data and analyses of covariance. Significance was determined at $p < 0.05$.

RESULTS AND DISCUSSION

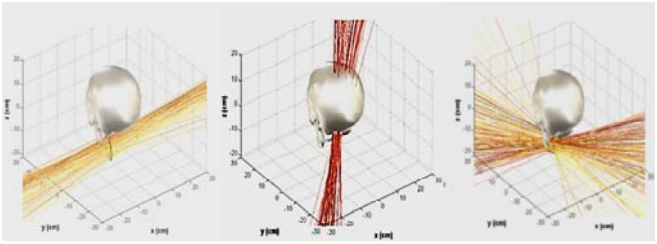

Figure 1: graphical representation of FHA distribution for active flexion-extension, axial rotation and lateral bending motions in a control subject

The FHA parameters did not show significant and clinically important age and gender dependency. During the flexion-extension movements controls show significantly larger PL (227.4mm vs 187.1mm) and CH ($273.7mm^2$ vs $206.6mm^2$) values than the neck-pain patients. MA was also larger (3.4° vs 3.3°) but this finding was not statistically significant. During axial rotation and lateral bending movements all parameters differed significantly lower values for the NP group. Acute neck-pain patients did not show any significant differences with healthy controls, but within the migraine and the non-specific neck-pain groups differences as observed within the whole group were equally present.

Studies investigating spine kinematics using the helical axis approach were so far mainly performed in the lumbar spine and related to surgical interventions. The present results may seem intuitively confusing as one would expect that movements would demonstrate less stability and more dispersed FHA's in patients. However, one could interpret these results in terms of more restrained motion patterns demonstrating less 'natural' variability due to changed and restricted motor control.

CONCLUSIONS

The validation of the FHA approach using CH, MA and PL to discriminate between healthy and pathological subjects could have several implications in the clinical field. It could become an instrument that quantifies the joint kinematics behavior and it could be introduced as an outcome measure in rehabilitative programs for conditions characterized by movement impairments or it could be used to develop more sophisticated interventions and types of cervical prosthesis.

INTRODUCTION

Traumatic cervical facet dislocation (CFD) is often associated with devastating spinal cord injury [1]. The injury mechanisms leading to traumatic CFD are complex and have not been replicated in biomechanical testing [2]; however, anterior shear and flexion loading modes are likely associated with dislocation [3]. Concomitant facet fracture is commonly observed in cases of CFD [4], yet quantitative measures of facet strain, stiffness and failure load have not been reported. Strain behaviour [5] of the posterior elements during facet loading has been measured in isolated lumbar vertebrae, but not for the cervical spine. A better understanding of the mechanical behaviour of the facets during cervical trauma is important for the validation of finite element models and the development of preventative measures. The aim of this study was to determine the mechanical response of the facets when loaded in directions thought to be associated with traumatic CFD.

METHODS

Twelve functional spinal units (FSUs) (3×C2/3, 2×C3/4, 3×C4/5, 2×C5/6, 2×C6/7) were dissected from five fresh-frozen human cadaver cervical spines (mean age = 74 yrs [range 48-92], two male and three female). Musculature was removed and the vertebral disc and bilateral facet joint capsules were preserved. Vertebral bodies of each FSU were embedded such that a rectangular block of polymethylmethacrylate (PMMA) protruded approximately 50mm from the superior endplate of the superior vertebra. The specimen-PMMA assembly was rigidly mounted to the base of a materials testing machine (Instron 8874) via a custom support apparatus attached to a rotary table. Using the rotary table, the inferior articular facet surfaces of the inferior vertebrae were positioned relative to the actuator to simulate *in-vivo* 1) flexion and 2) anterior shear loading. Three cycles of uniaxial sub-failure loading to 100 N (10 N pre-load) were applied bilaterally at 1 mm/s using 6 mm diameter hemispherical loading pins, in each loading direction; the last cycle was used for analysis. Each specimen was failed in a randomly assigned direction at 10mm/s. Deflection of the facets was measured using a motion capture system (Optotrak Certus, Northern Digital). Peak principal strains at the base of the bilateral articular pillars were calculated from the output of rosette strain gauges (TML, Tokyo). Apparent facet stiffness was determined from the linear region of load-displacement data and peak failure load was determined. Paired and independent t-tests were used for comparisons ($\alpha<0.05$). For this analysis FSUs from different vertebral levels were grouped together.

RESULTS AND DISCUSSION

Apparent facet stiffness and peak failure load tended to be greater in flexion than in anterior shear (Figure 1). Facet deflection was similar for both directions (0.31±0.09 mm vs 0.34±0.12 mm, p=0.264). There was no significant difference in maximum principal strains (Left facet: 212.8±225.8 vs 100.4±72.1 μstrain, p=0.072; Right: 194.1±131.6 vs 156.2±77.4 μstrain, p=0.219). Failure occurred through the facet tip when subjected to anterior shear loading, while failure through the pedicles was most common for simulated flexion loading.

A further 8 specimens will be tested and subsequent linear mixed effects models will be used to account for vertebral level and specimen age.

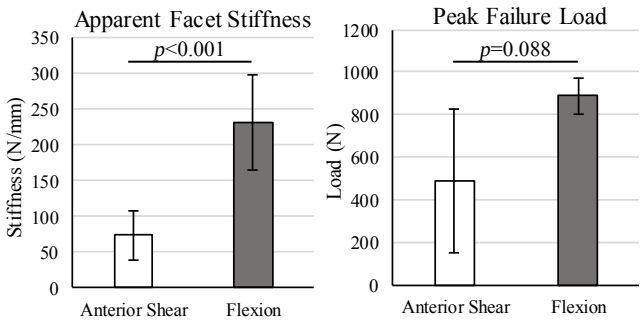

Figure 1: Mean (±1SD) facet stiffness (left) and failure load (right) for anterior shear vs flexion loading directions.

CONCLUSIONS

Cervical facets tended to be stiffer, and have a higher failure load, when loaded in flexion compared to anterior shear, and failure location was dependent on loading mode. Linear mixed effects models will be developed to compare the outcome measures between loading directions while accounting for vertebral level and donor age.

THE INFLUENCE OF THORACIC INCLINATION, GENDER, BMI, DOMINANCE, AND AGE, ON THE RESTING POSTURE OF THE CLAVICLE AND SCAPULA IN HEALTHY INDIVIDUALS

[1]**Yaheli Bet-Or**, [1,2]Shaun O'Leary, [1]Wolbert van den Hoorn, [1]Venerina Johnston
[1]The University of Queensland, St Lucia, Australia
[2]Royal Brisbane and Women's Hospital, Queensland Health, Brisbane, Australia

INTRODUCTION

Resting posture of the clavicle and scapula (in relaxed upright standing) is standardly defined in three axes of scapular rotation (internal/external rotation, upward/downward rotation, and anterior/posterior tilt) and two axes of clavicular rotation (protraction/retraction and elevation/depression). Resting posture of the scapula and clavicle are commonly assessed clinically for both shoulder and neck conditions. However, normative postural data is lacking and factors affecting scapula and clavicle resting posture have not been thoroughly investigated. Various factors such as age, gender, hand dominance, BMI, physical activity levels, and thoracic alignment, have been suggested to influence shoulder girdle posture. Therefore, the aim of this study was to investigate the normative range of clavicle and scapula resting posture in healthy individuals, and to explore other individual characteristics that may influence resting posture of the scapula and clavicle.

METHODS

One hundred healthy volunteers, 57 females (mean (± SD) age in years 33.1 ± 10.6, body mass index (BMI) 22.8 ± 3.3 kg/m^2, 9 left handed) and 43 males (age 37± 11.6, BMI 25.4 ± 4.7 kg/m^2, 9 left handed) were recruited from staff and students within the university and general population.

An eight-camera 3D movement registration system (T40, Vicon Motion Systems, Nexus Software v1.8, Oxford, UK) was used to record the positional data of reflective markers and clusters attached to the right and left scapula, clavicle, sternum, and thoracic spine (120 samples/s) following the ISB recommendations [1]. Participants were recorded in upright standing with feet shoulder width apart and arms in a resting position beside their trunk.

All data were analyzed in Matlab (version R2012b, Mathworks, Natick, MA, USA). Thoracic spine inclination was defined as the angle between the vertical and the line between the thoracic markers corresponding to the level of the inferior angle and root of spine of the left and right scapulae. The scapula and clavicle orientation was expressed in the external reference frame. All statistical analyses were performed using SPSS version 24.0 (IBM Corporation, New York, NY, USA). Significance level was set at $P<0.05$. Descriptive, univariate and multiple regression analyses were calculated with age, gender, hand dominance, BMI, physical activity (measured by IPAQ), thoracic inclination, and clavicle posture (in relation to the scapula) as independent variables. Three scapula and two clavicular positional angles (performed bilaterally; left (L), right (R)) as calculated as dependent variables.

RESULTS AND DISCUSSION

Mean and Standard Deviation (SD) scapula and clavicle angle at rest for the different rotational axes are displayed in Figure 1. Multiple regression analysis results demonstrated that scapula internal rotation was mostly influenced by clavicle protraction ($p<0.001$) while scapula tilt was strongly influenced by thoracic inclination ($p<0.001$). Scapula upward rotation was influenced by both clavicle elevation ($p<0.001$) and clavicle protraction ($p<0.001$), but also by thoracic inclination (right-$p<0.018$, left-$p<0.001$). The clavicle orientation, although significant with thoracic inclination (right clavicle elevation $p<0.025$) and age (right and left clavicle protraction $p<0.001$) did not show a strong influence (max R^2 0.14). Level of physical activity, gender, and hand dominance, did not seem to influence either scapula or clavicle resting posture. Age and BMI had a significant but weaker influence on scapula posture compared to factors such as thoracic inclination and clavicle posture.

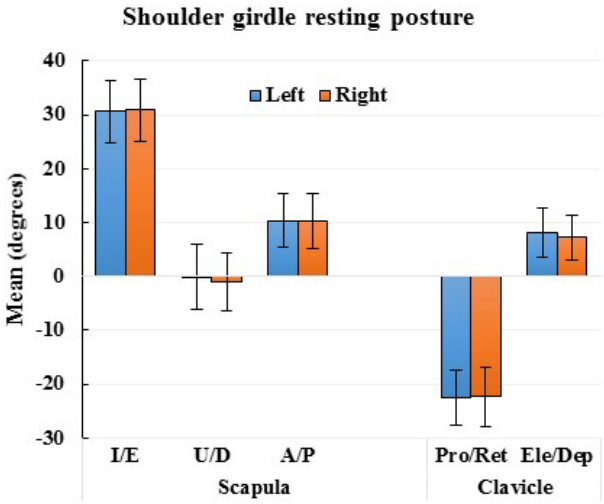

Figure 1: Means in degrees and SD of left and right scapula (Int/External (I/E), Up/Downward (U/D), Ant/Posterior tilt (A/P)) and clavicular (Pro/Retraction (Pro/Ret), Elevation/Depression (Ele/Dep) rotational angles at rest.

CONCLUSIONS

Individual variability of clavicle and scapula resting posture in healthy individuals is reported. This study has demonstrated the strong influence of thoracic inclination and clavicle orientation on scapula resting posture. The relationships between the scapula, clavicle and the thorax highlight the importance of multiple segment measurement in studies describing upper limb and shoulder girdle function.

IMPACT OF THE WINDLASS MECHANISM ON ENERGY RETURN IN THE ARCH OF THE FOOT

[1] **Lauren Welte**, [2]Glen Lichtwark, [2]Luke Kelly, and
[1]Michael Rainbow
[1]Queen's University
[2]University of Queensland
Corresponding author email: l.welte@queensu.ca

INTRODUCTION

The human foot is a complex structure with many different components. Within the medial longitudinal arch, multiple bones, muscles and ligaments modulate arch stiffness over the gait cycle. The plantar fascia, a thick band of tissue on the bottom of the foot, is the integral passive component in controlling the shape and stiffness of the arch. In 1954, Hicks proposed that the foot's transition from compliant to rigid at the end of mid-stance is a function of the windlass mechanism, whereby the plantar fascia wraps around the metatarsal head and causes increased arch height during metatarsophalangeal joint (MPJ) dorsiflexion [1]. The purpose of this study was to examine the effect of toe position on the dynamic arch stiffness *in vivo*. We used an extension of Ker et al.'s experimental paradigm to compress the arch while measuring the applied load and foot kinematics [2]. Based on [3] and [4], we hypothesized that for constant applied forces, toe plantarflexion would lead to increased elongation and subsequent energy transfer in the arch of the foot. In this position, the plantar fascia would be closer to its resting length, and would be less stiff in the toe region of the typical non-linear force-displacement ligament curve.

METHODS

Nine healthy subjects (8M, 1F, mean +- std. dev., mass 80 +- 12 kg) with no history of lower limb injury participated in the study and provided written informed consent. An electromagnetic actuator was used to apply a compression force through the shank, directly vertical to the navicular, with the shank between $5 – 15^0$ to the vertical (similar to late mid-stance in gait). Loads of ½ * BW or 1* BW were applied to the knee in a fast or slow condition, compressing the arch of the foot. The effect of the MPJ angle was tested by fixing the MPJ joint at 45^0 of plantarflexion, or 45^0 of dorsiflexion (passively, with respect to the ground). Two compression impulses were applied to the foot for each trial and condition. Six 3D motion capture cameras (Qualisys, Sweden), sampling at 185 Hz, captured 14 retro-reflective markers (9.0 mm) placed on the skin of the foot and shank. A multisegment foot model was developed from these markers [5]. A 6 DOF force platform (Bertec, USA) was placed under the foot. The medial longitudinal arch angle (MLA) and the MPJ angle were calculated as based on an established foot model [5]. The arch was modelled similarly to Gefen [6], where the navicular is assumed to be a pin joint at the top of a truss formed by the first metatarsal and the calcaneus. The deformation of the arch is measured as the elongation from the head of the first metatarsal to the base of the calcaneus. This displacement was considered to be proportional to the vertical displacement resulting from the applied force through the shank. The integral of the vertical applied force and the elongation of the arch was used to determine a metric proportional to the energy transfer through the foot. We performed paired t-tests with unknown variance to examine the effect of toe flexion angle on energy stored in the arch for a given load. All analysis was completed using custom MATLAB software (Mathworks, Inc.).

RESULTS AND DISCUSSION

Contrary to our hypothesis, more energy was absorbed (+) and released (-) during toe dorsiflexion ($p<0.01$) (Figure 1). This increased energy transfer is a function of arch stiffness, which is consistent with the decreased slope of the forceelongation curves for dorsiflexed toe trials. The magnitudes of forces and elongation were similar to those found in [2].

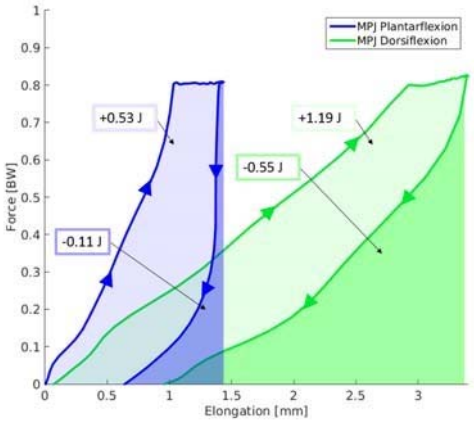

Figure 1: Example plot of a vertical force- arch elongation curve during a 'slow' trial at 1 BW. The area under the curve is a metric proportional to energy absorbed by the arch (+) and released from the arch (-) during a compression trial for each toe condition.

The dorsiflexion of the MPJ caused an increase in the height of the arch, as predicted by the windlass model. It is likely that other structures (muscles, ligaments) crossing the arch are shorter with the higher arch, causing them to be more compliant (with behavior closer to the toe region on a typical ligament force-displacement curve). The base of the arch is also shortened with the higher arch, with its effective length shorter in MPJ dorsiflexion compared to MPJ plantarflexion ($p<0.001$), with magnitudes similar to the windlass model [1]. While the toe position is not identical to that in activities such as walking and running, it provides insight into the effect of MPJ angle on arch behaviour. These results indicate that the plantar fascia may serve to modify the arch bone positions, using the windlass, to make other arch structures more compliant and alter the dynamic energy transfer in the foot.

CONCLUSIONS

Our results indicate that the MPJ dorsiflexion increases arch height and reduces arch length. These mechanical changes appear to influence the magnitude of energy stored and

returned within the arch. However, the underlying mechanisms for these alterations remain unclear.

BLOCKING INTRINSIC FOOT MUSCLE MOTOR FUNCTION MAY INCREASE HUMAN FOOT COMPLIANCE

[1]**Dominic J. Farris**, [1]Luke A. Kelly, [1]Andrew G. Cresswell and [1]Glen A. Lichtwark
[1] Centre for Sensorimotor Performance, The University of Queensland
Corresponding author email: d.farris@uq.edu.au

INTRODUCTION

The human foot is known to act in a spring-like manner, the medial longitudinal arch (MLA) compressing and recoiling as it is loaded and unloaded [1]. This function occurs during ground contact in both walking and running [2], in line with the behavior of the whole leg. Historically this spring-like function of the MLA has been largely attributed to the passive elastic contribution of the plantar aponeurosis. However, recent evidence suggests that active contraction of intrinsic foot muscles helps to modulate MLA compression in response to loading [3]. This study seeks to further elicit the contribution of intrinsic foot muscles to MLA stiffness during controlled loading of the lower limb. We hypothesised that blocking motor function of the intrinsic foot muscles would increase MLA compression in response to external forces.

METHODS

At time of submission six participants have been studied. Each had intramuscular EMG recorded from the flexor digitorum brevis (FDB) muscle while they sat and had controlled loads applied to their distal right thigh via a linear actuator. Applied forces ranged from 0.5 to 2.0 body weights and ground reaction forces (GRF) were measured by a force plate under the foot. Motion capture was also employed to capture foot motion and analysed to compute the angular displacement of the MLA in the sagittal plane of the foot during each loading cycle. Greater angular displacement of the MLA indicated greater MLA compression. This procedure was completed under two experimental conditions: Unblocked (UB), where the participant had normal foot function; and Blocked (BK), where a local anaesthetic injection was administered to the posterior tibial nerve at the level of the ankle to prevent intrinsic foot muscle contraction. A motor block was confirmed by incremental stimulation of the posterior tibial nerve to supramaximal levels, while recording the EMG signal. This was performed for both UB and BK, and M-wave recruitment curves were determined and compared for the two conditions (Fig 1B).

RESULTS AND DISCUSSION

An example of the FDB EMG response to loading cycles in both conditions is plotted in Fig. 1A and shows FDB being activated in response to load for UB (blue) and unable to activate under the same load in BK (red). The data also shows greater compression of the MLA (indicated by a greater increase in MLA angle) when the participant was unable to activate the intrinsic foot muscles in response to the same applied load (Fig 1A). A motor block was confirmed in BK by the lack of an M-wave response to supramaximal stimulation, contrasted with a normal recruitment curve in UB (Fig 1B).

In Fig 1C it can be observed that for both UB and B, the compression of the MLA increased with increasing magnitudes of GRF, in accordance with the compliant nature of the foot. Furthermore, a trend for increased MLA compression in the BK condition was observed in group data at all levels of loading (Fig 1C). This supports our hypothesis that removing the active contribution of intrinsic foot muscles would increase the compression of the foot in response to loading. Due to the ongoing nature of this work and small current sample, no tests have been run to statistically confirm these trends.

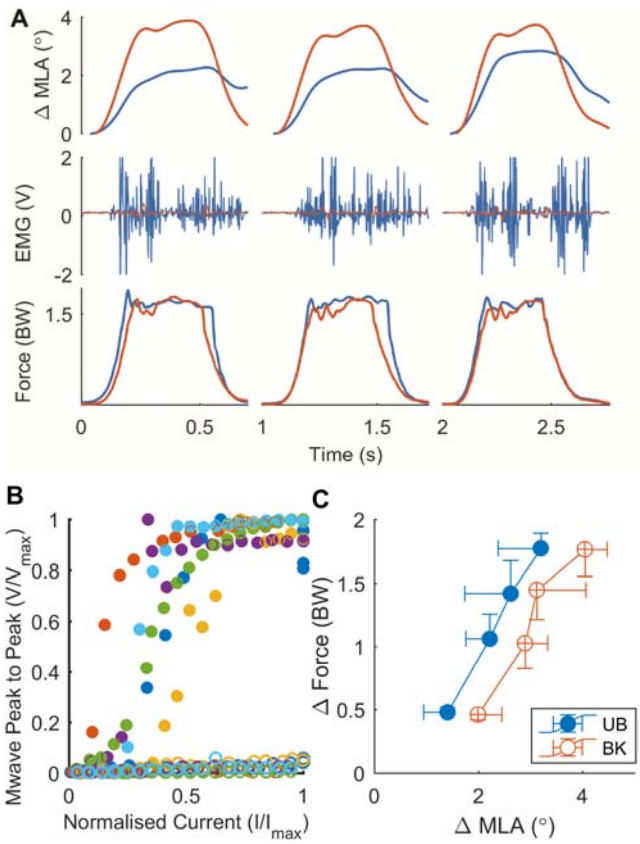

Figure 1: A) Exemplar MLA angle change, FDB electromyograms and vertical GRF traces recorded from 3 consecutive loading cycles at 1.5 BW (UB – blue, BK – red). B) M-wave recruitment curves for all participants (individual colours) for UB (filled) and BK (open) conditions. C) Group mean (± s.d.) change in MLA angle vs. ground reaction force magnitude (UB-blue, BK-red).

CONCLUSIONS

Preliminary data point toward supporting the notion that active contraction of the intrinsic foot muscles is important for controlling the compression of the foot that occurs when the leg is placed under load. Further data collection will provide more data to confirm these findings.

MEASUREMENT OF PLANTAR FASCIA ELASTICITY BY USING SHEAR WAVE ELASTOGRAPHY: SITE-DEPENDENT DIFFERENCES AND RELATIONS TO ANKLE JOINT POSITIONS

Hiroto Shiotani, Xiyao Shan, and Yasuo Kawakami
Waseda University
Corresponding author email: elpivote@asagi.waseda.jp

INTRODUCTION

The plantar fascia (PF) is a sheet of dense connective tissue extending from calcaneus to the proximal phalanx of each of the five toes. PF is considered to be a major contributor to the foot arch, but there have been only few studies directly measuring its morphological and mechanical properties *in vivo*. A previous study using ultrasonography revealed differences in thickness among different sites of PF [1]. One study attempted to evaluate PF elasticity using ultrasound strain elastography, and suggested that PF becomes compliant with aging and with plantar fasciitis [2]. Similar results were reported in a study using shear wave elastography [3]. However, in those studies the posture of subjects was not perfectly controlled, and the site-specificity of the elasticity of PF or its dependence on ankle joint positions has never been tested.

The purpose of this study was to measure PF elasticity by using shear wave elastography when the foot arch was under different tensions by changing ankle joint positions. It was hypothesized that shear modulus of PF would show site-dependent differences and increase as a function of passive ankle plantar flexion torque.

METHODS

Eight healthy males (22.0 ± 0.7 yr, 173.3 ± 5.8 cm, 62.6 ± 6.2 kg, ; mean ± SD) participated in this study. Each subject was seated with the right knee extended and the right ankle positioned at a 20˚, 10˚, 0˚, -10˚, and -20˚ angle (0 = neutral position, positive values for plantar flexion) while passive ankle plantar flexion torque was measured by a custom-made dynamometer. The thickness and shear modulus were measured by shear wave elastography (Aixplorer 2, SuperSonic Imagine, France) at two sites of PF: the site in the proximity to calcaneus (CAL) and the site below the navicular bone (NAV). Intraclass correlation coefficients of test-retest measures for the passive ankle plantar flexion torque (1.00), the thickness (0.96 at CAL and NAV), and shear moduli (0.98 at CAL and 1.00 at NAV, respectively) demonstrated reliability of the measurements. Two-way (2 sites × 5 ankle joint angles) repeated measures ANOVA with a Bonferroni post hoc test was performed. The level of significance was set at $p < 0.05$.

RESULTS AND DISCUSSION

The passive ankle plantar flexion torque was significantly increased by ankle dorsiflexion (4.6 ± 1.2 Nm at 20˚ to 39.0 ± 9.7 Nm at -20˚). The thickness of PF was significantly decreased by ankle dorsiflexion while it was significantly thicker in CAL (2.7 ± 0.3 mm at 20˚ to 2.4 ± 0.3 mm at -20˚) than NAV (1.9 ± 0.3 mm at 20˚ to 1.6 ± 0.2 mm at -20˚) at all ankle joint positions. The shear modulus was significantly increased by ankle dorsiflexion and it was significantly higher for CAL than NAV at all ankle joint positions (Figure 1).

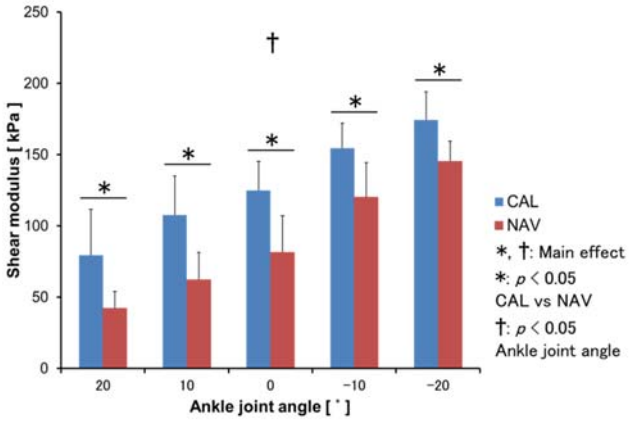

Figure 1: Shear modulus of plantar fascia close to calcaneus (CAL) and navicular (NAV) at different ankle joint positions

The values of shear modulus were much higher than in a previous study [3], and this discrepancy may be due to differences in the posture and fixation of ankle joint positions. The results of this study indicate that PF becomes thinner and stiffer with ankle dorsiflexion. This is possibly due to elongation of PF induced by the passive stress developed in the foot system. Furthermore, the elongation of PF implies that mechanical properties of the longitudinal arch of the foot can change by the passive stress. Differences between CAL and NAV in thickness and shear modulus clearly demonstrate site-specificity of these parameters. Our findings partly support the previous study [1] and further add to the inhomogeneity of PF elasticity. This feature of PF would reflect different degrees of resistance to the mechanical stress, which may be congruent with the distribution of loading on PF along its length during various exercises.

CONCLUSIONS

Shear modulus of the plantar fascia is higher in the site proximal to calcaneus than below the navicular bone, and at both sites, shear modulus of the plantar fascia increases with the increase of passive ankle plantar flexion torque by ankle dorsiflexion.

A SUBJECT-SPECIFIC FOOT MODEL FOR THE ESTIMATION OF SUBTALAR JOINT KINEMATICS

INTRODUCTION

Functional anatomy suggests that the ankle joint complex allows multiple degrees of freedom with relevant roles to be ascribed to tibiotalar (i.e. between tibia and talus) and subtalar (i.e. between talus and calcaneus) joints. Despite the difficulties associated to measuring the foot inversion/eversion motion, experimental data have been previously used to estimate the kinematics of the subtalar joint [1]. Anatomical models may increase our understanding of skeletal biomechanics by means of image-based personalisation. Small progress, however, has been made in this direction and most of current modelling approaches focus only on the ankle plantar/dorsiflexion, mainly due to the difficulties in identifying the joint geometrical parameters. This paper aims at providing a solution to overcome this problem. In particular, in this study we propose a methodology to include personalised tibiotalar and subtalar joints in a musculoskeletal model to quantify the movement of both joints during gait. Starting from 3D bone segmentations obtained from MR images, a morphological fitting was implemented, following an approach already validated in-vitro for 3D reconstructions obtained from surface-scanning [2].

METHODS

Within the context of a larger project, medical images and gait data have been collected from five children (4 females, 1 male, age: 14.0 ± 1.9 years, mass: 64 ± 15 kg, height: 159 ± 14 cm) affected by Juvenile Idiopathic Arthritis (JIA). For all patients, the disease had been inactive for at least six months. Bone geometries were segmented from 3D multi-echo fast field echo (mFFE) with water selective sequence (WATS) MRI in the sagittal plane. The bone geometries of ten feet were used to build subject-specific models using NMSBuilder [3].

The ankle-foot complex was split into four segments: toes (including phalanges), calcaneus (including metatarsals, mid-foot bones, and calcaneus), talus, and tibia plus fibula. The joints were defined using the following proximal and distal anatomical coordinate frames: tibiotalar joint articulating between tibia and talus, subtalar joint between talus and calcaneus. The tibiotalar joint axis was identified as the axis of a cylinder fitted to the talus surface. The subtalar joint axis was estimated from the talus morphology as the axis connecting the centers of the two spheres fitted to its anterior sustentaculum and posterior calcaneus facets [2].

Movement data were collected using a stereofotogrammetric system the markers were positioned according to the modified Oxford Foot Model [4] protocol. Data from a static trial were used to identify the pose of the subject's foot and measure the angle between the subtalar axis and the horizontal plane, in order to evaluate the modelling results against the dataset reported in [5]. Simulations of the gait trials were then run in OpenSim [6] and the inverse kinematics (IK) tool was used to estimate the tibiotalar and subtalar angles using a global optimisation approach. Articular ranges of motion were calculated for each subject as the average of the values recorded over a minimum of three gait trials.

RESULTS AND DISCUSSION

The inclination of the subtalar joint axis with respect to ground was found to vary in a range of 34°- 45° and to have an average value of 40° (±4°), in agreement with the 41° (± 9°) reported in the literature for in-vitro measurements [5].

The tibiotalar and subtalar kinematics estimated for one subject are plotted in Figure 1 as an example. For all the ten modelled feet, the maximum tracking errors outputted by the IK tool was smaller than 1cm for all considered frames, suggesting a good agreement between the modelled and the experimental data. The articular ranges were found to be 28.9° ± 6.2° for the tibiotalar joint and 18.1° ± 5.1° for the subtalar joint. These values compared well to previous results reported from in-vitro experimental studies on specimens from normal adults [7].

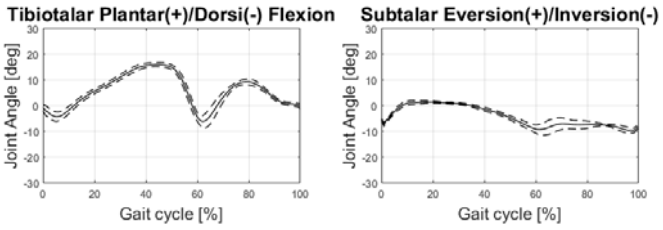

Figure 1: Kinematics of tibiotalar and subtalar joints normalized to the gait cycle for one subject. Average from four trials (solid line) ± 1SD (dotted lines).

CONCLUSIONS

This study showed the feasibility of using morphological fitting of MRI based subject-specific bone geometries to build juvenile patient-specific models of the foot. Obtained results were in excellent agreement with in-vitro studies from adult subjects. The proposed approach enables to personalize the anatomy of the tibiotalar and subtalar joints and discriminate their individual contribution to the kinematics of the ankle-foot complex, facilitating their adoption in the context of the quantification of lower limb biomechanics.

STRESS ANALYSIS OF INTACT ANKLE JOINT USING FINITE ELEMENT METHOD

[1] **Subrata Mondal**, Rajesh Ghosh
[1] School of Engineering, IIT Mandi
Corresponding author email: rajesh@iitmandi.ac.in

INTRODUCTION

Ankle arthritis causes swelling, pain, loss of function at the ankle joint. Total ankle replacement (TAR) has been the common method to overcome the problem related to ankle arthritis and fracture [1]. However, early and late failure of the ankle prosthesis is one of the major causes of concerns. Finite element analysis is one of the most efficient methods for evaluating the implant performance, pre-clinically. Before going to analyze an implanted ankle joint, it is necessary to develop a realistic 3-D FE model intact ankle that can predict accurate stress-strain distribution around ankle joint. The aim of the study to develop a realistic 3-D FE model of ankle joint with inclusion of all musculoskeletal loading and boundary condition, proper material property distribution.

METHODS

In order to obtain 3D FE model of intact ankle-joint, CT scan data sets of 35 year of a female was used. Cortical and cancellous bones were separated from CT-scan data sets, based on threshold value of density of 1.3 $g\ cm^{-3}$ as similar to earlier study. The cortical bone was considered as elastic, isotropic, homogenous, where young's modulus and poison's ratio were assigned as 19000 MPa and 0.3. The cancellous bone material property assigned as heterogeneous and material property was distributed using CT-scan data sets. Each ligament was represented with four parallel springs in order to distribute appropriate load transfer. Uniform thicknesses of cartilages were created between all the bones. Material properties for ligaments and cartilages were assigned as similar to earlier study [1]. Static loading condition was considered for the present analysis. Achilles tendon force and reaction forces were set, during balance standing position. Surface to surface contact simulation was performed to simulate the interaction between bone-to-cartilage and cartilage-to-bone, where frictionless contact was assumed to represent wet lubricating surface. For the convergence of the non-linear solution a normal contact stiffness of 10 $N\ mm^{-1}$ and a penetration factor of 0.1 were chosen. The FE model is shown in Figure 1.

RESULTS AND DISCUSSION

The effect of muscle forces, ligaments, and material properties of bone was analyzed in this present study. The maximum stress was observed in the tibia cortical bone, where stresses are ranging from 1 to 7 MPa. In the case of same loading sceneario, the stress in the talus cortical bone was observed in between 1 to 3 MPa. In the tibia cancellous bone stresses ranging from 0.1 to 2 MPa, whereas for the talus cancellous bone it was observed from 0.1 to 1.5 MPa. It was observed that, due to the Tibiocalcaneal (TiCa) ligament, the deviation in von Mises stress of tibia cortical bone was found to be more (6.78%) than the other ligaments. For the talus cortical bone, deviation in stress (1.6%) was observed due to the anterior tibiotalar (ATiTL), Posterior tibiotalar (PTiTL) ligaments. The analysis result showed that the ligaments play a very important role in stress distribution across the bones. It was observed that, range of maximum stress was reduced considerably 1 to 5 MPa for the tibia cortical bone, when the Achilles tendon force was not included. There is no significant deviation in stress distribution was observed in the talus cortical bone due to the inclusion of Achilles tendon force.

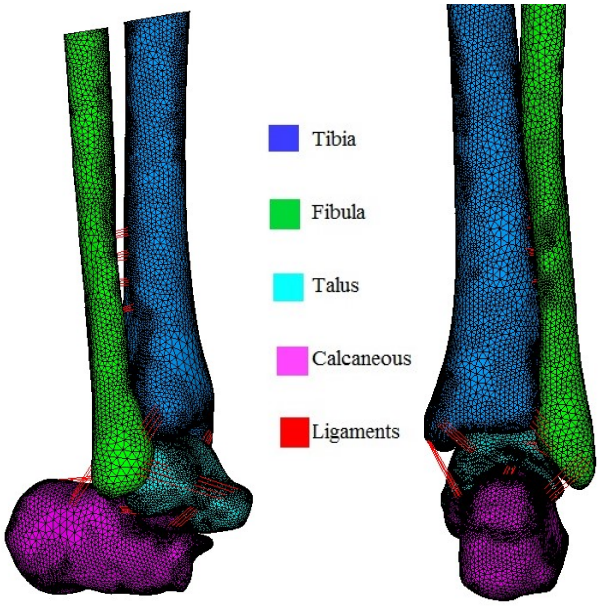

Figure 1: Three dimensional finite element model of the ankle joint

CONCLUSIONS

3-D FE model of intact ankle joint was developed. Model comprises bones (tibia, fibula, talus, and calcaneous), muscle forces, ligaments, and cartilages. Based on the present study, it may conclude that present model can accurately predict stress-strain distribution across the ankle joint and that can be use further for evaluation of implanted ankle joint.

ASSOCIATIONS OF FOOT BIOMECHANICS TO KNEE PAIN IN WOMEN WITH JOINT HYPERMOBILITY SYNDROME

[1] Rania Almeheyawi, [1]Sara SP Marreiros and [1]Jody Riskowski
[1]Glasgow Caledonian University
Corresponding author email: Jody.Riskowki@gcu.ac.uk

INTRODUCTION

Patients with joint hypermobility syndrome (JHS) have an increased risk of knee but not ankle injuries [1]. Although joint laxity is assumed to be an underlying cause of injuries, research also suggests that foot biomechanics may be a latent factor in lower extremity conditions, such as anterior cruciate ligament deficiency and patellar femoral pain. Therefore, the purpose of this study was to evaluate the foot biomechanics in participants with and without JHS and to evaluate the associations of foot biomechanics to knee pain.

METHODS

There were 35 female participants with JHS (age=32.7±8.0 years; BMI=27.8±5.9 kg/m^2) and 17 age-matched healthy women (age=33.4±7.8 years; BMI=23.6±3.0 kg/m^2). Five barefoot walking trials at a self-selected pace were used to collect Footscan® data (RSscan Lab Ltd, Belgium) on the participants' most symptomatic lower limb in those with JHS or dominant lower limb (defined as limb used to kick a soccer ball) in the control participants. Pedobarographic data were sampled at 384Hz and were continuously calibrated using force plate data (model 9286BA, Kistler, Switzerland).

To obtain regional pressure and vertical reaction forces the foot scan data were masked into eight regions: medial and lateral rearfoot, midfoot and forefoot, hallux and lesser toes (toes 2-5). Data from the five foot scans and trials, including gait speed, were averaged.

Participants were queried on average knee pain over the past seven days in their most symptomatic limb using a 0-100mm visual analog scale (VAS).

Means and standard deviations of participant knee pain and foot biomechanics were calculated for each group. Student's t-tests were used to evaluate demographic and biomechanical variables between groups, and a linear regression was used to determine the association between the regional peak pressures and maximum forces to knee pain, adjusting for gait speed and BMI. Alpha was set to $p \leq 0.05$.

RESULTS AND DISCUSSION

Participants with JHS had a significantly higher BMI (p=0.027) and walked significantly slower than their counterparts without JHS (1.06±0.20 m/s v 1.22±0.15 m/s, p=0.038). Participant with JHS had a significantly longer stance periods compared those without JHS, even after accounting for gait speed and BMI (0.48±0.08 s v 0.40±0.08 s, p=0.040).

Average knee pain was significantly higher in the JHS group compared to the control group (100mm VAS: 35.0±24.9 v 0.3±1.1, p<0.001).

After adjustment, individuals with JHS had higher medial midfoot and forefoot pressures (p=0.004-0.035) and forces (p=0.002-0.047) compared to those without JHS (Figure 1).

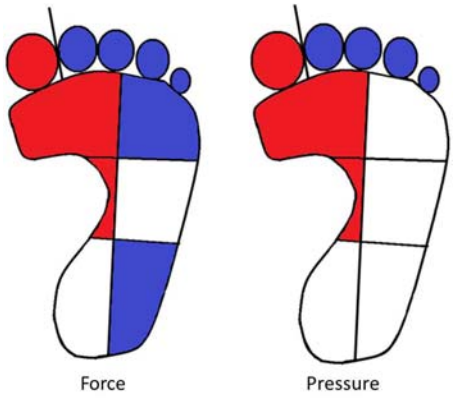

Figure 1: Differences in regional maximal vertical force and peak pressure between participants with and without JHS. Red regions indicate significantly higher pressure or force, blue regions indicate significantly lower pressure or force, and white regions indicate no signification difference, relative to the control participants.

Knee pain between groups was strongly associated with increased forces and pressures through the medial midfoot (p=0.041), medial forefoot (p=0.030), and hallux (p=0.014) and reduced lateral rearfoot force (p=0.049).

CONCLUSIONS

Plantar pressure and force profiles the participants with JHS displayed are consistent a more pes planus foot type. The medial excessive loading noted with JHS was also strongly associated with knee pain, in line with prior studies [2].

Given the connections between foot type and risk of lower extremity ailments [1,2], the lower arch foot type seen with JHS suggests these patients may be at risk for knee injuries, pain or knee osteoarthritis. The cross-sectional nature of this study does not allow for a cause-effect relationship to be examined; however, the implications of this research suggest that those with JHS may have altered foot biomechanics that may play a role in the development of knee complications.

ASSOCIATIONS OF KNEE ADDUCTION MOMENTS AND KNEE INSTABILITY IN WOMEN WITH JOINT HYPERMOBILITY SYNDROME WITH AND WITHOUT KNEE INSTABILITY

[1] **Sara SP Marreiros**, [1]Jody Riskowski and [1]Martijn Steultjens
[1]Glasgow Caledonian University
Corresponding author email: sara.marreiros@gcu.ac.uk

INTRODUCTION

Patients with joint hypermobility syndrome (JHS) are at an increased risk of developing knee osteoarthritis (KOA) [1]. Although the cause of the increased risk for KOA is unknown, aberrant loading and a high external knee adduction moment (KAM) or episodes of knee buckling associated with knee instability may play a role. As both high KAM and instability are associated with JHS, the mechanism of KOA development is unclear. Therefore, the purpose of this study was to evaluate KAM in women with JHS with and without self-reported knee instability and in healthy women.

METHODS

Kinematic and kinetic data from 46 female participants with JHS (age=32.7±8.2 years; BMI=27.9±5.7 $kg \cdot m^{-2}$) and 23 age-matched healthy women (age=33.5±8.0 years; BMI=23.8±3.1 $kg \cdot m^{-2}$) were collected for a minimum of 5 trials each of level walking, ramp ascending and ramp descending at a self-selected speed. Participants with JHS were subdivided into (1) no self-reported knee instability (JHS-NI, n=23) and (2) self-reported knee instability (JHS-I, n=23). The self-reported most symptomatic knee was tested for those with JHS and the dominant limb (defined as the limb used to kick a football) for controls.

Gait data were collected using a 14-camera system (Qualisys, 128 Hz) with an embedded forceplate (Kistler, 2560 Hz). Marker trajectories and force data were filtered with a low pass 4th order Butterworth filter at 6Hz and 25Hz respectively. External knee adduction moment (KAM) was calculated during the stance phase (vertical force threshold of 20N) in OpenSim v3.3 [2] through inverse dynamics using a subject-scaled modified version of the musculoskeletal model Gait2392 [3] to allow knee adduction-abduction and internal-external rotation.

First and second KAM peaks and KAM impulse (total area under the curve) were calculated and normalized for body weight and height (%BW×Ht). ANOVAs with Tukey's post-hoc test evaluated differences in KAM first and second peak and impulse, controlled for walking velocity, between groups. Alpha was set to $p \leq 0.05$.

RESULTS AND DISCUSSION

Significant lower first peak KAM (mean±standard deviation) was obtained for the JHS-I group compared to the control group during level walking (2.22±0.42 v 2.75±0.58 [p=0.001]), ramp ascent (1.90±0.59 v 2.24±0.45 [0.05]), and ramp descent (1.97±0.83 v 2.55±0.76 [0.01]), and for the JHS-NI group compared with the control group (2.40±0.50 v 2.75±0.58 [0.03]) during level walking. No significant differences were obtained between JHS-NI and JHS-I in first peak KAM.

Significant lower second peak KAM was obtained during ramp ascend for the JHS-I group compared with both the control group (1.78±0.79 v 2.45±0.69 [0.02]) and the JHS-NI group (1.78±0.79 v 2.37±0.68 [0.02]). No significant differences in second peak KAM were obtained in any other activity or combinations of groups.

Significant lower KAM impulse was obtained for the JHS-I group compared with the JHS-NI group (1.01±0.56 v 1.25±0.46 [0.02]) during ramp ascent. No significant differences in KAM impulse were obtained in any other activity or combinations of groups.

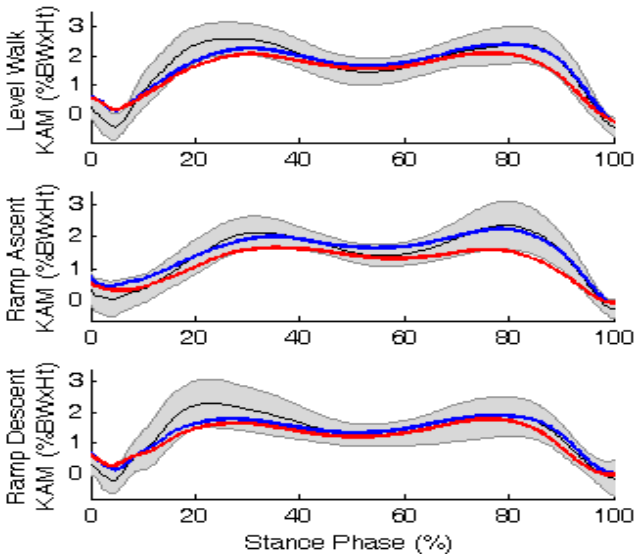

Figure 1: External knee adduction moment (KAM) during level walking, ramp ascent and ramp descent (top to bottom respectively). Mean and standard deviation in control group (grey), mean for JHS-NI (blue) and mean for JHS-I (red).

CONCLUSIONS

Participants with JHS and self-reported knee instability have an overall reduction of first peak KAM during level walk and ramp ascent and descent. A reduction of the second peak KAM and KAM impulse during ramp ascent in those with JHS compared to controls suggests an external KAM may not be a predictor of KOA or the mechanism of action for the increased risk of knee osteoarthritis.

EFFECT OF POSTERIOR ROOT TEAR OF THE LATERAL MENISCUS ON THE ARTICULAR CARTILAGE DURING THE STANCE PHASE OF GAIT CYCLE: A FINITE-ELEMENT STUDY

INTRODUCTION

The intact circumferential fibers of the menisci are crucial for the normal functioning of the human knee joint. Complete radial tears close to the posterior root of the meniscus can affect the circumferential integrity and result in meniscus extrusion, overloading and damages to articular cartilage, formation of osteophyte, and joint space narrowing [1]. Many cases involving root avulsions and complete radial tears near the root have been reported in Asia caused by high knee flexion activities like sitting on the floor and squatting [2]. Acute radial tears near the medial meniscus posterior root are difficult to repair and often leads to arthritis in the medial compartment [2]. Radial tears millimeters away from the posterior root of the lateral meniscus were given less attention when compared with the medial meniscus. A comparative study on the influence of lateral meniscus radial tears and total lateral meniscectomy on biomechanical behavior of human knee joint for the complete stance phase of gait cycle has not been reported yet. Hence, the goal of this study was to assess the effect of a complete radial tear near the lateral meniscus root and total lateral meniscectomy on contact pressures on the tibial cartilage and meniscal displacement using a validated finite element (FE) model of the knee joint.

METHODS

A 3D FE model of the subject-specific knee joint was developed using the knee joint substructures inherited from the Open Knee project [3] and validated with the experimental measurements in the literature. Menisci and ligaments were modeled as transversely isotropic nearly incompressible neo-Hookean material; cartilages were modeled as linear elastic material, and the bony structures were modeled to behave as rigid bodies [4]. The bones were meshed with tetrahedral elements and the soft tissues were meshed with hexahedral elements. The contact surfaces were modeled using frictionless sliding contact elements. Mesh sensitivity analysis was performed to ensure the model predictions were not affected by the mesh size. The FE simulations were performed for the complete stance phase of gait cycle using knee joint models with intact lateral meniscus, total lateral meniscectomy, and a complete radial tear 3 mm from the lateral meniscus posterior root (Figure 1a). The contact pressures on the tibial cartilage and meniscus displacement were determined and compared as a function of gait.

RESULTS AND DISCUSSION

Figure 1b shows the maximum contact pressures induced on the lateral tibial plateau. Radial meniscal tear increased contact pressures on the lateral tibial cartilage by 35% at 21% of gait cycle (mid-stance phase) and by 37% at 55% of gait cycle (pre-swing phase). At 21% of gait cycle and 55% of gait cycle, total lateral meniscectomy increased contact pressures on the lateral tibial cartilage by 35% and 42%, respectively. Compared with the intact knee model, an increase in meniscal displacement by 90% and 94% is observed for the knee joint model with a radial meniscal tear at 5% (loading response phase) and 33% (terminal stance phase) of gait cycle, respectively (Figure 1c). The results show that a complete radial tear near the posterior root of the lateral meniscus results in a functional lateral meniscectomy. These critical findings drive to presume that strategies for repair of posterior root tears of the lateral meniscus should be developed and evaluated to reduce the progression rate or delay the onset of knee osteoarthritis.

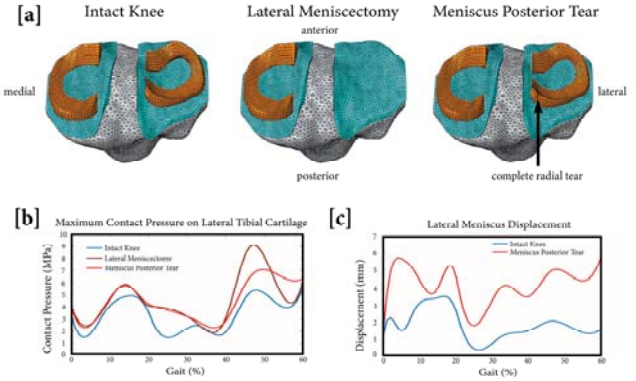

Figure 1: (a) knee joint models with intact lateral meniscus, total lateral meniscectomy and a radial tear 3 mm from the lateral meniscus posterior root attachment site, (b) peak contact pressures on lateral tibial plateau, and (c) average lateral meniscus displacement in the axial plane

CONCLUSIONS

The intact posterior meniscal horn attachment is crucial for maintaining the biomechanical integrity of the knee joint. This study demonstrated the significant effects of a complete radial tear near the lateral meniscus posterior root attachment site on knee joint contact mechanics and showed this type of tear is similar to total lateral meniscectomy in terms of its effect on tibial cartilage contact pressure and meniscus extrusion. The FE model developed in this study will be utilized to investigate the biomechanical effects for repair of posterior root tears of the lateral meniscus.

INTRODUCTION

A lateral thrust indicates dynamic instability of the knee in the frontal plane and an acutely increased stress in the medial compartment during the initial stance phase of walking has known as the risk factor for knee OA progression [1]. The presences of lateral thrust have associated several factors such as age, BMI, knee extensor strength and static malalignment [1]. Especially, static malalignment might reflect the pathological change in medial compartment including of capsule, ligaments, and meniscus.

Pathological medial meniscus such as a degenerative tear leads to medial meniscus extrusion (MME). On this displacement of medial meniscus, the previous study has been reported to relate the incidence of lateral thrust in knee OA [2]. However, there is few study to clear direct relationship between lateral thrust and MME. To clear the relevance, MME might provide with useful information about its elucidation of the mechanism. The aim of this study was to investigate the relationship between lateral thrust and MME.

METHODS

This cross-sectional study included 21 knees from 16 patients with diagnosed the knee OA (sex, 13 females; mean age, 73.6 years). Kellgren-Lawrence grading scale (K/L) and femorotibial angle (FTA) were evaluated using radiography (K/LII: 13, III: 8; FTA: 178± 2.3). MME was measured using the ultrasonography device (Hivision Avius, Hitachi ALOKA, Japan) with a 6-18 Hz linear-array probe. The distance from the cortex on the medial tibial plateau to the outermost edge of the medial meniscus measured as the value of the MME using the ultrasound. The measurements were performed in two conditions: supine (non-weight bearing; NWB) and unipedal standing (weight bearing; WB). The average values of three measurements for each condition were used in the statistical analyses. The differences in the values of MME between the WB and NWB condition were calculated and shown as ΔMME.

Lateral thrust was assessed using two triaxial accelerometers (WAA-010, ATR-Promotions, Japan) during 10m walking at a comfortable speed with a sampling frequency at 100 Hz. The devices were fixed on the tibial tubercles and foot by an elastic bandage. A lateral thrust was defined as the first lateral acceleration peak (LP) after the heel strike according to the vertical acceleration of the foot, and the average LP values for five steps excluded first five was used for analysis.

All statistical analyses were conducted using the SPSS software program (statistics ver19, IBM, Japan). Univariate analysis was performed to calculate Pearson's correlation coefficient or Spearman's rank correlation coefficient between the FP, MME and ΔMME for each condition and K/L grade. The critical value for significance was set at $p < 0.05$.

RESULTS AND DISCUSSION

The mean values of the MME in WB condition significantly increased when compared with that in NWB condition (NWB: 4.0 ± 1.6 mm, WB: 4.9 ± 1.8 mm; $p < 0.05$).
There were significant positive correlations between FP and MME in WB condition and ΔMME, but not that in NWB condition. Each K/L grade, a moderate positive correlation was observed between FP and ΔMME in K/L II, but not that in K/L III (Table 1).

Table 1 Associations between FP and MME in each K/L grade

	MME (NWB)	MME (WB)	ΔMME
OA	0.40	0.55*	0.61*
K/L II	0.12	0.42	0.75*
K/L III	0.12	0.71	-0.25

Values represent significant correlation coefficient with FP,
* $p < 0.05$.

In the present study, a positive correlation was observed between ΔMME and FP in mild OA cases such as K/L II, but not in moderate OA cases such as K/L III. This result supported the previous study that the incidence of lateral thrust related to MME in the early stage of knee OA [2]. Additionally, Thawait *et al.* have demonstrated that the ΔMME in patients with knee OA was significantly higher than that in healthy individual [3], suggesting that the medial meniscus in knee OA has abnormal movement during weight bearing. Therefore, this abnormal movement might reflect the characteristic motion of knee OA.

CONCLUSIONS

The present study showed that the association between ΔMME and the incidence of lateral thrust in mild knee OA. Extruded meniscus by WB is one of the related factors as the incidence of lateral thrust in the early stage of knee OA.

INTRODUCTION

Shoulder pain is one of the most common pain syndromes. However, the cause of many shoulder conditions has not been studied adequately [1]. Over the past decade, a number of experimental and computational studies have been conducted to improve our understanding of the in vivo functioning of the shoulder complex, including computer simulation studies using finite element (FE) method. However, most of the FE shoulder models developed were over-simplified due to the high complexity of the shoulder musculoskeletal system, and the in vivo biomechanical conditions of the shoulder complex were not appropriately represented. The objective of this study is to develop and validate a large-scale subject-specific FE model of the shoulder complex to investigate the in vivo biomechanical functioning of the shoulder joint using a novel integrated modelling technique by combining three-dimensional (3D) motion analysis, multi-body musculoskeletal modelling and medical imaging based FE modelling (see Figure 1).

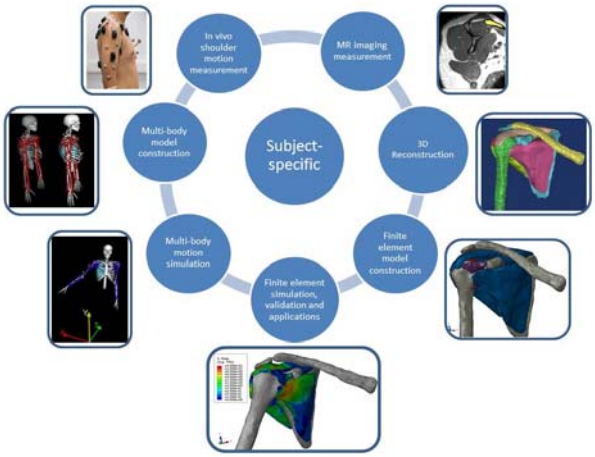

Figure 1. The integrated subject-specific modelling framework used in this study

METHODS

First, the in vivo shoulder motions during different motor tasks were collected using a 3D motion analysis system. Thereafter, a multi-body shoulder musculoskeletal model was constructed using OpenSim software to estimate the in vivo subject-specific muscle forces defined by the measured motions. Driven by those estimated in vivo muscle loads, a subject-specific FE shoulder model with detailed representation of all the major bones, muscles, tendons, ligaments, and cartilages etc. was carefully constructed based on the high-resolution MR images of the same subject used in the shoulder motion measurements. Quasi-static FE analysis was conducted to simulate the in vivo scapular abduction. The calculated bone-on-bone contact forces and the humeral head superior movement were validated against the literature data. Finally, the FE model was used to investigate the biomechanical effect of rotator cuff tears on the glenohumeral joint stability during the propagation of the tears. The propagation of the tears was defined as initialling from the anterior side of the bone-tendon insertion site of the supraspinatus tendon and propagating posteroinferiorly until full tear in all three posterior rotator tendons i.e. supraspinatus, infraspinatus and teres minor tendons. A novel integrative stability index was proposed and used to quantitatively assess the glenohumeral joint stability.

RESULTS AND DISCUSSION

The calculated bone-on-bone contact forces and humeral head superior movement by the FE simulations are in very good agreement with previous experimental and computational data. In addition, the simulated stress distributions were comparable to those of previous FE studies. In the rotator cuff tears FE simulations, the calculated superior-anterior movement of the humeral head relative to the glenoid was in good agreement with the phenomenon observed in medical practice and scientific reports [2]. The glenohumeral joint stability index decreases from 100% to 0.18% from intact to full tear.

CONCLUSIONS

A large-scale subject-specific FE model of the human shoulder complex has been constructed and rigorously validated and also successfully used to investigate the biomechanical effect of rotator cuff tears on glenohumeral joint stability. It was found that: (1) the stability of the glenohumeral joint generally decreases with increasing tear sizes; (2) smaller sizes of tears do not significantly affect the joint stability, in addition, the critical tear size in which the influence of the rotator cuff tears becomes severe was determined as the half torn of the infraspinatus with the simultaneous completely torn of the supraspinatus tendon; and (3) the dominant factor in which the rotator cuff tear destabilises the glenohumeral joint is the change of direction of the bone-on-bone force.

INTRODUCTION

The human foot is a complex structure comprising 28 bones and 25 joints that are configured to play multiple crucial roles in attenuating ground impacts, supporting against gravity, providing mobility and stability in various surfaces during varying degrees of weight bearing, and transmitting or generating propulsive power during locomotion [1].

Biomechanical analyses that provide information on the stress distribution within the ankle joint will help provide insight into the physiological behavior, allowing quantification of the interaction between the different structures. For the past few decades, substantial efforts has been put into quantifying the intra-articular contact stress distributions, but the validity of cadaver studies of human foot and ankle biomechanics is dependent on the ability to accurately simulate physiologic kinematics, including the geometric complexity of the articulating members.

Numerical modelling has the potential to provide an effective tool for the analysis of ankle joint mechanics and stability, and will enable the understanding of the various geometric and mechanical factors that play a crucial role in the joint. Furthermore, a patient specific quantitative contact stress information would be advantageous in predicting the efficiency of therapeutic procedures, both pharmocological and surgical.

METHODS

Starting from Computed Tomography (CT) image scans of a subject with no congenital or acquired pathology, the ankle geometry is segmented as a castellated surface using open source software 3DSlicer; subsequently the bones are smoothed and decimated. The cartilage is included as a uniform thickness extruded layer. A high-resolution Cartesian mesh, with predominately hexahedral cells and a minority of polyhedral cells in the transition region, has been generated using open-source software cfMesh. The bone Young's modulus distribution is assigned in the model based on the CT image Hounsfield intensities (Figure 1). Gait data and 2D radiography images of the same subject is obtained and used to physiologically position the tibia relative to the foot in the model. Visual alignment of the surfaces to 2D images as well as the angles between tibia, talus, calcaneous are used to position the bones in the model. The inferior surface of the foot is fixed to the ground (zero displacement), and the superior tibia surface is displaced in the tibial axial direction into the talus in order to obtain the required joint forces. The remaining surfaces are specified as traction free. The stance phase of the gait cycle is simulated using a cell-centred Finite Volume Method implemented in open-source software OpenFOAM.

Figure 1: Ankle Joint Model Material Distribution (Cortical bone in green and Cancellous bone in blue)

RESULTS AND DISCUSSION

The contact pressure distributions have been analysed in the mid-stance, heel-strike and toe-off phases gait. It can be observed that the peak stresses were found to occur in the lateral region for heel strike, anterior for mid-stance and posterior medial for toe-off. Quantitative analysis of peak stresses and areas of contact has been performed

In order to determine the sensitivity of the relative positioning of the bones with respect to each other, the position of tibia is shifted relative to the talus in the x-y plane and stress analysis has been performed. The effect of cartilage thickness has also been examined. As expected, it has been found that there is an inverse relationship between the cartilage thickness and maximum contact pressure.

CONCLUSIONS

The natural ankle joint has been numerically analysed using the Finite Volume Method over the stance phase of the gait cycle; the predicted contact pressures are consistent with previous studies. The sensitivity analysis highlights the importance of the relative positioning of the articulating bones on the intra articular pressure distribution. Further improvement of the current model will be focused on examining the effect of implant inclusion.

INTRODUCTION

Pre-operative, lower extremity analysis for total hip and knee arthroplasty is a critical aspect for successful surgery and most importantly, patient satisfaction [1]. Supine analysis, typically MRI and CT scans, are commonly adopted as pre-operative sources of information. The effectiveness of these tools, however, might be limited since observed joint alignment (Hip-knee-ankle angle, HKA) might not be comparable to everyday living [2]. Weight bearing analysis, on the contrary, typically consists of invasive measures such as standing radiographs and only recently EOS has been introduced as a possible low-dose alternative [3, 4]. However, clinical viability of this tool is still limited. Ultrasound aided motion capture might provide a method to locate internal landmarks, which could be used for radiation free estimates of the HKA in both standing and supine positions [5]. This study aimed to validate an ultrasound integrated motion capture system, OrthoPilot® (Aesculap, Tuttlingen), by assessing its accuracy and reliability on a phantom and on healthy subjects in standing and supine positions.

METHODS

The accuracy and reliability of the system was assessed through inter and intra-operator tests on a phantom and on healthy subjects. Phantom measurements were performed to gauge whether the system could perform accurately with respect to known measurements for 6 variables (varus/valgus, flexion/extension, femur and tibia length, and femur and tibia torsion). Four operators were asked to take complete measurements of the phantom at -15°, -10°, -5°, 0°, 5°, 10° and 15° (-ve valgus, +ve varus) for a mimicked left leg. All processes are integrated into the device, meaning the immediate post-processing involves geometric evaluation of each ultrasound image (circle fitting of the femoral head for example) which outputs real time summaries of the results. For subject analysis, supine examination took place across a bed and foot rest. Standing examination was conducted with feet just over shoulder width apart. Three operators repeated all measurements three times on three male subjects on both legs with body mass indexes (BMI) of 19.9kg/m², 26.2 kg/m² and 29.9 kg/m², respectively, and age 27.7±1.5.

RESULTS AND DISCUSSION

OrthoPilot can accurately and reliably detect both angles and lengths when used on a phantom. Measurements on the phantom were consistent across the operators and also intra-operatively. Varus/valgus mean error across the 4 operators with respect to the 7 chosen angles was 0.4°±0.3°. The remaining variables were all slightly under estimated. Flexion/extension (set at 0°) and was estimated at -0.5°±0.1° across the operators. Femur and tibia measurements (actual lengths 510mm and 338mm respectively) for all operators (506±1.1mm and 337±0.7mm respectively). Femur and tibia torsion values (set at 37° and 89° respectively) were consistent across all operators (34.8°±0.5° and 87.3°±0.6°).

Inter-operator results on the three subjects are shown in table 1. Results were consistent for the three subjects, irrespective of their different BMIs. For all measures of length, in standing and supine, ICC values were > 0.99. For measures depending on these length vectors (varus/valgus and flexion/extension), in standing and supine, ICC values were > 0.93. For measures of the torsions, except supine femur torsion measurements, the ICC drops below 0.90 to as low as 0.65.

Table 1. Inter-operator results across three healthy subjects

Variable	Pos.	Average[¥]	ICC (95% CI) [§]	P-value[¢]
Varus/ Valgus (°)	Stan.	0.2 ± 2.8	0.97 (0.86 – 0.99)	0.61
	Sup.	0.3 ± 1.8	0.93 (0.71 – 0.99)	0.63
Flexion/ Extension (°)	Stan.	3.6 ± 8.1	0.99 (0.97 – 0.99)	0.39
	Sup.	1.7 ± 4.2	0.99 (0.97 – 0.99)	0.80
Femur Length (mm)	Stan.	456 ± 35	0.99 (0.99 – 1.00)	0.66
	Sup.	455 ± 33	0.99 (0.99 – 1.00)	0.49
Tibia Length (mm)	Stan.	428 ± 22	0.99 (0.98 – 0.99)	0.55
	Sup.	425 ± 21	0.99 (0.98 – 0.99)	0.17
Femur Torsion (°)	Stan.	31.7 ± 12.2	0.68 (-0.09 – 0.95)	0.43
	Sup.	26.2 ± 13.3	0.95 (0.78 – 0.99)	0.74
Tibia Torsion (°)	Stan.	28.5 ± 10.4	0.69 (-0.61 – 0.96)	0.17
	Sup.	33.5 ± 8.9	0.65 (-0.35 – 0.95)	0.78

[¥]Mean and SD across all operators. [§]Inter-rater correlation coefficient (ICC) and 95% confidence intervals (CI). [¢]One-way ANOVA values for the mean SD of the operators. Significant difference (<0.05).

CONCLUSIONS

OrthoPilot is able to reliably detect certain lower extremity variables in a quick and efficient manner. It has shown to be effective for standing analysis which warrants further experimentation to quantify the differences between supine and weight bearing positions in both healthy individuals and patients with knee osteo-arthritis. Further validation should include comparison with standing radiographs.

SIMULATING THE COMBINED EFFECT OF MUSCLE FATIGUE AND MUSCLE WEAKNESS IN REVERSE SHOULDER ARTHROPLASTY: MODIFICATIONS TO THE NEWCASTLE SHOULDER MODEL

INTRODUCTION

The incorporation of existing muscle deficiency models into a biomechanical shoulder model would make it possible to predict the changes to shoulder functionality as a result of said deficiencies. This type of modification is of particular interest for the optimization of reverse shoulder arthroplasty (RSA) as recipients of the prosthesis often exhibit signs of muscular deficiency, either due to pre-existing conditions or as a result of the shoulder replacement [1]. The aim of this study was to incorporate muscle fatigue and weakness into the Newcastle Shoulder Model (NSM) and evaluate the effect of these deficiencies on the force generating capabilities of the muscles in reversed shoulders.

METHODS

The NSM, in its original state, represents a healthy shoulder joint and includes 31 muscles and 3 ligaments of the upper extremity [2]. The NSM makes use of an adapted Hill muscle model [3] to derive the limits of the force generating capacity of each muscle. These limits are then used by a load-sharing optimization algorithm to calculate the muscle force to simulate a predefined motion using an inverse dynamic approach. The NSM's Hill muscle model was modified with the capability of simulating muscle weakness and/or muscle fatigue. Muscle weakness parameters were adapted from Thelen, 2003 [4] and applied to all 31 muscles. Key weakness parameters included a 30% reduction in maximum force generation capability and a 20% reduction in maximum muscle contraction velocity. Muscle fatigue was incorporated into the NSM using a three-compartment muscle fatigue model [5]. This model assumed that the muscle fibres must be in one of three states: resting (*R*), active (*A*) or fatigued (*F*). The fatigue model iteratively calculated the proportions of these states during each step of the motion (values calculated during the i^{th} step were used as the input to the $i+1^{th}$ step) and the corresponding non-fatigued factor (*1-F*) was applied to the maximum force generating capabilities of 11 muscles that cross the glenohumeral joint.

A virtual RSA on the NSM was performed in MIMICS (Materialise NV, Belgium) using the Biomet Comprehensive Reverse Shoulder System (Biomet, USA). A full thickness tear of the rotator cuff was also simulated during the virtual surgery. The forces exerted by the deltoid, trapezius, latissimus dorsi and pectoralis major muscles were then estimated during humeral elevation in the frontal plane from 0° to 150° (abduction) using four muscle configurations: 1) healthy non-fatigable muscles (HNF), 2) healthy fatigable muscles (HF), 3) weak non-fatigable muscles (WNF), and 4) weak fatigable (WF) muscles. $A = R = 0.45$ and $F = 0.1$ (non-fatigued factor= 0.9) were selected as the initial conditions for configurations 3 and 4 to demonstrate the effect of fatigue during abduction.

RESULTS AND DISCUSSION

The muscles most affected by the change in muscle configuration were the deltoid (all three compartments) and the pectoralis major, the thoracic compartment (PMT) in particular (Table 1). The average middle deltoid force decreased in all three deficient configurations, whereas average anterior and posterior deltoid and PMT forces increased (Table 1). While these four muscles responded to the deficiencies differently (either increasing or decreasing exertion), it was evident that weakness had a greater net effect on muscle exertion compared to fatigue.

Table 1: Average muscle forces exerted (in N) during abduction for all muscle configurations. Bold numbers represent the percentage change in force compared to HNF).

Muscle	HNF	HF	WNF	WF
Ant. Delt.	42.7	44.5 (**4**)	46.1 (**8**)	63.9 (**50**)
Mid. Delt.	111.8	99.2 (**-11**)	87.5 (**-22**)	70.7 (**-37**)
Post. Delt.	34.7	50.3 (**45**)	56.0 (**61**)	56.2 (**62**)
Trap. Clav.	2.1	2.1 (**0**)	1.7 (**-16**)	1.3 (**-38**)
Trap. Scap.	112	118.3 (**6**)	119.1 (**6**)	119.9 (**7**)
Lat. Dorsi	20.9	21.9 (**5**)	18.8 (**-10**)	14.9 (**-29**)
Pec. Maj. Clav.	29.5	30.7 (**4**)	31.7 (**8**)	21.2 (**-28**)
Pec Maj. Thor.	69.1	78.5 (**14**)	87.4 (**27**)	137.6 (**99**)

Deltoid deficiency is a common post-RSA problem. This study was able to give further insights into how the compartments of deltoid are affected. Furthermore, the model predicted increased force levels from anterior and posterior deltoid and PMT muscles to compensate for reduced functionality of the middle deltoid muscle. An on-going EMG study investigating muscle fatigue in healthy shoulders will be used to support the results of this study. If the experiments corroborate these results, they have potential to impact RSA design and/or surgical technique and/or deltoid-targeted post-surgical rehabilitation techniques in order to increase the success rate of RSA.

CONCLUSIONS

The incorporation of muscle deficiencies in the NSM has the potential to provide deeper insight into the behaviour of reversed shoulders. This may provide more realistic platform upon which RSA can be evaluated and optimized.

INTRODUCTION

Musculoskeletal modeling (MSKM) provides insights into the normal or abnormal biomechanical behavior of human musculoskeletal system [1]. However, assumptions made while developing such models make them generic and limit their clinical utility. Shoulder MSKM faces a huge challenge of subject specificity, in particular, muscle insertion sites are always almost approximated, considerably affecting the muscle force and moment arm predictions [2]. Statistical shape modeling (SSM), uses the statistical variability of the 3D structures for applications such as registration (automatic segmentation) to the new imaging data, predicting missing shape, evaluating 3D bone morphological characteristics etc. This study focuses on using the SSMs ability to incorporate statistical variability for predicting subject specific muscle regions. Here we report the feasibility of an SSM based pipeline to predict muscle insertion regions on human scapular bone to develop subject-specific shoulder MSKM.

METHODS

Scapula SSM built using iterative median closest point – Gaussian mixture model (IMCP-GMM) method [3] from 27 dry bone CT scans was used in this study. All the further work was performed using the open-source toolbox SCALISMO (https://github.com/unibas-gravis/scalismo). The original scapular bone shapes were first brought in point-to-point correspondence (15,000 vertices) with the mean scapular shape. On these 27 mesh models in correspondence, regions of Teres major (T-M) and Infraspinatus (I-S) muscle attachments were identified and masked by two observers in Meshlab (http://meshlab.sourceforge.net/). Inter-rater reliability was quantified by comparing the average area of each muscle region obtained by each expert. Reliability was also confirmed by quantifying dice similarity coefficient for I-S muscle region. Using 27 sets of each muscle region, representative vertex identifiers (VIDs) for each muscle were established using a threshold frequency of appearance (>60%). The threshold was selected to ensure the exclusivity of each VID for single muscle region.

To understand the feasibility of predicting subject-specific insertion capability, the scapula SSM was deformed to total ten scapular bone shapes that were randomly selected from an available subset of scapular shapes that were not included in building the SSM. A method of non-rigid iterative closest point fitting [4] was used to deform the SSM to external bone shapes. The muscle region on the fitted surface (external bone shape) was identified by tracking the muscle region VIDs from the SSM during fitting. On the predicted bone shapes, the feasibility of the muscle regions was determined in two different ways. First, an expert (clinician) visually confirmed if the predicted muscle attachment were "anatomically feasible". Second, a gold standard (manually segmented regions on 10 scapulae) was used to compare with the result of the region prediction using various distance measures and similarity index (Dice coefficient).

RESULTS AND DISCUSSION

Excellent intraclass correlation coefficient (ICC) for inter-rater reliability was reported for both T-M (ICC = 0.942) and I-S (ICC = 0.927) muscle regions. Dice coefficient ranged from 0.821 to 0.987 indicating high I-S region similarity between observers.

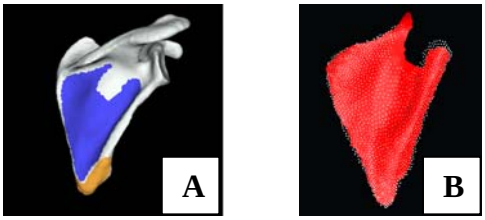

Figure 1: A) Mean scapula shape with Teres Major muscle VIDs in SCALISMO environment B) Infraspinatus muscle insertion region feasibility: manual segmentation in dark blue mesh and predicted region in yellow points.

Feasibility of region prediction was visually confirmed by the expert in all 10 external scapulae. Distance measures indicated higher predictability for both the muscle regions (Table 1). Average dice coefficient was also high for both the muscle regions (Table 1). Previous studies to predict muscle insertion contour or attachment sites have used scaling (linear or non-linear) or morphing techniques [5], but the mean distance errors reported were up to 15mm using cadaveric shoulders as gold standard. Although this study does not employ cadaveric shoulders, more validations are warranted for all the shoulder joint muscles.

Table 1: Average feasibility error of muscle region predictions on ten external scapulae. T-M = Teres Major, I-S = Infraspinatus, MD = Mean Distance, SD = Standard Deviation, RMS = Root Mean Square, HD = Hausdorff Distance, AD = Area Deviation, DC = Dice Coefficient

Muscle	MD (± SD) (mm)	RMS (mm)	HD (mm)	AD (mm^2)	DC
T-M	0.09 (0.38)	0.39	3.06	5.49	0.96
I-S	0.20 (0.64)	0.68	4.82	7.05	0.98

CONCLUSIONS

This study reports an effective use of SSM based MSKM in generating subject-specific shoulder biomechanics models. Future work will extend this method to other shoulder bones and muscle region predictions and build an MSKM pipeline using SSMs.

THE POTENTIAL INFLUENCE OF TENDON COMPLIANCE ON SENSORY FEEDBACK FROM LOWER LIMB MUSCLES

[1] **Glen A Lichtwark** and [1]Andrew G Cresswell

INTRODUCTION

The role of sensory feedback from muscles and tendons in the control of movement has been well researched, with irrefutable evidence that muscle length and velocity influences muscle control at different levels of the corticospinal tract. However, research in human sensorimotor control has typically applied principles based on the assumption that muscle length is proportional to muscle-tendon unit length. Contrary to this assumption, there is now an abundance of evidence demonstrating that, even in isometric conditions, muscles fibres change length as a function of force due to their connection to elastic tendons. This is particularly pertinent in muscles of the lower limb, which have short fibres attached to long tendons.

The aim of this invited talk is to examine different scenarios where interpretations of muscle motor output or sensory feedback from human lower limb muscles may be influenced by the role that elasticity within muscle-tendon units plays during muscle contractions or movements. We will show that ultrasound imaging can be an invaluable tool in assessing human muscle fascicle lengths or velocities during contractions and how this important information can influence our understanding of sensorimotor control.

We have developed methods for dynamic ultrasound imaging of several muscles in the lower limb (e.g. gastrocnemius, soleus, tibialis anterior, intrinsic foot muscles) to assess the length changes of their muscle fascicles during contractions and/or passive joint rotations that induce muscle-tendon unit length changes. A custom written algorithm for tracking fascicle length changes has been developed [1], enabling sub-millimeter length changes of muscle to be assessed during contractions.

This talk will focus on how fascicle length changes can be interpreted and how tendon compliance can influence both sensory feedback and motor output.

RESULTS AND DISCUSSION

During isometric contractions of the ankle plantar flexor muscles, fascicles of the gastrocnemius shorten substantially. Therefore, muscle fascicles are shorter, possibly at less optimal lengths, as muscle force increases and the rate of force development also impacts on the force generating capacity of the muscle. Small force fluctuations during ‘constant’ force contractions may therefore also result in lengthening and shortening of the muscle fascicles, which need to be interpreted when considering afferent output and corticospinal control of these muscles.

We have also conducted experiments where we impose stretches to human lower limb muscles during both passive movements and active contractions. We show that while passive length changes are certainly transmitted to muscle fascicles, activation of the muscle often decouples the length of the fascicles from the muscle-tendon unit. Rapid stretches of the muscle-tendon units can drastically increase force output. However we show that this is not a result of stretch to the contractile tissue, but instead a reduction in the overall velocity of shortening, which in turn increases force output and increases the stretch of elastic tendinous tissues. This paradigm can be extended to active whole body movements. For instance, during quiet standing the tibialis anterior muscle experiences length changes that are concomitant to ankle angle changes, however once the system is perturbed or active sway is induced, its fascicles often shorten while the muscle-tendon unit lengthens and vice versa. Therefore the feedback from muscle spindles during active contractions may not directly represent sway direction.

Recent experiments on the intrinsic foot muscles, demonstrate a similar phenomenon. The intrinsic foot muscles have been shown to activate in response to load applied to the foot that compresses the medial longitudinal arch. Ultrasound imaging during foot compression suggests that these muscles indeed lengthen during early foot compression, however this stretch is not sustained during contraction. Therefore, while passive muscle stretch may induce reflex muscle activation, sustained contraction must be controlled through other feedback mechanisms.

These results have implications for our understanding of position control of joints, or muscle-tendon units, and how muscle spindle feedback might be used to in this control problem.

INFLUENCE OF RESIDUAL FORCE ENHANCEMENT AND ELONGATION OF ATTACHED CROSS-BRIDGES ON THE STRETCH-SHORTENING CYCLE

INTRODUCTION

Muscle force is enhanced in the shortening phase of stretch-shortening cycles (SSC). Although many studies have been conducted, the precise mechanism underlying force enhancement in SSC remains unknown.

Recently, we suggested that residual force enhancement, the increase in the steady-state force observed after active stretching compared to a purely isometric contraction at the corresponding length, may contribute to the force enhancement in SSC (SSC effect) for human plantar flexor and knee extensor muscles (Fukutani et al. 2016). However, there is the possibility that the enhanced force in SSC is caused by an elongation of the attached cross-bridges (Bosco et al. 1982). Also, tendon elongation has been suggested to contribute to the SSC effect (Kawakami et al. 2002).

Here, we conducted skinned fiber experiments and carefully excluded the influence of tendon elongations. In order to determine the contribution of residual force enhancement and elongation of attached cross-bridges on the enhanced force during SSC, we conducted SSC with and without a transition between the stretch and shortening phases. Since cross-bridge cycling occurs several times per second, the influence of cross-bridge stretching induced by active lengthening should be lost in such a transition phase. Therefore, if cross-bridge stretching is the single factor for the SSC effect, then the SSC effect should be eliminated for SSC that include a transition phase. However, if the SSC effect is still observed when a transition phase is provided, another factor, possibly residual force enhancement, may contribute to the SSC effect.

METHODS

Three experiments were conducted using skinned fibers (n=49) isolated from rabbit soleus muscles. For control tests (Figure 1, black line), fibres were passively stretched from an average sarcomere length of 2.4 µm to 3.0 µm in 2 s, and then activated. Once maximal force was reached, muscles were actively shortened to 2.4 µm in 2 s. In the transition tests, (Figure 1, red line), fibres were activated at an average sarcomere length of 2.4 µm, stretched actively to 3.0 µm in 2 s, held isometrically for 2 s, then actively shortened back to 2.4 µm. Finally, the SSC tests were identical to the transition tests, except that the active stretch was followed by active shortening without a pause (Figure 1, blue line).

Work performed by the fibres during the active shortening phase (see Figure 1) and force at the onset of shortening were compared among the three test conditions.

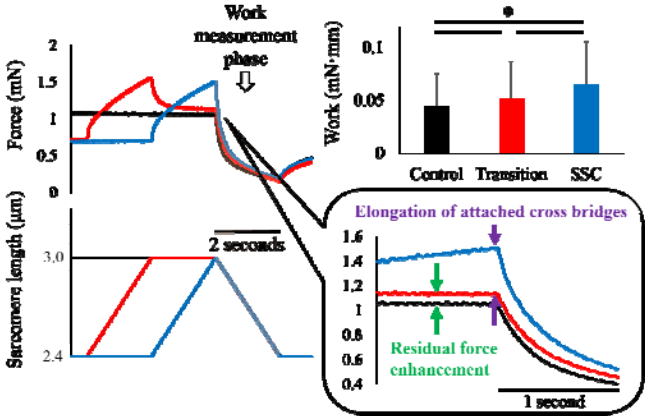

Figure 1: Force and sarcomere length changes as a function of time for the three test protocols, and work performed during the active shortening phase. Black: Control fibers, Red: transition fibers; Blue: SSC fibers.

RESULTS AND DISCUSSION

Work done during the active shortening phase was significantly greater in the SSC than the transition tests (0.065 ± 0.041 mN·mm for the SSC, and 0.052 ± 0.035 mN·mm for the transition tests). This difference may possibly be explained by the loss of elastic energy in the attached cross-bridges during the transition phase. Work was also significantly greater in transition compared to control tests (0.044 ± 0.031 mN·mm for the control tests). This result indicates that elastic energy stored in cross-bridges and residual force enhancement likely contribute to the observed SSC effect. Force at the onset of shortening was significantly greater in the transition compared to the control tests (0.62 ± 0.24 mN for the transition, and 0.55 ± 0.24 mN for the control tests), suggesting that residual force enhancement may have contributed to the enhanced force in the SSC protocols.

CONCLUSIONS

We conclude that residual force enhancement and stretching of attached cross-bridges and associated storage of elastic energy contribute to the SSC effect.

DIFFERENCES BETWEEN CONCENTRIC AND ECCENTRIC CONTRACTION ON THE ACTIVATION OF BICEPS, BRACHIORADIALIS AND TRICEPS MUSCLE

[1]**C. Disselhorst-Klug**, [1]A.K. Laßek and [1]S.C.F.A. von Werder

INTRODUCTION

During freely performed movements synergistic and antagonistic muscles are activated by the central nervous system in a well-controlled pattern [1] resulting in a precise execution of tasks relevant for various activities of daily life. Thereby describes the direction of the movement, whether a muscle is activated while shortening (concentric contraction) or while lengthening (eccentric contraction).

From the force-velocity relationship it is well known that the force generated by a single muscle fibre depends not only on the velocity of changing fibre length but also on the contraction type (concentric or eccentric contraction) [2]. Furthermore, Herzog has shown that the rule of contractile proteins at the sarcomere level is different for concentric contractions and eccentric contractions [3]. Herzog proposed a three filament model in which beside actin and myosin a third myofilament, titin, contributes to the force regulation increasing the force generated by single muscle fibers during eccentric contractions.

The envelope of the surface-electromyogram (sEMG) reflects the number of muscle fibers activated by the central nervous system to generate a certain muscle force. From the force-velocity relationship and the findings of Herzog the hypothesis can be formulated that in freely performed movements including concentric and eccentric components of muscle contraction the sEMG envelope depends on movement velocity and contraction type.

METHODS

15 healthy subjects (7 male, 8 female, age 26.2 ± 3.2 years) performed elbow flexion and extension tasks against a constant external torque of 0.4 Nm and comprising the full range of motion. The forearm was held in neutral position. Movements have been performed with different self-selected movement velocities in which the subjects have been animated to change the movement velocity when repeating the movement by visual feedback. Movement analysis has been used to measure the elbow flexion/extension angle in which 0° corresponds to the fully extended position. From the elbow flexion/extension angle angular velocity has been calculated representing the contraction velocity of the muscle.

sEMG has recorded from the biceps, brachioradialis and triceps muscle according to the recommendations of SENIAM. Signals have been full wave rectified and smoothed (moving average filter; 80 ms window length). The resulting sEMG envelope has been normalized to the 75% percentile of the maximal amplitude for each contraction type separately.

sEMG-data have been categorized [4] with respect to contraction type, joint angle position and movement velocity in order to compare only sEMG data, which reflect the same boundary conditiones.

RESULTS AND DISCUSSION

Figure 1 shows the results for a joint angel of 75° ± 5°. During concentric contraction all three muscles show an increase in sEMG envelope with increasing contraction velocity indicating the activation of a larger amount of muscle fibers to generate the desired force. This increase is less in the triceps muscle compared to the other two.

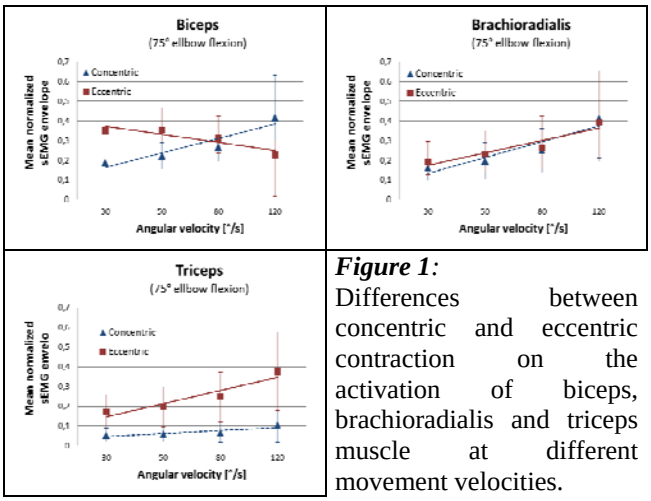

***Figure 1**:* Differences between concentric and eccentric contraction on the activation of biceps, brachioradialis and triceps muscle at different movement velocities.

In contrast, in eccentric contractions the muscles are activated differently. Brachioradialis and triceps show a clear increase of activated muscle fibers with increasing velocity. However, a decrease in normalized sEMG amplitude has been found with increasing movement velocity in the biceps muscle.

The values of the sEMG envelopes cannot be compared directly between the concentric and eccentric situation since they have been normalized to the 75% percentile of the maximal amplitude for each contraction type separately. Additionally, it has to be taken into consideration that biceps and brachioradialis are synergists which might share the force differently in different movement velocities [1].

CONCLUSIONS

There is a clear effect of contraction type on the activation of different muscles, which depends on the movement velocity. This effect is well known in concentric activations, but it has to be considered in eccentric ones, too.

THE APPLICATION OF ULTRASONOGRAPHY IN MINIMALLY INVASIVE SURGERY IN HAND SURGERY

I-Ming Jou, MD, PhD

Ultrasonography is widely available in many departments and with the advantages as providing dynamic images in real time, and capability of identification of soft tissue, bone or lesion, and without radiation exposure. Recent reports have also noted that ultrasonography guided percutaneous surgical intervention have gain popularity as an effective, safe, and less- invasive alternative to open invasive operations in general surgery, gynecological and obstetrical procedures. However, it has only received anecdotal use of musculoskeletal fields, including the hand surgery.

We propose a novel operative technique for percutaneous release of the trigger digit (TD) and carpal tunnel syndrome (CTS) using real-time ultrasonographic guidance since 1998. This sonographically assisted percutaneous release (SAPR) provides the advantage of direct visualization of the release and avoids the inherent risks of incomplete release and injury to adjacent neurovascular structures associated with current percutaneous release techniques.

In this talk, I will present our several attempts in cadaveric and clinical studies to determine whether the real time and dynamic multiple-plane observation capabilities of ultrasonography would allow us to see and precisely monitor the percutaneous division of the A1 pulley/ transverse carpal ligament and, therefore, avoid the inherent risks combined with the reported minimal invasive release (e.g. blind percutaneous or endoscopic release). In addition to the benefits of a shorter period of disability and less postoperative discomfort for the patient, this tech also valuable for the simplicity for the surgeon (need only local infiltrative anesthesia, no assistant or tourniquet is needed for the percutaneous release),

In summary, because of the effectiveness of these techniques, we have undertaken over twenty- thousands cases of trigger digit and carpal tunnel syndrome. In addition to the beneficial results in clinical practice, with the rapid accumulation of these cases has also brought several basic studies on these disorders.

THE CLINICAL OUTCOMES AFTER SONONGRAPHYICALLY ASSISTED PERCUTANEOUS RELEASE OF TRIGGER DIGITS: A SERIES OF 1167 DIGITS

INTRODUCTION

Trigger fingers, one of the most encountered hand problems caused by thickened of the A1 pulley, affect approximately 2.6% of the general population. To date, there are rare study evaluating the outcomes after surgical release for locked digits. Yet, the surgical results between non-locked and locked are unclear. In our previous study, only 3% of 107 patients are locked digits. Thus, our purposes were to evaluate the 1-year outcomes after SAPR for trigger digits and to compare the outcomes between locked and non-locked digits. We hypothesize that SAPR for trigger digits would improve the functional outcomes and relieve the pain and that non-locked digits have better functional improvement than locked ones during follow-up..

METHODS

A total of 1167 digits underwent SAPR were included. The affected digits divided into locked or non-locked digits based on the disease severity. Visual analogue scale (VAS), functional scores (Quick-DASH[1], modified functional status scale (mFSS)[2]), functional strength (grip, pinch and three-jaw-chuck power), and satisfaction scores were evaluated and compared post-operatively, 1 week and 1, 3, 6, and 12 months after the operation.

RESULTS AND DISCUSSION

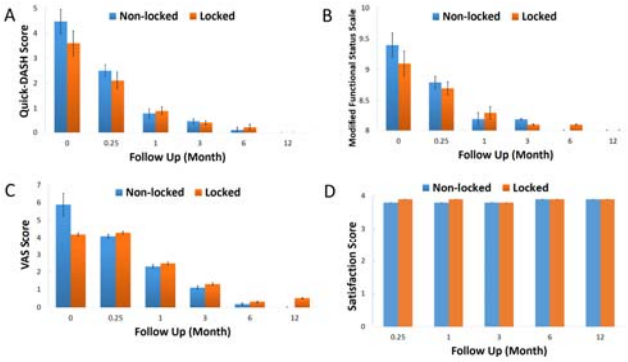

Table 1: Quick-DASH scores (Fig. 1A), modified functional status scale (mFSS)(Fig. 1B), visual analogue scale (VAS) score (Fig. 1C) and satisfaction score (Fig. 1D) measured pre-operatively and post-operatively at the 1 week, 1 month, 3 months, 6 months and 12 months between non-locked and locked groups.

At 1-year follow-up, both groups (non-locked vs. locked) showed high pain-free rate, high complete remission rate, and high satisfaction rate in non-locked digits than in locked digits. The post-operative Quick-DASH scores, mFSS scores, VAS score continues to improve from one week to 12 months after operation in both groups (Table 1). However, the non-locked digits have better results in all 3 functional strength parameters and pain-free rate ($p<0.01$, all) than the locked digits one year after SAPR. At our final clinical and sonographic evaluation, no patients had infection, neurovascular injuries or flexor tendon injuries.

CONCLUSIONS

SAPR is an effective and efficient methods for trigger digits with high satisfactory rate, high complete remission rate and good functional outcomes after 1-year follow-up. Based on disease severity, non-locked digits has higher complete resolution rate, post-operative pinch strength and pain-free rate than locked digits. Early intervention may be suggested for better strength restoration and functional recovery.

A MATHEMATICAL MODEL OF THE EFFECT OF PARTIAL EXCISION OF THE A2 AND A4 PULLEYS BASED ON IN-VIVO MEASUREMENTS

[1] **Michael C K Mak**, [1]Pak-Cheong Ho, [2]Victor T F Fung
[1]The Chinese University of Hong Kong
[2]Environmental Protection Department, Government of Hong Kong Special Administrative Region
Corresponding author email: michaelck_mak@hotmail.com

INTRODUCTION

In flexor tendon repair of the hand, it has been thought that the A2 and A4 pulleys should be preserved as far as possible to prevent bowstringing. However, in some cases that may lead to decreased range of motion or even re-rupture due to adhesion or catching of the repair site at the edge of a pulley. Partial pulley excision may facilitate tendon repair, ensure smooth tendon gliding, and prevent catching. The acceptable extent of pulley excision before significant bowstringing occurs is debatable. Some researchers have advocated preservation of as much of the A2 and A4 pulleys, while some have suggested that partial excision of up to 75% may not result in a significant decrease in function [1] (Mitsionis 1999). There is also a lack of precise anatomical data of the pulleys with respect to the skeletal structure and joint centres in literature. An adaptable and anatomically accurate mathematical model could therefore serve to illustrate the effect of pulley excision.

METHODS

Fine cut (1mm) magnetic resonance imaging of the index fingers of 5 healthy volunteers were obtained after obtaining ethical approval. In the sagittal plane, anatomical landmarks including the joint rotation centers of the metacarpophalangeal and interphalangeal joints, and the A2 and A4 pulleys and their most proximal and distal points were delineated. Based on their trigonometric relationships, a mathematical model of a two-pulley (A2 and A4) system and the proximal interphalangeal joint is derived (fig. 1) where *b* and *a* are the distances of the A2 and A4 pulleys from the joint center at the head of the proximal phalanx, *h* is the moment arm of the flexor tendon, and *z* is the length of the tendon between the pulleys. The effect of 25%, 50%, 75% and complete pulley excision on moment arm and tendon excursion is investigated, and compared with the normal anatomical situation in a cadaveric study by An et al. [2].

RESULTS AND DISCUSSION

The A2 and A4 pulleys were well visualized in all subjects. It was found that for the flexor digitorum superficialis, excision of 75% of the A2 pulley results in 4% increase in tendon excursion at 90 degrees of flexion, whereas excision of 75% the A4 pulley results in 34% increase in tendon excursion. For the flexor digitorum profundus, excision of up to 75% of the A2 pulley resulted in no significant increase in tendon excursion, and excision of 75% of the A4 pulley resulted in 21% increase in tendon excursion. The amount of tendon excursion at 90 degrees flexion at the proximal interphalangeal joint would produce 13 degrees less if 50% of both pulleys were excised. The linear relationship between pulley excision and change in joint range of motion is demonstrated.

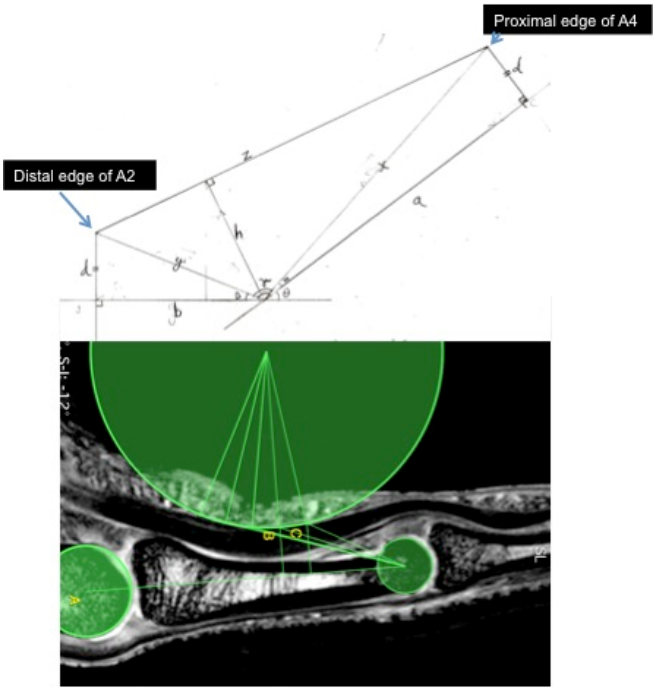

Figure 1: The MRI image of the A2 pulley with simulated excisions and the mathematical model.

CONCLUSIONS

It is shown in this study that excision of the A2 pulley results in less increase of tendon excursion required and less decrease of range of motion than excision of the A4 pulley. This is due to the shorter distance between the A4 pulley and the joint center. From the result of this study it can be seen that the effect of excision of the A4 pulley may have a greater effect on tendon function than that of the A2 pulley, and that the A2 pulley can be excised partially without a significant loss of total range of motion. This is the first normative model of the flexor system of the proximal interphalangeal joint with respect to the lengths of the phalanges, and thus can be adapted to altered anatomy such as in a shortened digit after trauma or in congenital anomaly.

HIGH-FREQUENCY ULTRASOUND CHARACTERIZING INDIVIDUAL TISSUE IN THE FIRST ANNULAR PULLEY SYSTEM

[1,4]***Tai-Hua Yang**, [2]Yi-Hsun Lin, [2,4]Shyh-Hau Wang, [2,4]Yung-Nien Sun, [5]I-Ming Jou, [3,4]Li-Chieh Kuo, [1,4]Fong-Chin Su

INTRODUCTION

In trigger finger, the pulleys thicken or the tendons swell, impeding tendon movement and causing the finger to snap and lock painfully. Although medical history and physical examinations generally determine diagnosis, objective quantification is critical. Ultrasound (US) scanners of 5-17 MHz have been used to assess pulley tissue lesions, but they cannot well assess pulley structure injuries or discern the normal pulley [1]. Accurate identification of the pulley's thickness could help distinguish normal and pathological pulleys, and follow-up images could aid in choosing treatment. USs higher than 20 MHz should be able to accomplish this [2,3].

METHODS

The IRB of National Cheng Kung University Hospital, TAIWAN, approved the study and waived the need for informed consent. We used the normal A1 pulley, hypodermis and superficial digital flexor tendon (SDFT) from 14 fresh frozen human cadaveric hands with no diagnosis or indications of musculoskeletal disease, metabolic disorder or major trauma. The tissue was flattened and fixed on a custom plexiglass plate and immersed in a saline tank for measuring. A 30 MHz US transducer (NIH Ultrasonic Transducer Resource Center, USC, University Park, LA, USA) was placed approximately 7.7 mm above the tissue for signal acquisition. B-mode images and measurements were taken from the finger's sagittal and transverse planes (10 times for each direction from different tissue locations). All experiments were performed in an air-conditioned laboratory at room temperature. Each B-mode image covered a 5(width)×1.5(depth) mm area from 250 A-lines at 20 μm intervals. Data analysis and imaging were performed with MATLAB (The MathWorks, Natick, MA, USA). ANOVA was used to investigate the significance of US parameters, i.e., sound speed, attenuation slope and coefficient, integrated backscatter (*IB*) and Nakagami parameter (*m*), on distinguishing the A1 pulley and surrounding tissues. We used a paired t-test ($p<0.05$) to study the significance of *IB* and *m* on distinguishing the parameters from the transverse and sagittal planes.

RESULTS AND DISCUSSION

The hypodermis, A1 pulley and SDFT were 2.60±0.30, 0.64±0.14 and 1.84±0.32 mm thick, respectively. The B-mode images had a much better resolution than the low-frequency images. Textures could be easily distinguished in the transverse and sagittal images of the A1 pulley and SDFT but not the hypodermis. (Fig. 1A) The linear regression fitting of the attenuation slope of the hypodermis, A1 pulley and SDFT was 0.274±0.042, 0.183±0.050 and 0.190±0.027 dB/mm/MHz, respectively (*R*-square>0.9). The hypodermis had a significantly larger attenuation slope than the A1 pulley and SDFT ($p<0.001$), and the A1 pulley and SDFT had similar slopes ($p=0.891$). The estimated hypodermis, A1 pulley, and SDFT attenuation coefficients, corresponding to the use of the 30 MHz US, were 7.0±0.81, 4.3±0.90 and 5.8±1.2 dB/mm, respectively. The attenuation coefficient differed significantly between the A1 pulley and hypodermis ($p< 0.001$) but not the A1 pulley and SDFT ($p=0.891$).

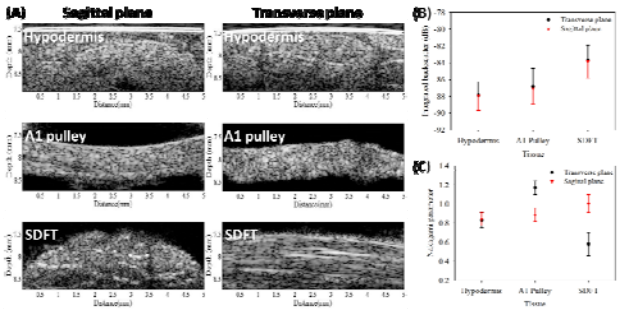

Figure 1: (A) Sagittal and transverse images, (B) *IB* and (C) *m* of the hypodermis, A1 pulley and SDFT.

The transverse and sagittal planes had similar estimated *IB*: −87.9±1.6, −86.8±2.1 and −83.7±1.9 dB, respectively, for the hypodermis, A1 pulley and SDFT in the transverse, and −87.9±1.7, −87.1±1.8 and −83.8±2.0 dB in the sagittal (Fig. 1B). The region of interest (ROI) of the hypodermis, A1 pulley and SDFT had an average estimated *m* of 0.83±0.08, 1.17±0.07 and 0.58±0.12, respectively, in the transverse and 0.85±0.07, 0.89±0.07 and 1.00±0.10 in the sagittal (Fig. 1C). The A1 pulley had a significantly larger estimated *m* than the hypodermis ($p<0.001$) and SDFT ($p<0.001$). In the sagittal plane, the A1 pulley had a significantly different *m* from the SDFT ($p<0.001$) but not the hypodermis ($p=0.299$).

CONCLUSIONS

The results demonstrated that US images have high resolution and can sufficiently differentiate tissue. Moreover, the hypodermis has a larger attenuation slope than the A1 pulley and SDFT. The A1 pulley has about the same *IB* as the hypodermis but not the SDFT. The A1 pulley also has a different *m* than the hypodermis and SDFT. Therefore, high-frequency US images in conjunction with US parameters can characterize the A1 pulley system and surrounding tissues.

INTRODUCTION

Trigger finger is a common pathology in which fibro-cartilaginous metaplasia of the A1 pulley generates a mismatch between the pulley and the tendon sliding inside. In case of failure of conservative treatment, surgical release is mandatory to restore a free sliding of the flexor tendon. Open release is the classic approach. Blinded percutaneous release has been described for long and give the advantage to shorten the recovery time for the patients. However, this technique present some risks of tendon and neuro-vascular complications. The use of these procedure should then be avoided for the thumb and the fifth finger where de neurovascular bundle path may cross the tendon. The use of sonography to guide percutaneous release give to the surgeon the possibility to accurately identify the structures at risk and proceed to a very selective release of the A1 pulley. The use of sonography should then decrease the complication rate of the percutaneous technique keeping the advantage of early recovery of the percutaneous technique. The effect of A1 pulley release on the flexor tendon excursion have already been described [2].

The purpose of this study is to compare the modification induced by A1 pulley release after percutaneous sonography guided technique with the open technique. The hypothesis is that there is no difference between the two techniques.

METHODS

Six fresh frozen cadaver hands were used. Specimen were prepared using in a standardized technique. After a radio-carpal amputation, specimen was mounted on a motorised testing device allowing passive motion of the long fingers. A cord was suture on the flexor and extensor tendons of each long finger and a free load was applied. A reflective marker was attached on each cord and, using an optoelectronic device (Vicon®) 3D tendon excursion was recorded and measured. Assessment was performed in intact situation, after sonographycally guided intra-sheath A1 pulley release and finally after open release. A three-way ANOVA followed by a LSD post hoc test was performed for statistical analyse. The type of procedure, the long finger involved and the type of flexor tendon excursion was assessed. A $p<0.05$ was considered as significant.

RESULTS AND DISCUSSION

The higher excursion measured was by 43.2mm and the lower was by 20.9mm. There was no significant difference between percutaneous sonographycally guided technique and the intact condition. Open release decreased significantly by 4.5% the flexor tendon excursion and there was no difference between flexor digitorum superficialis and profundus.

Before open release of A1 pulleys, inspection of the pulley was performed to assess the amount of release obtained percutaneously. This evaluation revealed that only 50% of percutaneous release was complete and less than 25% of the pulley was released in 12.5% of cases. This low rate of complete release could be explained by the low definition of the sonography probe (Sonosite® 10/5 Mhz) an may explain the non-significant effect of the percutaneously sonographycally guided release on the tendon excursion.

CONCLUSION

We found that only open release of A1 pulley decrease the excursion of long fingers flexors tendons. In clinical cases, high definition sonography probe should be use to decrease the high rate of incomplete release observed in our study.

MEASURING AND MODELLING THE MECHANICAL POWER BALANCE IN SPEED SKATING

INTRODUCTION

Power is a familiar metric to sportsmen since the introduction of SRM systems in cycling. Speed skaters often train with these systems in their cycling trainings and expressed their desire to also have a power meter during their speed skating practices. The design of such a system requires, apart from a measurement method, a simple model which can determine power, preferably real-time. For the verification of such a simple power model, a reliable verification model is necessary.

Looking into the terminology in literature, the term power seems to have been more and more detached from its physical origin over the course of research. Several methods and terms have been introduced which all determine a certain 'power', but the terminology is ruffled up and the consequences of the assumptions made in the methods are often disregarded.

The goal of this paper is to design a reliable verification power model for speed skating which in future work can be used for the verification of a simple skater power model. Additionally the mechanical power balance is determined with measured kinetic data of a speed skater.

METHODS

A seven rigid body segment 3D speed skater model is proposed as the verification model, incorporating two skates, two shanks, two thighs and a HAT (head, arms, trunk). The formulated mechanical power balance consists of joint power, gravitational power, kinetic power and frictional power. Joint power was assumed to be the best estimate of the power generation.

Kinematic data of a skater were captured with a Qualisys motion capture system at an indoor ice rink, covering 50 m of the straight. Additionally a wireless instrumented klapskate was used to measure the push-off forces of the skater [1]. These captured data were used to determine the mechanical power balance in speed skating. A global optimization method was applied for the inverse kinematics.

Regarding the inverse dynamics, to solve for the joint moments, a new least-square error method is proposed (ELS), incorporating the power balance into the least-square error fit. This new method was compared to the consecutive solving method (CS), in which the joint forces and moments are solved consecutive, starting at the extremes and working up, and to a least-square error method (LSE) in which the Newton-Euler equations are incorporated into the least-square error fit [2].

It is important to grasp which inaccuracies have most effect on the verification model of power estimation. The sensitivity of the model was therefore determined by changing the specific variable or parameter by adding a relative error to the estimated or measured data and compare the power outcomes.

RESULTS AND DISCUSSION

The main drawback of the CS method is that the Newton-Euler equations are not satisfied at the HAT segment,

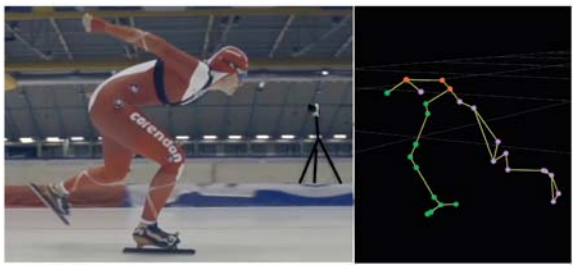

Figure 1: Motion capture of a speed skater on an ice rink.

leaving a residual of 482N in forces and 550Nm in moments. The least-square optimizations reduce these residuals to 58 N and 48 Nm for LSE and 46 N and 10 Nm for ELS. Apart from the Newton-Euler equations, the ELS method also takes into account the power balance as a constraint. Theoretically the kinetic power, the gravitational power and the frictional power should add up to the joint power. The kinetic + gravitational power cannot be larger than the joint power at any point in time, since this would imply that there is a positive frictional power at that instant. In the powers obtained with the LSE method we see that this does occur at several moments in the stroke. This is due to either the measurement accuracy or model assumptions. The ELS method solves this problem and thereby improves the mechanical power balance significantly. The difference in peak joint power estimation between the CS and ELS is 5 to 8% in peak power.

The sensitivity analysis showed that an error in orientation of the skate causes the largest deviation in joint power estimation. This is due to the fact that it is this orientation of the skate that rotates the locally measured push-off force into a global coordinate system. A measurement error of 5^0 in steer angle already causes a difference in peak joint power estimation of over 10%. Next, the measured forces have most influence on the joint power estimation.

CONCLUSIONS

The joint power determined with the mechanical power balance of a seven rigid body segment 3D model can be used for the verification of a simple skater power model. The new proposed least-square error method for the inverse dynamics improves the power balance significantly in speed skating. The sensitivity analysis showed that the power estimation is highly sensitive to the accuracy with which the orientation of the skate is measured.

LOWER LIMB NET JOINT MOMENTS AND CONTROL PRIORITIES DURING THE GOLF SWING

[1]**Travis J. Peterson** and [1]Jill L. McNitt-Gray
[1]University of Southern California
Corresponding author email: travispe@usc.edu

INTRODUCTION

Regulating golf shot distance is critical to player performance during competition. Previous research has revealed that whole-body angular impulse increases when hitting golf shots of increased distance [1]. Reduction of golf shot distance within a club has also been associated with decreases in reaction force magnitude from the rear and/or target legs [2]. These findings suggest that lower limb joint kinetics will be regulated to meet these whole-body mechanical demands. Understanding how the joint kinetics vary when regulating golf shot distance provides insights into how players can manage their control strategies on the course. The aim of this study was to determine if increases in golf shot distance are associated with increases in support moment and net joint moment magnitudes (NJMs). We hypothesized that target and rear leg support moments and NJMs would increase using a driver compared to a 6-iron.

METHODS

Skilled players (n = 7, handicap < 5) volunteered to participate in accordance with the local institutional review board. Each player performed ten full golf shots towards a target with a 6-iron (6I) and a driver (D, TaylorMade-adidas golf). Golf swings were initiated using player preferred address positions with each foot supported by a force plate (Kistler, 1200 Hz). Segment kinematics were captured using retroreflective markers and a 16-camera motion capture system (100 Hz, Natural Point Optitrack; Acquire3D, C-Motion). Joint kinetics were calculated using inverse dynamics. Net joint moment (NJM) magnitudes were chosen at peak support moment for each leg (summation of ankle, knee, and hip NJM) prior to ball contact and were normalized by body mass. Statistical analysis determined group differences using the Sign Test ($\alpha = 0.05$).

RESULTS AND DISCUSSION

The target leg support moment significantly increased across the group when hitting with the driver compared to the 6-iron ($p = 0.008$, Figure 1a). Support moment increases arose from increases in target leg ankle ($p = 0.016$), knee ($p = 0.008$), and hip ($p = 0.016$) NJM. This occurred with no significant increases in target leg NJM percent contribution to support moment. When swinging with the driver, rear leg ankle NJM ($p = 0.016$, Figure 1b) and percent contribution to support moment ($p = 0.008$) significantly increased while rear leg knee NJM ($p = 0.008$) and percent contribution to rear leg support moment ($p = 0.016$) significantly decreased.

The distribution of mechanical demand imposed on the rear and target legs was determined by expressing the percent contribution of the ankle, knee, and hip NJM to the support moments. The results indicate that target leg control is dominated by the knee and hip whereas rear leg control is dominated by the hip. Swings with the driver imposed more demand on the rear leg ankle, while reducing the demand at the knee. These changes may have an impact on the control strategy employed by the player to accommodate these changes.

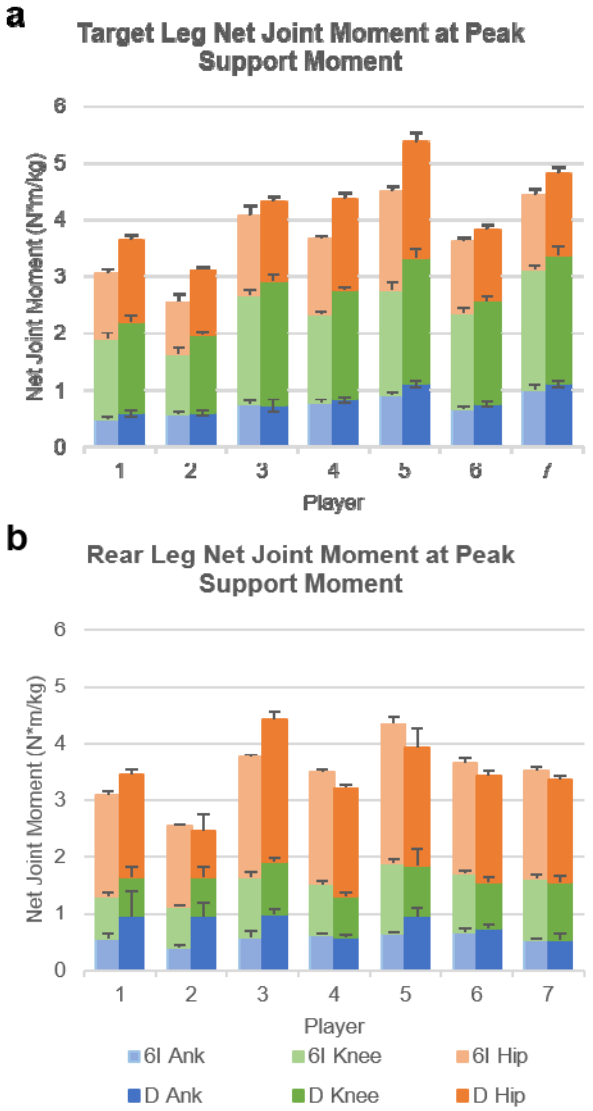

Figure 1: Mean (SD) of target (**a**) and rear (**b**) leg net joint moment distributions when swinging with the 6-iron and driver.

CONCLUSIONS

Regulation of golf shot distance involves coordination between the rear and target legs. The target leg support moments and NJMs increased when swinging with a driver, while rear leg NJMs varied across conditions. The distribution of mechanical demand imposed on the target leg was dominated by the knee and hip and remained consistent across tasks. In contrast, the distribution of mechanical demand imposed on the rear leg varied between tasks. These findings may have implications toward muscular control strategies players utilize to increase golf shot distance.

A PRELIMINARY EXAMINIATION OF MOVEMENT VARIABILITY IN THE PUTTING STROKE

[1]Sean Miller, [1]Matthew Sweeney, [2]Kerrie Evans, [2]Sean A. Horan
[1]Australian Catholic University, Queensland, Australia
[2]Griffith University, Queensland, Australia

INTRODUCTION

Despite the importance of the putting stroke in golf, a current paucity of research leaves coaches reliant on anecdotal evidence for their mechanical advice. One of the most common forms of this anecdotal advice is to reduce the complexity of the task by making individual segmental motions (e.g. trunk rotation) as consistent as possible [1]. Interestingly, recent research suggests that variability in individual segment motions, or movement variability (MV) has a more complex relationship with task performance, likely playing both a functional and dysfunctional role [2].

A starting point to providing insight into the functional role of MV in the putting stroke is to establish the magnitude of variability exhibited by golfers of different standards. The purpose of this study therefore was to investigate the magnitude of range of motion (ROM) MV at the trunk and wrist in experienced and novice golfers during the putting downswing.

METHODS

Twenty right handed males were recruited. All participants in the 'experienced' group had a current handicap below 18 (n =10, age = 29.10 ± 8.18 years; height = 182.40 ± 7.44 cm; weight = 88.22 ± 18.49 kg; handicap = 6.66 ± 7.42), while participants in the 'novice' group had never held an official handicap nor played more than 4 rounds in the preceding year (n =10, age = 25.00 ± 7.38 years; height = 181.30 ± 5.78 cm; weight = 84.17 ± 12.73 kg). Ethical approval was granted by the human research ethics committee of the Australian Catholic University (ACU) and written informed consent was obtained.

Following a five minute warm period, each participant performed 20 consecutive four metre putts on an artificial putting surface (Birdie Ball Inc., Colorado, USA). Each putt was captured with a 12 camera Vicon (Oxford, UK) 120 Hz MX system, tracking the motion of 31 retro-reflective markers affixed to the participants body and club. Kinematics of the wrists, trunk and pelvis were modeled from raw trajectories according to ISB conventions [3,4] using Visual 3D (C-Motion Inc., Germantown, USA). Standard deviations of ROM were then calculated and used to represent intra-individual MV. Putt outcome was calculated as the distance the ball finished from the hole, or mean radial error (MRE), measured from photographs taken using a GoPro Hero 4 camera (GoPro, Inc., California, USA) mounted directly above the hole.

RESULTS AND DISCUSSION

MRE of the ball relative to hole was significantly greater in the novice group (28.00±17.393cm v 59.08±24.17cm, p = 0.01, d = 1.57). There was a trend towards the experienced group displaying less variability across all segmental motions (see Figure 1). This may suggest that some decrease in MV occurs with practice in the putting action. However, despite this trend, no significant differences between groups were detected in ROM variability at any segment

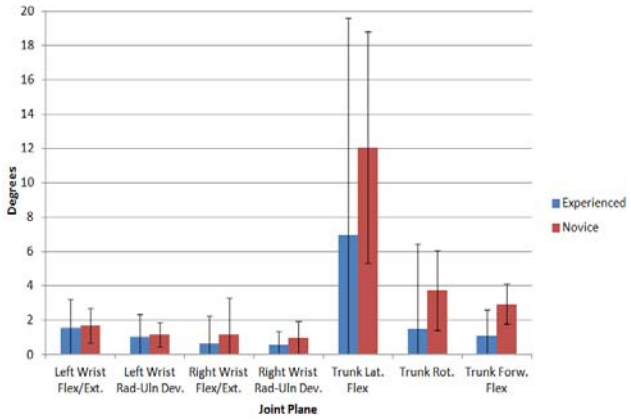

Figure 1: Comparison of ROM MV between experienced and novice golfers.

Importantly, the clear group differences in performance were not matched by clear differences in MV, appearing to downplay the potential importance of MV magnitude as a critical factor in optimal execution of the putting stroke. This, in conjunction with previous research into other motor tasks [2] indicates that the traditional advice of trying to eliminate all variability in individual segmental motion is likely oversimplifying the potentially complex role MV in skilled performance. Future research is required to investigate whether differences occur in other segmental motions in the putting action and, crucially, how the nature (as opposed to the magnitude) of MV may influence putting performance.

CONCLUSIONS

While the results of this study suggest a trend towards more successful putters exhibiting less MV than novices, differences were less than many would anticipate. Given the marked difference in outcome between groups, the modest differences in MV suggest the nature of MV in putting may be more important than magnitude. The current study highlights the importance of future research examining the nature of movement variability, and its likely important influence on performance in the putting stroke.

IN SEARCH OF GOOD PERFORMANCE INDICATORS FOR SPEED SKATING

INTRODUCTION

The force produced to propel a body forward in speed skating is directed almost perpendicular to the forward motion, because a skate moves nearly frictionless in the for-aft direction and more or less fixed (against the ice) in sideways lateral direction, resulting in a sliding point to push off against. This unique propulsion property makes speed skating challenging to master, the movement is quite different from propulsion methods in daily life like walking and cycling, and challenges the biomechanical interpretation[1]. In the present study we are looking for performance indicators that will predict the quality of a stroke or a section (curve or straight).

In close cooperation with Dutch elite coaches some promising performance indicators have been selected for an initial examination. One of them is the time both skates make contact with the ice simultaneously, the so-called double stance phase (DS). It is hypothesized that a shorter DS phase can lead a more effective the push-off. The data collection is used to: 1. develop good algorithms to get the DS phase automatically, and 2. to verify empirically whether the hypothesis is true. Here we specifically focus on the DS phase in the curve.

METHODS

Six skaters of a regional junior team were asked to wear IMU (Shimmer3, Shimmersensing Ireland) during their regular training twice a week. All speed skaters are performing on the Dutch national level or just below (age ~18, 3 men and 3 women). Data is collected over a whole season. The IMU sensors are attached to both left and right skate shoe and synchronized before hand as described by Shimmer. Accelerometer, Gyroscope, and Magnetometer data are collected at a sample rate of 500 Hz on the sensors and downloaded after the training (typically 1 hour). The data is analyzed to get an overview of the training as feedback to the coach (total time of activity during the training, number of curves during the activity, time per curve, etc.). Algorithms are being developed to automatically detect blocks of activity, curves and straights and strokes, that is, contact of the skate with the ice. From these parameters like, ice contact time for one skate, curve time, DS phase for left and right stroke are calculated. To verify the quality of the algorithm for stroke detection, the strokes during almost all curves are collected manually as well.

RESULTS AND DISCUSSION

Although the hand collected data is still more consistent then the automatic analysis, the same features are visible in both data sets. The DS phase both from Left to Right and Right to left vary between skaters: on average 346 ±83 306 ±80 ms. Left right uniformity varies significantly from subject to subject (60 – 220 ms). For some skaters, but not all, a relationship can be seen between the time it takes to round a curve (~ speed) and the time in DS (figure 1), a slower curve relates to a longer DS.

Two main factors contributing to the errors in the DS time are: 1. the accuracy with which the contact of the skate on the ice can be obtained from the IMU data (either manually or with the algorithm) and 2. variability introduced by the skaters due to 'external' factors. In speed skating skaters ride regularly in lines to shield head wind or to keep a certain pace. Riding at speeds of 40 km/h or higher with a distance to the skater in front of about 1-2 m, makes it inevitable to regularly adjust one's speed, which is most conveniently done in DS, and thus contributing to a larger spread in DS times.

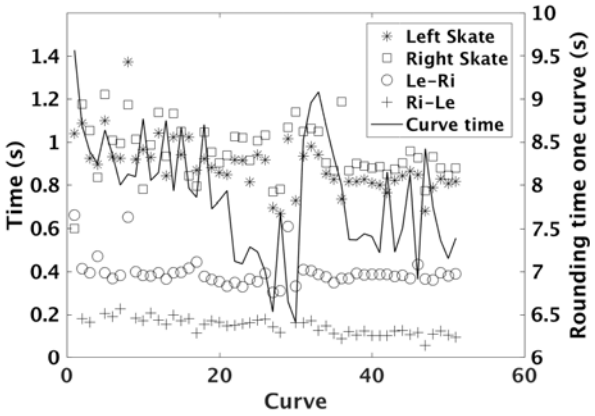

Figure 1: Round dots represent the average DS per curve for left to right and (+) for Ri to left. Stars: average per curve of the contact time per skate. The green line gives an estimate of the rounding time of a curve. The ragged line indicates the training schedule rather then the quality of the data.

CONCLUSIONS

The first performance indicator investigated shows clear differences between skaters. Results (e.g. fig. 1) show a relation between the DS and curve speed, supporting our hypothesis, but is not jet conclusive. Next step will be to investigate the speed and DS time relation in more detail, and experiments using Real-Time feedback will commence to investigate the possibility to influence the skaters behavior with respect to the DS timing. The feedback will be processed real-time and converted to a simple measure of performance; this will be presented to the skater in glasses. The currently developed instrumented Klapskate[2] will further broaden the possibilities to give feedback in real-time on the ice.

A KINEMATIC ANALYSIS OF TEN-PIN BOWLING TECHNIQUE OF ELITE BOWLERS

[1]Kent K. Klitgaard, [1]Christian H. Andersen, [2]Andreas Top Adler and [1]**Mark de Zee**
[1]Aalborg University, Denmark
[2]Team Danmark, Denmark
Corresponding author email: mdz@hst.aau.dk

INTRODUCTION

Ten-pin bowling is a sport where technical skills are very important. In 2010 it was estimated that 166 million people, in over 90 countries, play the sport of bowling [1].
Research in ten-pin bowling is mostly limited to the equipment and physiological parameters [1,2], while the kinematics of bowling has hardly been studied. Only a few studies have investigated the kinematics behind the bowling technique with 2D analysis [3].

Due to the lack of scientific analysis and thereby the understanding of the bowling kinematics, the purpose of this exploratory study was: To achieve a better understanding of the modern bowling technique through 3D motion capture. In particular, the focus was at the evaluation of the joint angles in the supporting leg, acceleration of the swing hand, the wrists movement, as well as the body's vertical movement through a throw.

METHODS

Nine Danish elite world-class male bowlers were recruited (Mean±SD, age: 27.3 ± 6.1 years; body mass: 84.5 ± 10.1 kg) to perform 20 bowling strokes. Kinematic data was recorded using a Xsens MVN link 3D motion capture system (Xsens Technologies B.V, Enschede, The Netherlands) at 240 Hz.
The subjects performed 20 throws on the 10 pin lane. The objective was to tilt as many pins as possible.

The collected variables were Knee-, ankle- and hip joint flexsion/extension for the support leg, resulting acceleration and vertical position of the swing hand, the swing hand wrist movement in ulnar deviation/radial deviation, pronation/supination and flexion/extension. Moreover, the L5 joint vertical movement was recorded.

RESULTS AND DISCUSSION

The Xsens MVN link was successfully used to collect kinematic data of the bowling technique. Figure 1 shows the group mean for all subjects. The top position of the hand, in the backwards swing, was found and 480 frames before and after the peak were utilized.
The results of the bowling technique analysis showed that the bowlers deliver the ball after the lowest point in a lift just prior to ball release. Knee and hip joint extends prior to ball release causing the body to move upwards. Further, the analysis did reveal that elite bowlers are highly consistent in their movements.

CONCLUSIONS

This study is the first that describes the technique in ten-pin bowling. Thereby, the study has increased the understanding of joint angles in the support leg, kinematics of the swing hand and the vertical displacement of the trunk. The Xsens technology based on inertial measurement units provides a mean to assess bowling technique away from the laboratory and out in the field.

ACKNOWLEDGEMENTS

The study was done in collaboration with Team Danmark, which provided technical guidance and competent feedback. Moreover, the authors thank the Danish national team in bowling which provided subjects, equipment and technical information concerning bowling lanes. Without collaboration and support from these strong collaborating partners, this study would not have been possible.

THE ROLE OF MUSCLE FUNCTION IN GAIT MECHANICS AT THE KNEE: OLDER VS. YOUNG ADULTS

[1]**Jocelyn F. Hafer,** [1]Jane A. Kent and [1]Katherine A. Boyer
[1]Department of Kinesiology, University of Massachusetts Amherst
Corresponding author email: jhafer@kin.umass.edu

INTRODUCTION

Gait impairments are important determinants of mobility through-out the lifespan. The mechanisms for alterations in gait mechanics in aging remain unclear but may result from physiological changes including decreased muscle strength, power, and fatigue resistance, and behavioral changes such as decreased physical activity. These age-related changes are especially prevalent in the knee extensors [1] and so may alter the function of the knee during gait. The interaction of habitual vigorous physical activity, muscle function and gait mechanics in the aged has not been characterized. The first aim of this study was to determine if knee extensor function (strength, power, and activation) and knee mechanics during gait differ by age and physical activity status. As knee extensor fatigue may alter gait throughout daily activity, the second aim was to test the sensitivity of gait mechanics to alterations in muscle function in response to a 30 minute bout of activity.

METHODS

Gait mechanics, knee extensor function and EMG activity were quantified for 17 young adults (Y; 28±3 years, 10 female), 18 highly active older adults (OHI; 62±4 years, 10 female), and 13 less active older adults (OLO; 63±3 years, 7 female). All participants were healthy with no history of major joint injury or pathology. Physical activity was assessed using accelerometers worn at the hip and was different between OLO and both Y and OHI ($p<0.001$ and $p=0.003$) but not between Y and OHI ($p=0.06$). All procedures were approved by the university IRB.

Overground gait analysis at 1.4 m/s using the point cluster technique and isokinetic knee extensor testing were performed before and after a preferred-speed, 30-minute treadmill walk (30MTW). Peak concentric power at 270°/s and isometric torque were obtained from isokinetic testing. EMG was collected from vastus lateralis, vastus medialis, and rectus femoris (knee extensors) as well as the semitendinosis and biceps femoris (knee flexors) during the first and last minute of the 30MTW, and normalized to the signal from maximal voluntary contractions. Primary gait outcomes were: knee flexion angle at heelstrike and midstance and range of motion during stance; peak external knee flexion moment; and femoral anterior translation relative to the tibia at heelstrike and during midstance. A co-contraction index was calculated as the ratio of knee flexor to the sum of knee extensor and flexor integrated EMG during terminal swing and early, mid, and late stance.

Statistics: All variables were compared between groups (Y, OHI, OLO) and across time (pre vs. post 30MTW) using repeated measures ANOVAs with $\alpha \leq 0.05$. Where a significant main effect was found, Tukey's post-hoc test was used to determine between-group differences.

RESULTS AND DISCUSSION

At baseline, Y produced more knee extensor power than OLO (+37%, $p=0.02$) but not OHI ($p=0.09$) at 270°/s. In response to the 30MTW, knee extensor isometric torque decreased ($p=0.003$) and power at 270°/s ($p<0.001$) decreased by 10, 4, and 20% in Y, OHI, and OLO, respectively. Femoral anterior translation relative to the tibia during midstance was smaller in Y compared to OHI ($p=0.045$) and OLO ($p=0.008$). All groups had a more flexed knee at heel strike ($p=0.01$) and a smaller range of motion at the knee ($p=0.001$) after the 30MTW. Finally, there was a group x time interaction for the peak knee flexion moment ($p=0.05$, Figure 1).

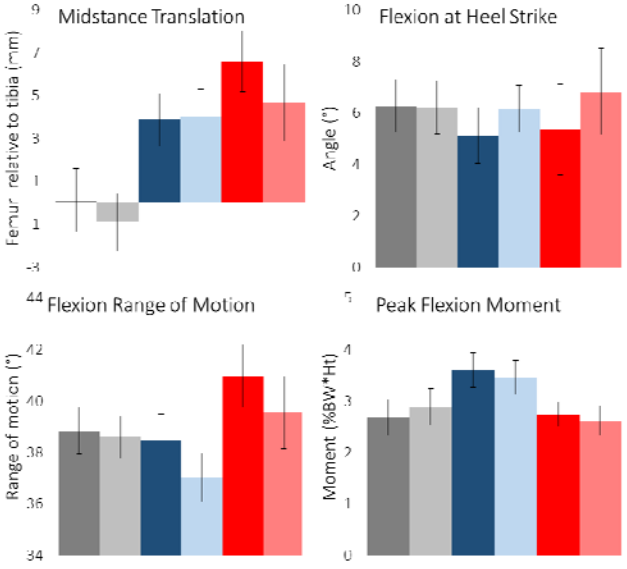

Figure 1 Knee mechanics (mean, SE) pre- and post-30MTW. Y: gray, OHI: blue, OLO: red. Light shades indicate post-30MTW data.

The co-contraction index differed between groups ($p<0.05$ for all phases of gait). There was also an effect of time on co-contraction during early stance ($p=0.033$) where OHI and OLO had 10 and 5% increases from the beginning to the end of the 30MTW. Finally, there was a group x time interaction during terminal swing where Y had a 3% decrease and OHI had a 9% increase in co-contraction.

CONCLUSIONS

Knee extensor function differed by age and habitually high levels of physical activity appear to be protective for knee extensor power and fatigue. Despite differences in strength, there were few differences between groups or pre- to post-30MTW in gait mechanics. The decreases in knee flexion at heel strike and range of motion across stance in response to the 30MTW were driven by the older groups in this study, both of which had increased co-contraction during early stance. These results suggest that adults may have differing strategies for managing knee mechanics in response to decreased knee extensor power.

COMPARING UNI AND BIMANUAL USE OF HAPTIC TOOLS AND THEIR EFFECT ON WALKING

Wyatt Cowell, Aaron Awdhan, Abhishek Kumar, Regan Santoro, Joel Lanovaz, and Alison Oates
University of Saskatchewan
Corresponding author email: wec343@mail.usask.ca

INTRODUCTION

Walking requires sensory input to maintain balance [1]. Adding sensory information via haptic input through light touch on a railing [2] or the use of haptic anchors [3] may enhance balance control during walking. Haptic anchors are small weights (125 g) attached to strings that are dragged on the floor while walking. Using a railing to add haptic input usually requires only one arm [2] whereas the anchors typically require two arms [3] to be held in a fixed position. The anchors have been shown to have a greater effect than a railing on balance control during walking [4]; however, it is not clear how much the postural configuration of using two arms (anchors) compared to one arm (railing) is responsible for the advantage seen with the anchors. The purpose of this study was to determine the effect of postural configuration and added sensory input on walking performance when using either a railing or anchors to add haptic input.

METHODS

Twenty-four young adults (27.8 ± 6.3 years) walked for 8 m while wearing six portable, inertial-based sensors MobilityLab (APDM, Oregon, USA). Participants performed one block of trials for each haptic tool. Each block included trials where participants actually used the tools with one or two arms or held their arms in the same position but did not touch the railing or hold the anchors (placebo use trials). Each condition was performed four times in a randomized order within each block and the block order was counter-balanced across participants.

Stride velocity and relative amount of time spent in double support (%DS) were used to evaluate walking performance. Peak arm swing velocity (ASV) was used to compare arm movement between the actual and placebo use trials. Peak medial-lateral trunk velocity (MLTV) was examined to understand the effects on trunk control during walking. Stride velocity was normalized to participant leg length [5] and MLTV was normalized to the normalized stride velocity to control for any effects of stride velocity [6].

A two-way repeated measures ANOVA (1 or 2 arms x actual or placebo condition) was used to compare postural configuration to type of use for each tool separately. A repeated measures ANOVA (1 or 2 arms x railing or anchors) was used to compare the effect of one or two arms between the railing and the anchors. Interactions were further investigated with paired t-tests (α=.05 for all tests).

RESULTS AND DISCUSSION

With regard to the railing as a haptic tool, there were no main effects for the number of arms used for stride velocity (F=.034, p=.856) or % DS (F=2.139, p=.157). Peak MLTV was reduced when using two arms compared to one arm (F=85.811, p<.001) suggesting improved trunk control with two arms. There were no main effects for the actual vs placebo use trials for stride velocity (F=1.593, p=.220), % DS (F=.0, p=.991), or peak MLTV (F=.116, p=.737). There were significant differences found for peak ASV in the two hand condition (p=.001; placebo>actual) but not the one hand condition (p=.370) suggesting there was more arm movement in the placebo than the actual use condition when two hands were used.

With the use of anchors, no main effects for the number of arms used were found for stride velocity (F=.25, p=.875) or %DS (F=.286, p=.598). Peak MLTV was reduced when two hands were used compared to one hand (F=41.390, p<.001). There were no main effects for actual vs. placebo use for stride velocity (F=2.915, p=.101), or %DS (F=.017, p=.899). Peak MLTV was significantly reduced in the actual use compared to the placebo condition (F=24.12, p<.001). There was also a significant interaction for peak MLTV (F=.8951, p=007). Paired t-tests revealed no significant difference between one hand or two hand use in the placebo condition (p=.063) and reduced peak MLTV with two hands compared to one hand in the actual use condition (p<.001). Peak ASV was not different when using one or two hands for the placebo condition (p=.719) but was reduced with two hands in the actual use condition (p=.017). These results suggest that receiving more sensory input from the anchors (i.e., from two arms) is most beneficial for trunk control when walking.

Similar to the results reported above, there was a reduction in peak MLTV for both tools when two hands were used (F=74.215, p<.001). There was no effect for the number of hands for stride velocity (F=.572, p=.457) or %DS (F=.544, p=.468). Participants walked faster (F=17.119, p<.001) and spent less time in double-support (F=4.896, p=.037) when using the anchors compared to the railing; however, there was no difference between tools for peak MLTV (F=2.129, p=.085). These results indicate using two arms to use the tools improves trunk control and that the railing may negatively impact walking more than the anchors.

CONCLUSIONS

Using two hands to add haptic input does not affect stride velocity or time spent in double support but does decrease trunk movement suggesting that the postural configuration of holding two arms in a fixed position may be beneficial for dynamic balance during walking. While the added haptic input from the railings does not impact walking performance or trunk movement, it does impact trunk movement when two hands use the anchors. These results, along with the decreased stride velocity and increased time in double support when using the railing, provide further support for the use of the anchors over a railing to improve walking.

CENTRAL PATTERN GENERATOR FOR LOCOMOTION WITH OPTIMAL SENSORY FEEDBACK

[1, 2] **Hansol Ryu**, [1]Art D. Kuo
[1]University of Calgary, [2]Korea Advanced Institute of Science and Technology

Corresponding author email: arthur.kuo@ucalgary.ca

INTRODUCTION

Animal locomotion appears to be controlled by central pattern generators (CPG) along with peripheral sensory feedback [1]. Although central neural oscillators appear capable of producing rhythmic, feedforward motor commands on their own, they can also be entrained by feedback, which by itself also appears capable of driving locomotion without a neural oscillator. Although CPGs can be combined with feedback on an ad hoc basis, there is no explanation for how much feedback should ideally entrain the CPG, and what the relative roles of feedforward and feedback should be. This problem could be resolved with optimization principles governing CPG performance.

Although either feedforward or feedback can in principle control the same nominal gait, the two extremes differ in response to a noisy environment. A previous modeling study [2] proposed that sensory feedback can be critical for correcting and stabilizing motion when there are noisy disturbances or imperfect motor commands. On the other hand, noisy sensory information can disrupt feedback control, thus favoring feedforward commands. Here we use a simple dynamic walking model to explore and demonstrate these opposing roles, along with the optimal combination of feedforward and feedback.

METHODS

We devised a computational walking model with a feedback-entrained CPG (Fig. 1A). The CPG was modeled to generate torque commands for the legs, with a variable feedback gain that could select between any combination of a purely feedforward rhythm, and a purely feedback driven reflexive behavior. The central oscillator was designed as a state estimator, which uses an internal model of leg dynamics to predict the leg state. The prediction can be corrected by sensory feedback, with a feedback gain L selecting the strength of correction, but the correction keeps the nominal characteristics of locomotion unchanged. We tested this controller with a dynamic walking model with pendulum-like legs, driven by hip torque commands.

We expected that, for a given amount of noise, there should be a single optimal gain. Too low a gain L should result in poor performance, due to sensitivity to disturbances without sufficient feedback correction. Too high a gain should also be detrimental to performance due to spurious commands generated by noisy feedback. State estimation theory explains how L should be optimally selected by balancing these two opposing effects, to yield minimum mean-square variability based on amount of process (environment) noise and sensor noise. We tested controller performance in terms of the RMS variability of step length, as a function of varying feedback gain (quantified by the maximum singular value of L, normalized by optimal L).

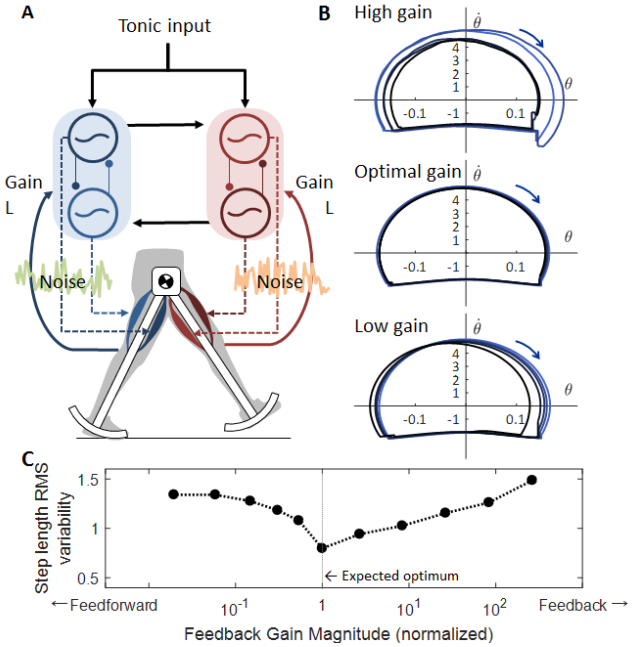

Figure 1: (A) A bipedal walking model using CPG with feedback, (B) phase plane plot of leg angle and angular velocity for High, Optimal, or Low gain L. (C) Root-mean-square (RMS) step length variability with respect to the feedback gain magnitude **(**normalized).

RESULTS AND DISCUSSION

The model was designed to produce the same nominal walking motion (a limit cycle), regardless of the amount of feedback. With noise affecting the system, the effect of L can be observed in the phase plane plot of leg angular velocity and angle (Fig. 1B). Overly high gain caused high variability due to sensitivity to sensor noise, and low gain also caused variability due to process noise. The optimal gain yielded least variability, summarized by a plot showing increasing step length variability for L either lower or higher than optimal (Fig. 1C).

These same principles could potentially be applied to other biological oscillators. State estimation theory is quite general, and could potentially explain how other oscillators should incorporate sensory feedback.

CONCLUSIONS

Sensory feedback improves robustness to noisy disturbances, whereas a central oscillator improves robustness to noisy sensors. A CPG can be designed to use sensory feedback optimally based on state estimation principles.

BALANCE-RHYTHMICITY BASED PROBABILISTIC MODEL FOR OPTIMUM WALKING PERFORMANCE IN HUMANS

INTRODUCTION

Quantifying variability in simple yet information-rich tasks such as walking and standing has provided preliminary knowledge towards understanding the functional adaptations associated with ageing and pathology [1]. It is likely that an *optimal window of output variability* characterises healthy neuro-motor function [1, 2]. Below this level, movement is likely *rigid*, while variability above this optimal level is associated with *unstable* movement, with both extremes indicating motor deficits. The selective effects of neuromotor pathologies such as Parkinson's Disease (PD) on different neurological structures, highlight the importance of understanding walking via the interplay between these critical characteristics in a holistic manner [1,2]. However, due to the common approach to select parameters in an arbitrary and *a priori* manner [1,2], the complex interaction between multiple features remains largely unexplored. For example, from a temporal perspective, *Stride Time* (ST; associated with *rhythmicity*) and from a spatial perspective, *Step Width* (SW; associated with *balance*) are known to be preeminent characteristics of gait performance [1]. An understanding of how these two features of gait are regulated to achieve optimum gait performance is critical for unraveling the *neuromuscular mechanisms* that are involved not only in walking, but motor performance in general [1,2]. With a vision to better predict healthy from pathological gait performance, we aim to extend our understanding of established optimal levels on the balance-rhythmicity plane (ST vs. SW, originally based on a meta-analytical approach) by estimating the uncertainty around the optimal boundaries, and therefore provide a more robust estimate of the window of healthy gait performance.

METHODS

Measures of variability reported through coefficient of variation (%CV) of ST were extracted from **thirty-six studies**, while those of SW from **three studies** [1]. In total, comparisons presented here are based on **768** (both ST & SW) pathological and **948** asymptomatic participants. The dataset from each study was statistically characterized by the group means and standard deviations. Uncertainties in each of these datasets were modelled by perturbing the baseline values with a normal distribution. *Monte Carlo Simulation* with 500 runs using *Latin Hyper Cube Sampling (Median method)* was performed on the input distribution. Non-positive entries from the sample population were removed, while the results served as inputs to a *binary logistic regression model*. The threshold values that distinguish the pathological and healthy groups were then calculated using an inverse binary logistic regression function [1]. The above procedure resulted in optimum windows for each individual dataset (or study) containing the uncertainty modelled at the input stage. The two-sided uncertainty estimates (in ±SD values) were then provided by the *68th%ile confidence limits*, calculated from the optimum windows. The above results were combined to represent gait performance on a 2-dimensional (balance-rhythmicity) plane for both healthy and pathological populations. Finally in order to highlight the effectiveness of such a multi-dimensional analysis approach, we superimposed independently collected ST and SW data from 11 healthy participants recruited previously in our laboratory. All data analyses were conducted in MATLAB R2016a (Mathworks Inc., USA).

RESULTS AND DISCUSSION

The probabilistic mean boundaries were 0.09 [±0.12] – 3.12 [±1.13] %CV for ST. Similarly, for SW the probabilistic boundaries were 18.90 [±4.91]– 34.30 [±2.63] %CV (Figure 1). In this collection of data, the majority of the pathological population **(23 studies; 56%)** suffered from basal ganglia disorders, including Parkinson's disease. Earlier, a hypothetical model of basal ganglia postulated the interplay between muscle tone and locomotion in basal ganglia diseases [2]. For the first time, we provide preliminary estimates of the uncertainties in these boundaries (including the likelihood estimates). Finally, the results from independent healthy young participants mostly fall (as indicated by the 95th %ellipse) within the probabilistic boundaries. In future, the sensitivity of this window will be further extended with newly collected data and other dimensionalities to walking performance.

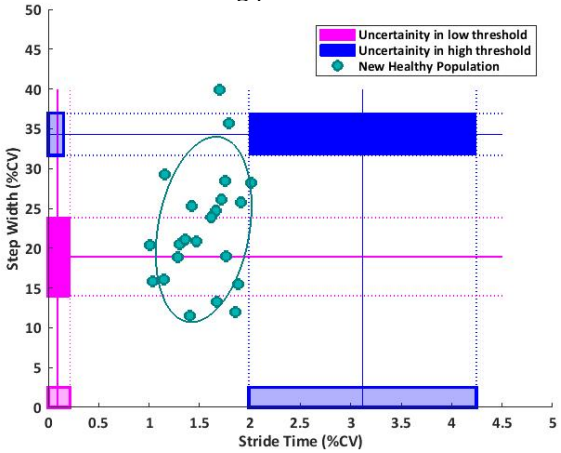

Figure 1: Probabilistic estimates of boundaries demonstrating optimum gait performance (with uncertainty windows) from ST and SW variability.

CONCLUSIONS

A 2D plane of gait performance with probabilistic estimates as presented here provides a basis for assessing neuro-motor deficits (e.g. balance vs. rhythmicity) in different pathologies.

EFFECT OF CHANGING GAIT PARAMETERS ON JOINT KINEMATICS AND MUSCLE ACTIVITIES OF THE LOWER LIMB DURING WALKING

Kazumasa Nishida, Koji Tagami and Yasuo Kawakami
Faculty of Sport Sciences, Waseda University
Corresponding author email: stay_free.nk@akane.waseda.jp

INTRODUCTION

Walking speed is determined by the stride length and cadence. It has been reported that stride length and cadence increase with walking speed[1]. The increase of stride length is attained by flexions and extensions of ankle, knee, and hip joints[2]. It has been also reported that activities of ankle plantar flexors increased as the stride length increased at the same walking speed[3]. Most of the previous studies have investigated only one gait parameter such as walking speed or cadence and not examined the cross-elemental effect. In this study, we aimed to investigate the effect of manipulating combinations of gait parameters (walking speed and cadence) on joint kinematics and muscle activities of the lower limb during walking.

METHODS

Eight healthy men (age: 22.4 ± 2.7 year, height: 173.1 ± 6.0 cm, mass: 65.4 ± 12.1 kg) participated in this study. Participants walked at speeds of 0.8, 1.2, and 1.6 m/s with cadences of 100, 110, 120, 130, and 140 bpm on a treadmill. Participants had walked for 30 s before they reached the target cadence and then walked for 30 s for measurements. Walking speeds were increased gradually and cadences were randomized at each walking speed. Kinematics were recorded by 2-axis goniometers over the ankle, knee and hip joints. Electromyogram (EMG) was measured from the lateral (LG) and medial (MG) gastrocnemii, soleus (SOL) and tibialis anterior (TA), and root mean square (RMS) values were calculated from measured data. RMS values of each muscle were normalized to the RMS value during isometric agonist contraction with maximum voluntary contraction (MVC). Maximal and minimal values of joint angles were recorded during walking. Three gait cycles within the 30 s were analyzed in the stance phase and swing phase. A two-way repeated measures ANOVA was performed to assess the effects of speeds and cadences on joint kinematics and muscle activities. Where the speeds x cadences interaction was observed, one-way ANOVA with a Bonferroni correction post-hoc test was performed to examine the effects of cadences at each walking speed. Statistical significance was set at $p < 0.05$.

RESULTS AND DISCUSSION

At 0.8 m/s in the stance phase, RMS values of the LG, MG, and SOL did not significantly change with the cadence changes. This suggests that at this speed, cadence has little impact on muscle activities during walking since the forward progression is not so much required at slow walking speeds[4]. At 1.2 m/s in the stance phase, these three muscle activities showed the lowest values at 130 bpm for LG (p<0.05, Figure 1), 120 bpm for MG (p<0.05) and 110 bpm for SOL (p<0.05). It is thus assumed that there is an optimal cadence for each plantar flexor that allows smallest muscle activity. Fukunaga et al. (2001) revealed spring-like behavior of the Achilles tendon that stores and releases elastic energy during walking on a treadmill at 0.8 m/s[5]. The present study suggests that the condition of 110-130 bpm at 1.2 m/s further ensures elastic energy usage by the Achilles tendon while saving muscle activation.

At 1.6 m/s in the stance phase, LG and SOL demonstrated significantly lower RMS values at 120-140 and 130-140 bpm, respectively, than the lower cadences while MG activities did not change across cadences. At this speed, the ankle joint range of motion significantly increased into plantar flexion regardless of cadence. Maximal hip flexion and extension angles also increased (p<0.05) at this speed. Together with a previous report on the stride length being larger with increased activities of plantar flexors at faster speeds, it is suggested that LG and SOL fibers were more efficiently interacting with tendons than MG to contribute to the increase in the stride length for speed, and that proximally located lower limb muscles were also recruited for forward progression.

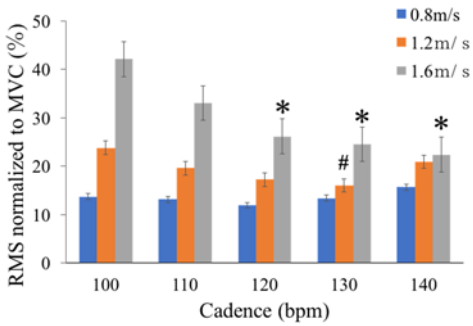

Figure 1: LG RMS values normalized to MVC for five cadences.
#: p<0.05 vs 100, 110, 120, 140.
*: p<0.05 vs 100, 110.
Significant differences across walking speeds were found but not shown in the figure.

CONCLUSIONS

This study indicated that the differences in cadence, stride length and walking speed affected muscle activities each of the plantar flexors differently. It is concluded that at a higher walking speed, muscle activities are efficiently saved with a higher cadence.

NET KNEE MOMENT ESTIMATION USING EXCLUSIVELY INERTIAL MEASUREMENT UNITS

INTRODUCTION

Knee joint loading is used as a clinical parameter in many musculoskeletal diseases, such as knee osteoarthritis. To assess the kinematic and kinetic quantities of interest, biomechanical models are widely used. One of these quantities is the net moment about the knee joint. Typically, this moment is calculated using bottom up inverse dynamics techniques driven by optical motion capture (OMC) and force plate (FP) input. However, this technique is restricted to a laboratory environment.

Estimation of kinematics in an ambulatory setting can be achieved with the use of inertial measurement units (IMU) [1]. In addition, recent work of the authors has utilized these kinematic estimates to predict the ground reaction forces and moments (GRF&M) during gait [2]. This study aims at evaluating the applicability of this method in assessing knee joint net moments using only kinematic input from IMUs during walking.

METHODS

The data collection took place at the Human Performance Laboratory (Dept. of Health Science and Technology, Aalborg University, Aalborg, Denmark). Eleven (11) healthy subjects volunteered after providing informed consent and the ethical guidelines of The North Denmark Region Committee on Health Research Ethics have been followed. An ambulatory motion capture system (Xsens MVN Link, Xsens Technologies BV, Enschede, The Netherlands), composed of 17 inertial measurement units was used to estimate the full-body kinematics in combination with the accompanying software (Xsens MVN Studio 4.2.4). Concurrently, for reference purposes, an 8-infrared-camera OMC system (Oqus 300 series, Qualisys AB, Gothenburg, Sweden) tracked the trajectories of 53 markers placed on the full body [2]. In addition, the GRF&M were measured using three (3) FP systems (AMTI, Watertown, MA, USA). The participants were instructed to walk straight at a self-selected comfortable walking speed over the FPs.

A biomechanical model composed of 16 body segments was constructed [2]. The 3D kinematics of the segments obtained from Xsens MVN were input to a whole-body inverse dynamics algorithm utilizing the Newton-Euler equations of motion. These equations estimated the total external force and moment, which, during the single stance phase, equals the GRF&M applied on the foot in contact with the ground. However, during the double stance phase, the equations result in the sum of the GRF&M applied to both feet. This sum was distributed between both feet based on a concept known as smooth transition assumption [2].
Following the estimation of the GRF&M applied on each foot, we calculated the net knee moments using a conventional bottom-up inverse dynamics approach in combination with the Xsens MVN kinematics of the foot and shank segments using the method reported by [3]. The estimated moments were compared to a similarly calculated reference, formed by FP and OMC input described in [2].

RESULTS AND DISCUSSION

The estimated net knee moments are depicted in (Figure 1). Strong Pearson correlation coefficients were found in the frontal and sagittal plane (ρ=0.73 and ρ=0.86, respectively) with relative root mean square error (rRMSE) values of 23.7±7.1% and 17.1±4.9%, respectively. Due to its relatively small magnitude, the transverse knee moment was estimated least accurately (ρ = 0.00, rRMSE = 34.4±4.8%).

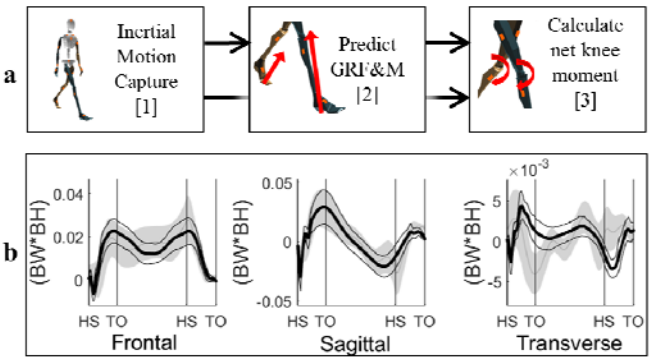

Figure 1: Workflow (a) and results (b) of the 3D net knee moment estimated using only Xsens MVN (mean (thin grey line) ±1 standard deviation (SD) around mean (shaded area)) versus OMC-FP reference (mean (thick line) (±1 SD (thin lines))). Values are normalized to body weight times body height and time to 100% of the stance phase averaged across all subjects and trials. Heel strike (HS) and toe off (TO) events are indicated.

CONCLUSIONS

In this paper, we have presented a method to estimate the net knee joint moments, using only an ambulatory motion capture system composed of 17 IMU modules. The results showed strong correlations for the frontal and sagittal plane moments. The proposed approach could allow the calculation of net knee moments outside gait laboratories. Future research should investigate the error sources and validate the clinical applicability of the technique.

PASSIVE ULTRASOUND PATCH FOR MONITORING JOINT CREPITUS

[1] **Davide Crivelli**, [1] Polly Blaikie, [1] Mark Eaton, [1]Cathy Holt
[1]Cardiff School of Engineering, Cardiff University, United Kingdom
Corresponding author email: crivellid@cardiff.ac.uk

INTRODUCTION

Arthritis Research UK states that 8.75 million people in the UK have sought treatment for osteoarthritis (OA). An early and reliable detection system for OA has clear potential to save large amounts of money on expensive diagnostic tools, such as MRI and x-ray, and greatly improve the lifestyle and health of patients.

When human joints develop OA, they can make audible grating or clicking noises during regular movement, indicating friction between bone and cartilage (Crepitus). This generally occurs during later stages of the disease, when it is too late to t to arrest further disease development [1]. Interestingly, joints and bones with earlier onset of the disease can also emit noise; however, this is confined to higher, non-audible frequencies.

In OA patients or people who have had joint trauma and are susceptible to early onset OA, being able to detect this noise, for example in joints with small cartilage lesions or instabilities, would allow for a much earlier stage detection (for example, in a GP surgery or even in self-monitoring linked to a mobile or tablet app), without expensive imaging costs and expertise. This would allow earlier intervention when the inflammatory and degenerative cascade processes have not fully developed. The technology to detect these signals is established in materials testing under the name of "Acoustic Emission" (AE). Biomedical research applications exist, but OA studies are limited.

METHODS

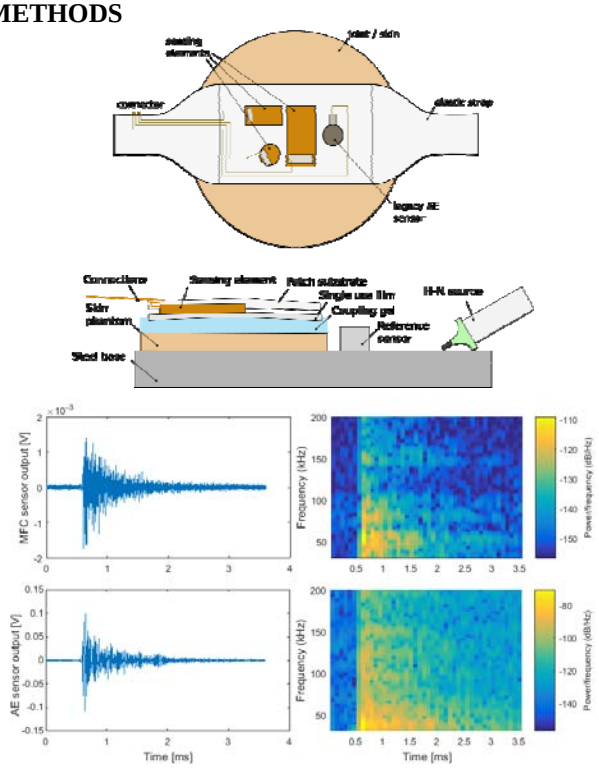

Figure 1: (a) design of the patch and experimental setup; (b) waveforms from MFC sensor (top) and legacy AE sensor (below), and their spectrograms (right).

The developed device consists of a flexible support that conforms to the patient's joint (Figure 1(a)). On the prototype patch, different transducers are mounted: one traditional AE sensor, with a bandwidth between 70kHz – 500kHz, a set of Macro Fiber Composite (MFC) sensors with different shapes and a Lead Zirconate Titanate (PZT) sensor.

To test the different sensors, a set of skin phantoms have been produced according to [2]. The phantoms are coupled to a steel block on which another sensor is mounted. Artificial AE signals are generated using a Hsu-Nielsen source; the performance of different sensors is then evaluated on different phantom thicknesses (1, 2, 5, 10 and 20mm). A sterile film is placed between the skin phantom and the sensor patch to simulate the operating conditions of the final device.

RESULTS AND DISCUSSION

An initial test to verify the output of the MFC sensors was performed. A MFC sensor and an AE sensor were bonded to a steel base using ultrasound grease. 10 calibration signals were generated around the sensors using a H-N calibration source. An example is shown in Figure 1(b).

The average measured Signal to Noise Ratio (SNR) for the MFC sensor was 24dB, whereas the average AE sensor SNR was around 40dB. According to [3], an OA knee releases AE with a recorded amplitude of $90dB_{AE}$ during a simple non-loaded movement (the reference being 1µV, and the H-N source 100dB or 100mV). The MFC sensor during the test outputted an average amplitude of $63dB_{AE}$ or 1.5mV. Assuming a proportional ratio between the calibration signal and the OA signal, it is reasonable to expect the OA signal as recorded by the MFC to be in the range of $53dB_{AE}$ or 0.45mV. This leaves a very good margin above the noise measured during the test and demonstrates the feasibility of using flat sensors for biomedical AE measurements. Further tests will be performed with different thickness skin phantoms in order to simulate the attenuation due to human tissues.

CONCLUSIONS

Tests performed so far demonstrate that the unamplified output of thin sensors can capture the signal amplitudes found in human joints without altering the information contained in the signal. Further tests will be performed to evaluate the effect of soft tissue on the signal propagation.

A NEW METHOD FOR MEASURING KNEE JOINT LAXITY

[1]**D. Pedersen**, [2]V. Vanheule, [2]R. Wirix-Speetjens, [3]O. Taylan [3]H.P. Delport [3]L. Scheys, [1]M.S. Andersen

INTRODUCTION

Knee joint laxity is a subject of great interest in research and orthopedics. However, the current methods for assessing laxity features several limitations e.g. non-quantifiable loads, soft-tissue artifacts and/or one-dimensionality [1]. Until now, the only methods not affected by any of those limitations have been invasive measures primarily performed intraoperatively. We propose a non-invasive method to accurately measure knee joint laxity in 3D.

METHODS

A device composed of a parallel manipulator and a multi-axis force/moment sensor have been developed. The device is capable of imposing multidirectional loads to the knee joint through a mounting unit. The device is designed to be used in conjunction with a low-dose biplanar x-ray system and 3D image data in order to track tibiofemoral kinematics under applied loads.

As proof-of-concept a cadaveric knee (female, age 73) was CT scanned (SOMATOM Definition Flash, Siemens) and subsequently mounted at 30 degrees of flexion in the device and placed inside a biplanar x-ray scanner (EOS, EOS imaging, France). Biplanar x-rays were obtained for eleven static load cases: anteroposterior loading (67 N, 134 N, -67 N and -134 N), mediolateral loading (12 N, 24 N, -12 N and -24 N) and internal/external moment (3 Nm, 6 Nm and -3 Nm). Subsequently, 3D bone geometry of femur and tibia were segmented from the CT image using Mimics (Materialise, Belgium). Bone position for each load case was reconstruction by registering the 3D bone geometry onto the biplanar x-ray images using an iterative closest point match between contours of the x-ray images and projected contours of the bone onto the image planes using Matlab (Mathworks, USA). The relative translations and rotations between the reconstructed tibia and femur were computed in AnyBody Modeling System (AnyBody technology, Denmark) following ISB recommendations.

RESULTS AND DISCUSSION

The primary tibiofemoral translation and rotation from the eleven different load cases is presented in Figure 1. Anteroposterior loading of 67 N, 134 N, -67 N and -134 N resulted in an anteroposterior translation of 3.49 mm, 4.22 mm, -6.55 mm and -7.87 mm respectively. Mediolateral loading of 12 N, 24 N, -12 N and -24 N resulted in a mediolateral translation of 3.11 mm, 4.17 mm, -2.46 mm and -5.48 mm respectively. Internal/external moment of 3 Nm, 6 Nm and -3 Nm resulted in an internal/external rotation of 10.15°, 12.72° and -20.23° respectively.

This method is combining concepts from robotic arthrometry and stress radiography into one unified solution that potentially enables unprecedented 3D joint laxity measurements non-invasively. However, the method is still under development and several aspects must be improved and validated before it becomes clinically relevant.

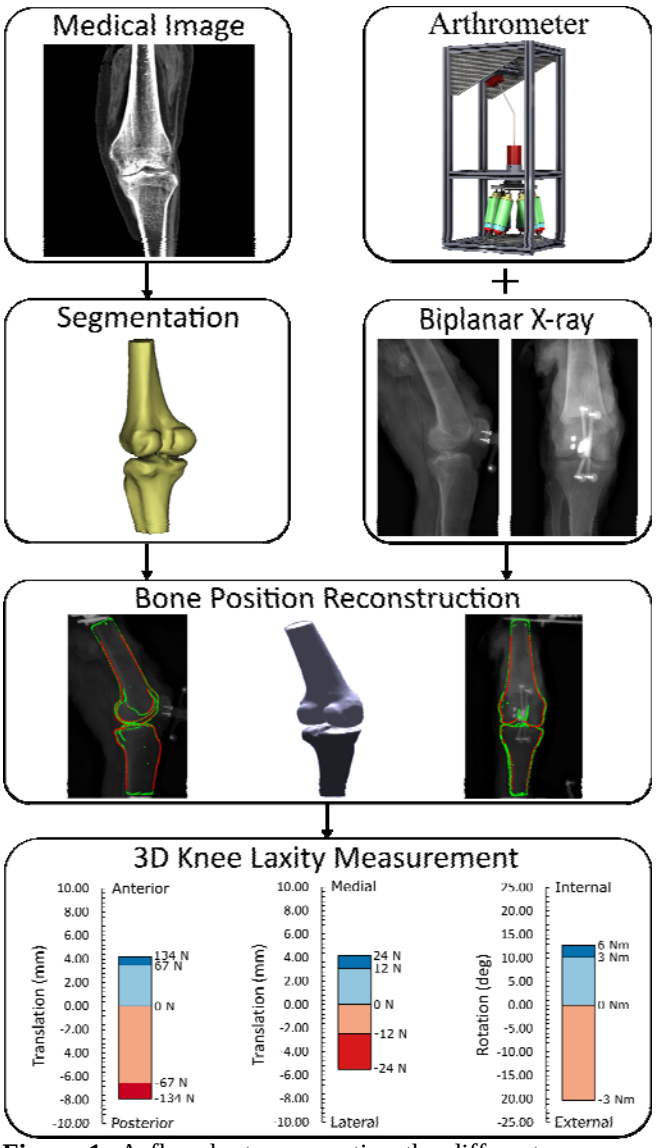

Figure 1: A flowchart representing the different processes in the proposed method. Included in the bottom of the figure are graphs displaying the primary tibiofemoral translation (mm) and rotation (degrees) in the different load cases.

CONCLUSIONS

We have displayed that the presented method is capable of obtaining knee joint laxity in 3D. The method enables advanced assessment of knee joint laxity and the interplay between ligaments. Furthermore, it may be used to improve subject-specificity of musculoskeletal models.

THE EFFECT OF BARREL SIZES AND SHAPES FOR HANDWRITING KINETICS

[1] Yu-Chen Lin [2]Chieh-Hsiang Hsu and [1,,3,4] **Li-Chieh Kuo**
[1]Insititute of Allied Health Sciences, College of Medicine, National Cheng Kung University

INTRODUCTION

Handwriting is one basic ability and common performance in our daily living activities. Especially, it is crucial for school-aged children mastering their school-life. One of the issues while teachers teaching children to write is how to choose the writing utensils. Many commercially available pens or pencils are claimed that the more comfort of gripping feeling or energy saving may be achieved by the users. The diameter of pencils and markers is about 7mm to 20mm. The large diameter and triangular shaped utensils are the common choices for children in kindergarten or first grade. However, previous research works did not provide a consistent result for the positive effect of these types of pen for better writing performance [1,2]. Moreover, the quantitative evidence with handwriting biomechanics for the effect of using pen with different barrel sizes and shapes are still limited.

The specific question raised in this study was that would the kinetic performance of the fingers and pen be significantly different when writing the tasks with different utensil sizes and shapes?

METHODS

The handwriting kinetics was collected using the Force Acquisition Pen (FAP) system. This custom system was established as a shape of a common ball-point pen which contains three thin-beam force sensors and one button-shape transducer (TBS-5 and SLB-50, Transducer Techniques, Temecula LLC, CA, USA) to simultaneously detect the forces between the digits (thumb, index and middle fingers) and pen barrel and also the contact force between the pen-tip and writing surface, respectively. The analog force data was converted and collected through the instruNet network device (iNet-100, GW Instrument, Inc., MA, USA). The sampling rate was 70 Hz. The force data was filtered using a Butterworth low-pass filter with a cutoff frequency at 3Hz.The barrel is made by aluminum and acrylic. There are three sizes of the diameter (13mm/17mm/21mm) of pen barrel. There are two types of shapes (Circular/Triangular).

Participants were asked to randomly use six different FAPs to trace different size of circles. They were asked to do the same task after three days for the test-re-test reliability.

This study conducted two kinetic parameters, namely average force (AF), force ratio (FR) to describe handwriting kinetics. The AF indicates the mean instant force. Four AFs were obtained (Thumb/Index finger/Middle finger/Pen-tip). The FR was defined as the instant force of the pen-tip divided by the instant total force of the three digits. The AF and FR were calculated only when the pen was touching the paper. The parameters were quantified using custom MATLAB programs (MathWorks Ltd., Natick, MA, USA).

The statistical analysis was performed using SPSS 20.0 (Statistical Package for Social Sciences Inc. Chicago, IL, USA). One-way repeated ANOVA was performed on the AF with three size levels. T-test was performed on AF and FR with shape difference. The level of significance was set at $p<0.05$.

RESULTS AND DISCUSSION

Five females and five males were recruited and the average age was 25.9 ± 4.5 years old. The intraclass correlation coefficient (ICC) of six FAPs was 0.854~0.927. Table 1 shows the detailed statistical results. For circular shaped FAPs, one-way repeated ANOVA shows significant differences in AFs of three digits and pen tip. For triangular shaped FAPs, one-way repeated ANOVA shows significant differences in AFs of index finger, middle finger and pen tip. For shape difference, except for the AFs of thumb and middle finger of 13mm FAPs as well as the FR of 21mm FAP, the other AFs and FRs of FAPs shows significant difference between two shapes. For the condition of using 13mm/17mm FAPs, compared to the circular FAP, participants used more force to manipulate the barrel rather than push the pen downward while using the triangular FAP.

Table 1: Statistical analysis results of handwriting kinetics for six FAPs.

Bonferroni post hoc test with significant difference:
[b]: 17mm>21mm [c]: 17mm>13mm [d]:17mm<13mm [e]: 17mm<21mm

CONCLUSIONS

Six FAPs were designed with three different diameters and two shapes. The tests of reliability show great results indicating the feasibility of the proposed system. The results of the effect on barrel sizes and shapes shows that the effect of shapes is different with different barrel sizes.

EVALUATING INERTIAL SENSORS AS A SURROGATE TOOL FOR JOINT LOADING

[1] **Shasha Yeung**, [1] Alex Wilson, [1,2]Thor Besier, [1]Ju Zhang, and [1,2] Justin Fernandez

INTRODUCTION

Standard gait and musculoskeletal analysis is used in many biomechanical studies but requires large gait laboratories with specialized equipment. However, mobile, real-time sensors have the potential to monitor and aid athletes' performance in the field. This could also be beneficial to the health sector in monitoring patient recovery especially after orthopaedic surgery. Therefore, there is a growing demand for portable gait and musculoskeletal analysis tools [1], and surrogate metrics for predicting joint loadings.

In this study we aim to evaluate the use of small commercial inertial measurement units (IMUs) as a surrogate metric for knee joint loading [2]. Inertial sensor-based gait recognition is a rapidly developing field. We evaluate Partial Least Squares Regression (PLSR) [3] as a statistical tool to predict knee joint adduction and tibial condylar loads from inertial sensor measurements of peak tibial accelerations, which we define as 'tibial-shock'.

METHODS

An IMU sensor was used to collect data simultaneously during a gait lab analysis of 27 male basketball players performing standard walking (age 32.6 ± 11.4yrs; weight 84.36 ± 15.55kg; height 185.3 ± 11.4cm, speed 1.1m/s). The marker placement used (Figure 1) gives an ideal marker-to-body-segment ratio to determine the complete position and orientation of each segment of interest for rigid body 3-D movement. Figure 1 also shows the placement of the IMU sensor (anterior-medial of the distal tibia). The sensor was placed accordingly to minimize soft tissue artifacts and correlate 'tibial shock' acceleration with musculoskeletal knee joint loading. 'Tibial shock' is defined at heel strike.

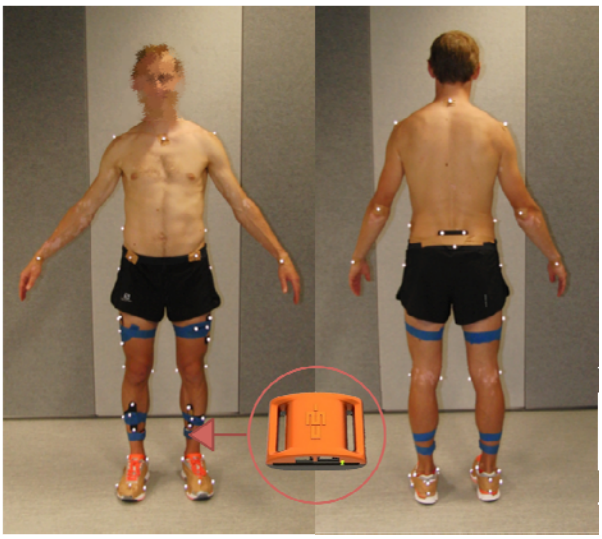

Figure 1: Subject marker set and IMU sensor placement.

Following each subjects trial, OpenSim was used to predict knee joint adduction and total tibial joint contact. A statistical analysis using PLSR was conducted to determine a predictive linear model between inputs of inertial 'tibial shock' and anthropometric measures (height, weight and condyle distance) to outputs of total knee tibial joint force and knee adduction. A 'leave-1-out' analysis was used to determine the error in prediction.

RESULTS AND DISCUSSION

When predicting the knee adduction torque simply from sensor 'tibial shock' a 'leave-1-out' analysis returned a root mean square (RMS) error of 6.8% of body weight (BW). However, when predicting medial condylar load from 'tibial shock' the RMS error was significantly higher at 54.6% BW. Adding anthropometric measurements did not significantly improve prediction results.

Further analysis revealed that the error in prediction of joint load was linear and not random reflecting that the model was missing some predictive parameters. Correction for the linear error reduced the prediction RMS error to 22.2% BW for tibial condyle load.

CONCLUSIONS

The study revealed that mobile IMU sensors are able to act as a surrogate measure to predict knee adduction well but tibial joint contact still requires further investigation into missing prediction variables, most likely additional anthropometrics. We hypothesize that since muscle force is a major contributor to joint load then muscle volume (an integral component of muscle force) is likely a missing factor.

THE MOBILIZE CENTER: ACCELERATING MOVEMENT SCIENCE WITH BIG DATA

Eni Halilaj[1], Jennifer L. Hicks[1], Joy P. Ku[1], Scott L. Delp[1,2]
Departments of Bioengineering[1] and Mechanical Engineering[2], Stanford University
Corresponding author email: delp@stanford.edu

INTRODUCTION

Mobility is essential for human health. Unfortunately, many musculoskeletal conditions, including cerebral palsy, osteoarthritis, running injuries, obesity, and stroke, limit mobility at a great cost to quality of life and healthy aging. The proliferation of wearable devices that monitor human activity is generating unprecedented quantities of data on human movement, behaviors, and health. Mobility data is also being collected daily by hundreds of clinical centers and research laboratories around the world. The mission of the Mobilize Center (mobilize.stanford.edu), an NIH Big Data to Knowledge (BD2K) Center of Excellence, is to overcome the data science challenges posed by mobility big data and improve human movement across the wide range of conditions that limit mobility. In this talk we will provide an overview of the Center's research, training, and dissemination activities and share specific ways in which the biomechanics community can become engaged.

METHODS

Our data science efforts center around four themes. We are developing (1) robust and flexible optimization tools to generate personalized biomechanical models and simulations from diverse experimental movement data, including wearable sensors; (2) new statistical learning algorithms to make predictions and discover patterns from large sets of noisy, sparse, and complex data, whether discrete or time-varying; (3) tools to model the role of behavioral and social dynamics in human health based on information collected with smartphones and wearable activity monitors; and finally, (4) machine-learning systems that integrate unlabeled data from diverse sources to aid clinical decision-making and transparently communicate with clinicians (Figure 1). We are disseminating these tools as open-source packages.

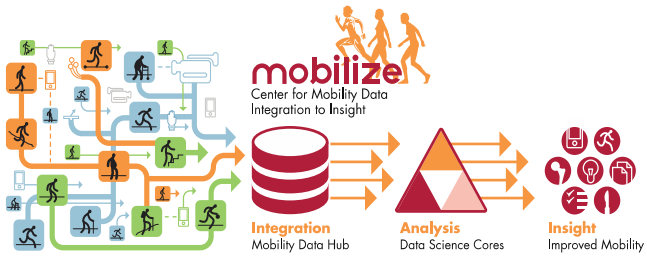

Figure 1: **Vision of the Mobilize Center.** We have partnered with hospitals, biomechanics labs, and industry affiliates to assemble a massive database describing human motions, including trajectories of markers placed on the body, video, ground forces, range-of-motion measurements, muscle electromyography, muscle strength, accelerometer and GPS recordings from wearable sensors, food intake, sleep records, and electronic health records. Analyses of mobility big data using our tools are generating important new insights for surgical planning, gait modification, prosthesis design, and exercise prescriptions.

To ensure that our data science research has a significant impact on human health, we are focusing our activities on a few critical biomedical problems. First, we are analyzing mobility data collected at Gillette Children's Specialty Healthcare to predict and improve the outcomes of surgeries in children with cerebral palsy and gait pathology. Second, we are integrating data from biomechanics labs, hospitals, and observational cohort studies to identify new approaches to optimize mobility in individuals with osteoarthritis, stroke, running injuries, and other movement impairments. Third, we are analyzing wearable sensor data from millions of people to discover factors that motivate individuals to be more active. Fourth, we are integrating omics and portable biosensor data to enable early diagnosis of pre-diabetes through convenient mobile health platforms.

In addition to the research, the Center is also training scientists at the intersection of data science and biomechanics. Our Massive Open Online Courses, including Mining Massive Datasets, Statistical Learning, and Convex Optimization, train tens of thousands of students and researchers. We have also established a Distinguished Postdoctoral Fellows and graduate student research program to create leaders in biomedical big data analytics.

RESULTS AND DISCUSSION

Our initial analyses of large datasets have already led to new insights that could inform public policy and clinical decision-making. For example, by mining smartphone data from millions of users, we have identified new social and environmental determinants of physical activity, which we are using to design evidence-based interventions aimed at increasing activity. We have built models to predict the pace of osteoarthritis progression over the course of eight years based on data collected in one visit and are starting to better understand how habitual physical activity affects cartilage microstructure. We have also identified key features that make children with cerebral palsy good candidates for surgery.

CONCLUSIONS

The proliferation of wearable technology and big data is poised to revolutionize movement research. In the face of growing volumes of data from varying sources, the biomechanics community must come together to discuss the challenges and opportunities that come with biomechanics big data and how proper application of statistical and machine learning methods, as well as sharing of data and tools, can help us overcome some of these challenges and lead to new insights. We hope that this session and similar future efforts can serve to accelerate research at the intersection of biomechanics and data science.

LONG-TERM MONITORING OF LOWER LIMB JOINT LOADS USING WEARABLE SENSORS: APPLICATION IN SPORT AND ORTHOPAEDICS

[1]**Thor Besier**, [2]Kaitlyn Weiss, [1]Alex Wilson, [1]Shasha Yeung, [2]Chris Whatman, [2]Michael McGuigan and [1]Justin Fernandez

INTRODUCTION

Mechanical loads play a critical role in the development, maintenance, and regeneration of musculoskeletal tissue. Knowledge of musculoskeletal tissue loads during activities of everyday living or during sport is critical to prescribe appropriate interventions or identify mechanisms of injury. Traditional methods to estimate internal loads, such as muscle and joint forces, involve motion capture, force measurement, and biomechanical modelling. Although powerful, these methods are typically constrained to lab environments, thus limiting the ecological validity of the results.

Wearable sensors, such as inertial measurement units (IMUs), provide an opportunity to measure and monitor human movement over an extended period of time in real-world settings. When attached to body segments, IMUs provide useful measurement of segmental linear accelerations and angular velocities, which can be interpreted on their own, or combined with a biomechanical model to derive joint kinematics.

This paper presents a framework that integrates data from body worn IMUs with biomechanical and statistical models to measure and monitor lower limb loads. Two applications of this framework include impact load monitoring for basketball players and knee load monitoring for patients who have experience total knee joint replacement.

METHODS

The framework we have developed consists of four components and uses accelerometer and gyroscope data sampled at 1000Hz from synchronised IMUs (IMeasureU Ltd, NZ) placed on the anterior distal third of each tibia.

1. Time Series Analysis. The first step when processing large IMU data files is to segment or classify the time-series data to obtain the epoch's of interest. This step can be performed using principal component analysis (PCA) or frequency-domain methods. For example, we might pull out regions of data during the day that correspond to walking and running if we wish to analyse those separately.

2. Mechanistic Model. Prior to data collection, we perform a series of calibration tasks with the purpose of developing a surrogate model to be used in the field. We collect motion capture and ground reaction force data and perform standard inverse dynamic analysis using an OpenSim biomechanical model (Stanford, CA). Our model is scaled to match the anthropometry of the subject using the Musculoskeletal Atlas Project [1]. We collect simultaneous IMU data during these trials for the purpose of improving the time series analysis (above) and developing the surrogate model.

3. Surrogate Model. Using the IMU data from the calibration trials in conjunction with the output variables from the mechanistic model (such as joint contact force) we create a surrogate of the mechanistic model. This is merely a statistical representation that mimics the response of the mechanistic model, given IMU data as input. To achieve this we use a Partial Least Squares Regression (PLSR), which is an efficient, multivariate-fitting method. This surrogate model can then be used to predict complex output variables, such as joint loads, from field-based IMU measurements.

4. Mechanobiology model. Finally, we combine knowledge of the tissue-level output variable with load frequency using a variance of the Daily Load Stimulus (DLS), which accounts for multiple loading events of different magnitudes [2].

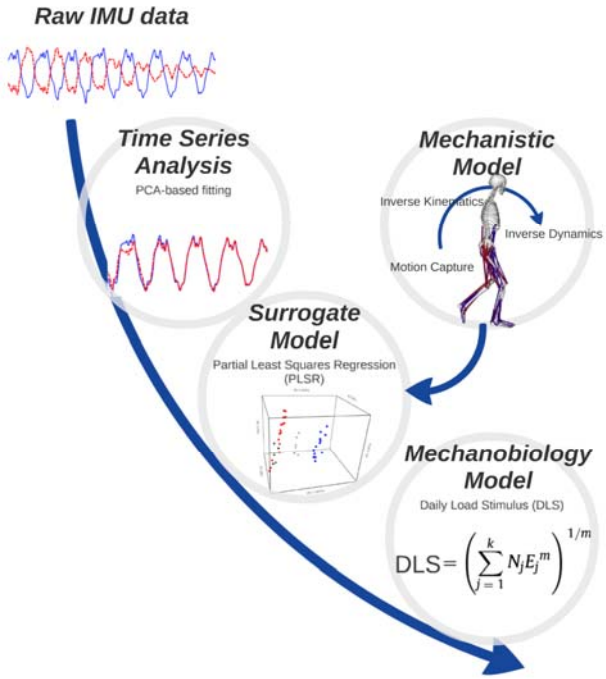

Figure 1: Framework for coupling wearable IMU data with various models to provide estimates of tissue-level loading stimulus.

CONCLUSIONS

We have presented a framework to incorporate wearable sensors with biomechanical models of tissue stress and will present example data collected from basketball players and patients who have had total joint replacement.

WALKING SPEED, MOTOR CONTROL, AND STRENGTH PREDICT RESPONSE TO SURGERY IN CHILDREN WITH CEREBRAL PALSY

[1]**Apoorva Rajagopal**, [1]Jennifer L. Hicks, [1]Scott L. Delp and [2,3]Michael H. Schwartz
[1]Stanford University, [2]University of Minnesota, [3] Gillette Children's Specialty Healthcare
Corresponding author email: apoorvar@stanford.edu

INTRODUCTION

Cerebral palsy (CP) is a neurologic motor disorder resulting from a brain injury at or near the time of birth. Each injury is unique, and there is large variability between individuals in both the severity and presentation of the movement disorder. Though there are many treatment options including musculoskeletal surgeries to improve the gait of children with CP, identifying good surgical candidates is challenging, and treatment outcomes are variable. Previous studies have shown greater pre-operative gait deformity [1] and better motor control [2] to be predictors of positive treatment outcomes after single-event multi-level surgery (SEMLS). However, because CP patients who undergo a SEMLS are likely to have greater gait deviation than the average CP patient, the data used to train these models represent a skewed subsample of the whole CP population. Thus, it is unknown if the estimated relative effects of various patient characteristics on treatment outcome are biased to better represent the more severely affected patients. In this study, we aimed to (i) build a regression model for predicting patient response to a SEMLS intervention and quantify patient factors that were most predictive of outcome while (ii) correcting for bias in our training data by weighting patients based on their estimated likelihood of having received a SEMLS.

METHODS

We analyzed the affected limb(s) of patients with a diagnosis of CP between the ages of 5 and 18. To be included, the patient had to receive two gait analyses spaced between 9 and 36 months apart with an intervening SEMLS on the affected limb. Normalcy of gait kinematics at the post-surgical gait visit was assessed using the Gait Deviation Index (GDI) [3].

A weighted linear regression model with l_1-regularization to choose a sparse subset of predictive features was computed to predict post-surgical GDI. Candidate predictor variables included features computed from motion capture measurements (gait kinematics, kinetics, and temporal-spatial parameters), physical exam measurements, patient history, and surgical procedures performed. All variables were standardized to have 0-mean and unit variance so that scales of the variables would not affect the l_1-regularization on the regression coefficients. The model was trained using 70% of the observations and tested on the remaining 30%. A 10-fold cross validation using the training data was done to choose the weight for the l_1-regularization on the regression coefficients. To correct for potential sampling bias in the data used to train our regression model, we used inverse propensity score weighting [4]. The propensity scores, or likelihood of receiving a SEMLS based on pre-operative gait variables, were calculated with a random forest classifier trained using the same candidate features as the regression model. Due to the stochastic nature of the model-building process, we averaged effect sizes of features in the linear prediction model over 100 runs.

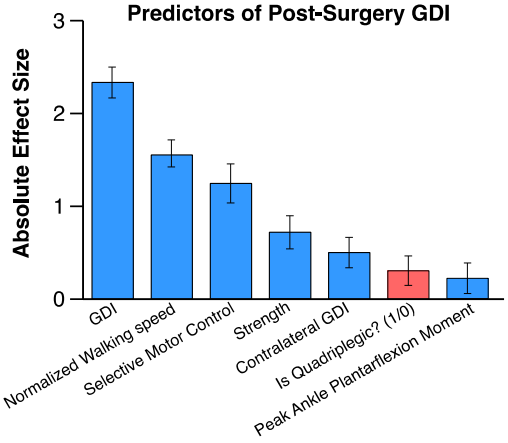

Figure 1: Effect size of pre-operative features in predicting post-operative Gait Deviation Index (GDI). Bars in blue indicate a (+) effect, and bars in red indicate a (-) effect. Height and error bars represent average and standard deviation of effect size, respectively, over multiple models.

RESULTS AND DISCUSSION

We analyzed 1,133 limbs that met all inclusion criteria. The final regression models to predict post-operative GDI included on average 9 variables. Effect size was defined as the change in post-SEMLS GDI per one-point change in the standardized predictor variable. The seven variables with the largest effect sizes were included in over 80% of the regression models (Fig. 1). The models accounted for, on average, 43% of variance in the training data and 40% of the variance in the test data. This performance is comparable to previously published models (e.g., [2]), even with our more conservative modeling approach.

CONCLUSIONS

Propensity score–based weighting provides a method to correct for sampling bias in observational data without sacrificing model performance. While pre-surgical GDI was the strongest predictor of post-surgical GDI, other patient variables including normalized walking speed, selective motor control, and strength were also strong predictors of post-surgical gait kinematics normalcy and were all stronger predictors than any specific surgical procedure. These results suggest that common "patient-intrinsic" factors play a role in determining surgical outcome regardless of the specific surgical procedures performed and should be considered when planning treatment.

ADVANCING A WORLDWIDE RESEARCH NETWORK AND DATABASE TO TRANSFORM BIOMECHANICAL GAIT RESEARCH

[1,2,3] **Reed Ferber**, [1,3] Sean T Osis
[1] Faculty of Kinesiology, University of Calgary
[2] Faculty of Nursing, University of Calgary
[3] Running Injury Clinic
Corresponding author email: rferber@ucalgary.ca

INTRODUCTION

Progress in data science methods, and the ability to collect, store and manipulate "big data," has the potential to improve biomechanical research methods and test broad hypotheses about biomechanical risk factors associated with walking and running gait-related musculoskeletal injury [1]. However, to build accurate classification models, an adequate number of samples are needed, which grows exponentially with the number of features used in the analysis. To directly meet this need, our group has developed the infrastructure and established a worldwide and growing network of clinical and research partners, all linked through an automated three-dimensional (3D) biomechanical gait data collection system: 3D GAIT.

METHODS

The 3D GAIT system is a deployed turnkey motion capture platform specifically designed for gait analysis using a treadmill. The overall system design is a nexus of three main principles: ease-of-use/automation, biomechanics best practices, and data science best practices. Consequently, the system uses off-the-shelf passive motion capture technology, consisting of between three and six infrared cameras (Vicon Motion Systems, Oxford) along with retroreflective markers that are pre-configured for ease of placement on the subject.

The 3D GAIT system derives a "characteristic" pattern from a spatio-temporal normalized set of gait cycles, which are segmented using a machine learning approach to account for inter-subject variability in technique [2]. These normalized gait cycles can then be analyzed by: 1) collapsing into a single representative time-series data set by various averaging techniques (i.e., median, weighted nearest-neighbor interpolant), and/or 2) extracting discrete features from each cycle separately, and merging into a representative feature set for a given subject (i.e., median peak angle, mean angular excursion).

The clinicians and biomechanics researchers who use the 3D GAIT system consists of a growing worldwide network spanning Canada, the USA, Brazil, the UK, Spain, the Netherlands, Australia, New Zealand, and South Korea. All clinical, demographic, and biomechanical data are automatically deposited into a centralized database which can then be applied to hypothesis-driven research.

RESULTS AND DISCUSSION

Despite the advancement of the 3D GAIT system, there are limitations. For example, variability in kinematic variables may be attributed to measurement error, skin marker movement, and inconsistencies in marker placement. Thus, we developed a novel software tool that uses real-time feedback to improve anatomical marker placement [3]. By directly addressing specific limitations, and developing novel solutions using a data science approach, we work towards achieving one of our overarching goals of providing new insights about how to improve gait biomechanics methods.

This mindset can equally be applied to improve clinical practice. For example, our research [4] identified two distinct subgroups of kinematic running gait patterns in healthy runners using a hierarchical cluster analysis without reliance on *a priori* knowledge. The results revealed that one cannot assume that running gait patterns within a sample will be representative of a population - a data science approach was able to reveal this insight.

We have also studied the use of pre-intervention gait kinematics and patient-reported outcome (PRO) measures to predict post-intervention response to a 6-week hip strengthening exercise intervention in patients with knee osteoarthritis (OA) [5]. The result: a unique combination of PRO measures and kinematic variables successfully sub-grouped knee OA patients with a cross-validated classification accuracy of 85.4%.

A final example involves new methods we developed to predict the timing of gait events, using only kinematics, during walking and running, and agnostic of forefoot or heel-toe running gait patterns [2]. This work represents a flexible yet unified approach that is *independent* of specific motion capture technology and can therefore facilitate and standardize the analysis of large volumes of data. We have since integrated the aforementioned techniques into the 3D GAIT software and they are now used across the network.

CONCLUSIONS

The development of our research-to-clinic knowledge translation paradigm is unique within our field and work has just begun to unlock the potential of applying data science methods to help answer complex clinical and biomechanical questions. We encourage the research community to openly share data, employ data science statistical methods, develop similar data research networks, and join our efforts to improve the field of gait biomechanics research.

THE BEGINNING OF A SPEECH MOVEMENT: APPLYING BIOMECHANICS TO ILLUMINATE FORM AND FUNCTION OF SOFT PALATE MUSCLES

Silvia Salinas Blemker
Multi-scale Muscle Mechanophysiology (M^3) Lab
Departments of Biomedical Engineering, Mechanical & Aerospace Engineering, and Orthopaedic Surgery
University of Virginia, Charlottesville, VA, USA; ssblemker@virginia.edu

The goal of my lab – called the Multi-scale Muscle Mechanophysiology (M^3) Lab – is to develop multi-scale computational models and utilize a variety of experimental techniques to study skeletal muscle biomechanics and physiology. We strive for uniting innovative ideas with opportunities to have clinical impact, and we are currently applying our muscle modeling work to wide range of areas, including movement disorders, vision impairments, muscle atrophy in space, aging, muscular dystrophies, sports medicine, and speech disorders. The goal of this talk is to describe our relatively new line of work over the last five years involving computational modeling of soft palate muscle function during speech (Fig. 1). We are developing these models in order to provide new insights into more effective approaches for cleft palate repair surgery. Since this clinical problem is not commonly studied in the ISB community, I hope this presentation will give the field an opportunity to learn about speech muscle function and provide an inspirational example of how our expertise and skills can have impact outside of traditional application areas of biomechanics.

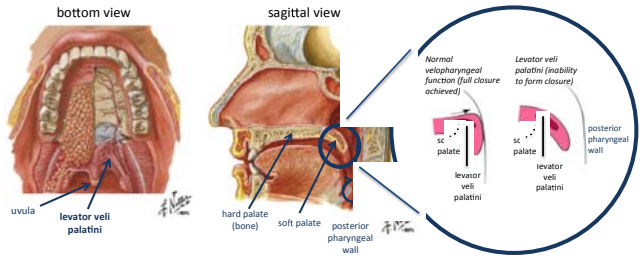

Figure 1: Illustration of the form and function of the soft palate.

Approximately one in every 700 infants is born with either a combined cleft lip/palate or an isolate cleft palate, making the cleft palate deformity one of the most common birth defects. Volunteer organizations such as "Operation Smile" allow children in third-world countries to undergo the same surgeries that are performed on children in first-world countries. However, there are many children in the U.S. and abroad who have long-lasting health problems after cleft palate repair: roughly 25% require one or more follow-on surgeries and never recover full speech function. Despite the existence of long-time established surgical treatments, palate deformities continue to have a significant negative long-term impact on a child's physical and mental development.

The palate is the roof of the mouth and is comprised of both hard and soft regions (Fig. 1). The palatine bone forms a hard palate on the roof of the mouth, and the soft palate is comprised of several muscles; the primary mover is thought to be the the levator veli palatini muscle. These muscles control the movement of the soft palate, which enables opening and closure of the airway between the nose and mouth. Lack of soft palate movement (velopharyngeal insufficiency) results in hypernasality and severe speech impairment; therefore, a successful soft palate repair is critical for speech development in children. Cleft palate repair is performed in an attempt to restore the anatomy of the palate musculature (including the levator veli palatini) and provide proper velum movement during speech. The interventions and treatments for children with cleft palates remain suboptimal because the mechanics of palate muscles and the repair surgery are complex and poorly understood. For example, before our modeling work, there were no answers to simple questions like "how does surgical tensioning of the levator veli palatini muscle influence its force generating capacity after surgery?" To address this need, we set out to create a modeling and simulation framework (Fig. 2) for predicting palate muscle function during speech with the goal of providing a more rationale basis for developing new approaches for cleft palate repair. In this talk, I will describe a series of modeling and imaging studies [1-4] that we have performed in order to (i) provide new insight into soft palate muscle form and function, (ii) answer the question of the effects of surgical tensioning on palate muscle function, and (iii) suggest novel approaches for cleft palate repair surgery.

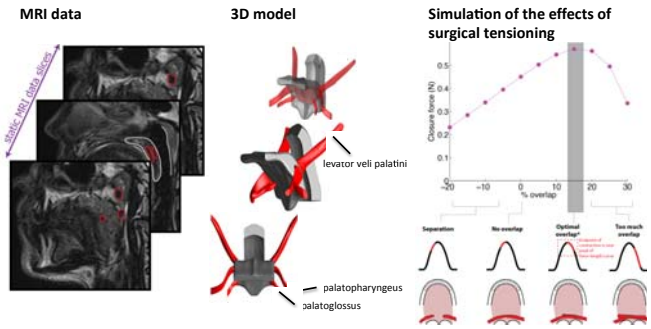

Figure 2: Image-based modeling of the soft palate leads to new insights into surgical approaches for cleft palate repair.

A COMPLETE AND COHERENT MUSCULO-SKELETAL DATASET FOR THE HUMAN SPINE

[1]Riza Bayoglu, [2]Leo Geeraedts, [2]Karlijn Groenen, [1,2]Nico Verdonschot, [1]Bart Koopman and [1]Jasper Homminga
[1]University of Twente
[2]Radboud University

INTRODUCTION

There has been a considerable increase in the number of musculo-skeletal models of the spine in the last decade. Some models were even applied in clinical practice [1]. However, the credibility of such models is largely dependent on the accuracy of the anatomical data they incorporate.

Previous studies showed that models are very sensitive to the spinal geometry and muscle attachment sites [2]. Moreover, morphological muscle parameters such as fiber length, sarcomere length, optimum fiber length, tendon length, pennation angle, mass, and physiological cross-sectional area can affect muscle and joint force estimations considerably [3]. Implementing these parameters in an accurate and consistent manner will facilitate more realistic simulation of the muscle contraction dynamics and, therefore, will increase models' credibility.

Earlier anatomical investigations on the spine primarily focused on the cervical and lumbar regions. Attachment sites and the morphological parameters of the neck muscles were measured from a single cadaver [4]. Other studies measured some of the morphological parameters and presented anatomical drawings to illustrate muscle attachments sites [5]. There is, however, no anatomical dataset which enables the development of a complete and coherent musculo-skeletal model for the entire human spine. The lack of such coherent dataset requires models piecing together data from several cadavers. This approach then necessitates scaling between the skeletal geometries of the cadavers and their muscle architectures. As a consequence, models using combined datasets may not be anatomically realistic. A musculo-skeletal dataset measured from a single body will enable a consistent model of the spine and is, therefore, a better approach for use in clinical practice [6]. Thus, the aim of this study was to obtain a complete and coherent anatomical dataset for the entire human spine.

METHODS

We obtained an embalmed body of a 79 years-old male (height: 154 cm, mass: 51 kg). We dissected muscles of the spine from the right side of the body and measured positions of muscle attachments at origin and insertion by using the NDI Hybrid Polaris Spectra tracking system. We also measured via points and wrapping surfaces for muscles with curved lines-of-action. Before dissection, we divided the muscles into a number of muscle-tendon elements to improve the simulation of the muscles' function. Finally, we measured fiber length, tendon length, sarcomere length (by using the laser diffraction method, Figure 1c), optimal fiber length, pennation angle, mass, and physiological cross-sectional area (PCSA) for each element [7].

RESULTS AND DISCUSSION

In total, we measured 49 muscles using 321 elements. All bones with muscle lines-of-action are shown in Figure 1d. Total muscle PCSAs ranged from 0.09 cm^2 for sternothyroid muscle to 18.50 cm^2 for longissimus thoracis muscle. Mean sarcomere lengths ranged from 2.10 µm for sternothyroid muscle to 3.91 µm for semispinalis cervicis muscle. Mean optimal fiber lengths ranged from 0.6 cm for rectus capitis lateralis muscle to 25.1 cm for rectus abdominis muscle. Mean tendon lengths ranged from 0.4 cm for sternohyoid muscle to 20.5 cm for psoas major muscle. Morphological muscle parameters we measured fit with the range of data reported in literature.

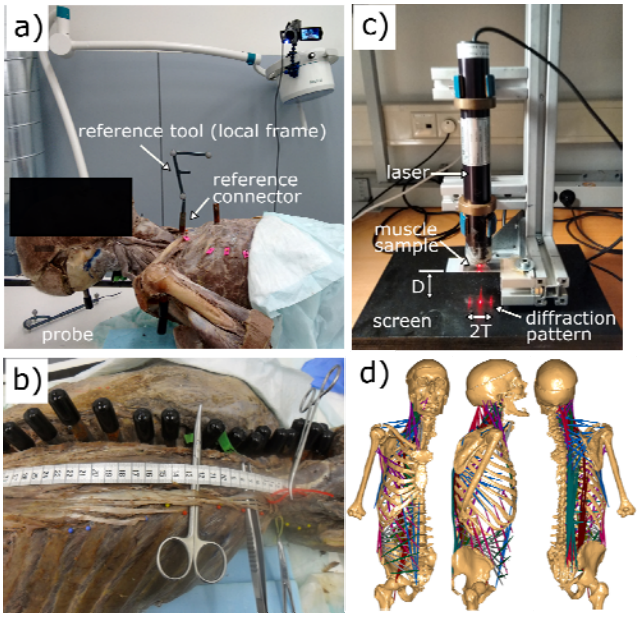

Figure 1: a, b, c: Experimental set-ups. d: The muscles measured in this complete dataset are highlighted.

CONCLUSIONS

In this study, we obtained a complete and coherent anatomical dataset for the entire human spine. This dataset includes segmented bone surfaces (in STL file format), three-dimensional coordinates of muscle attachment sites, and the morphological muscle parameters from a single male human cadaver. This dataset is freely available through http://www.utwente.nl/ctw/bw/research/projects/TwenteSpineModel.

EFFECT OF PROGRESSIVE DISSECTION ON THE 3D KINEMATICS OF A SHEEP SPINE

INTRODUCTION

Previous studies examining the kinematics of the thoracolumbar spine and rib cage have been limited by the number of motion segments for which motion was tracked [1,2]. Additionally, the biomechanical effect of the soft and osseous tissue structures of the rib cage on the segmental motion of the spine has not been fully quantified [2]. While previous investigations have examined changes in spinal segmental rotation in the plane of primary motion, little has been done to examine the out of plane motion or how these tissue structures affect the magnitude and directions of spinal movement [2]. This study therefore aimed to determine the three-dimensional movement of all motion segments in the thoracolumbar spine, with the spine in an intact state and following progressive dissection of the ribcage, including resection of the intercostal muscles, cutting of the sternum, and removal of the ribs.

METHODS

An ovine thoracolumbar spine segment with intact rib cage (T1 – L7) was obtained. The T1 and L7 vertebral bodies (VB) were potted in dental acrylic and positioned in a 6DOF robotic testing facility. The rotation of each individual VB was tracked using an Optotrack Certus. To achieve this, three-marker rigid bodies were affixed to each spinous process (T2-T14 and L1-L6) as well as to the base and robotic arm, for a total of 21 marker frames. 3D printed marker frames were custom designed for each level to ensure free unhindered movement and constant visibility of the marker frames during all movements of the spine.

Under displacement control, five cycles of movement were applied to the T2 VB with the last cycle being used for analysis. Three movements were conducted – flexion to a total of 27deg, lateral bending to 42deg and axial rotation to 25deg. The spine was tested for each load case, first in its intact state and then following three stages of progressive dissection including: i) resection of the intercostal muscles, separating the ribs from each other; ii) sectioning the sternum between T2 and T3; and iii) removal of the ribs, leaving approximately 50mm of rib attached to each VB. Three dimensional rotations of each VB were obtained from the rigid body markers as Euler angles using the XYZ convention.

RESULTS AND DISCUSSION

For lateral bending, progressive dissection of the spine resulted in a shift in the distribution of the VB rotations in the primary direction of motion (Figure 1). As the ribcage structures were dissected, increased rotation was seen from T2-T10 and decreased rotation from T11-L6. An out of plane buckling behavior was also observed. This was largest in the intact state, with T2-T12 experiencing a flexion of up to 13.2° (T5), and T14-L6 experiencing an extension of up to 11.2° (L4). After all stages of the progressive dissection, including removal of the ribs, this decreased in magnitude to -5.4° (T7) and 4.2° (L4). The progressive dissection also led to the neutral point between flexion and extension to be shifted down the spine from T13 to the L1/2 disc between the intact and no ribs conditions. A coupled axial rotation was seen throughout the upper thoracic spine (T2-T11), but did not change greatly with dissection.

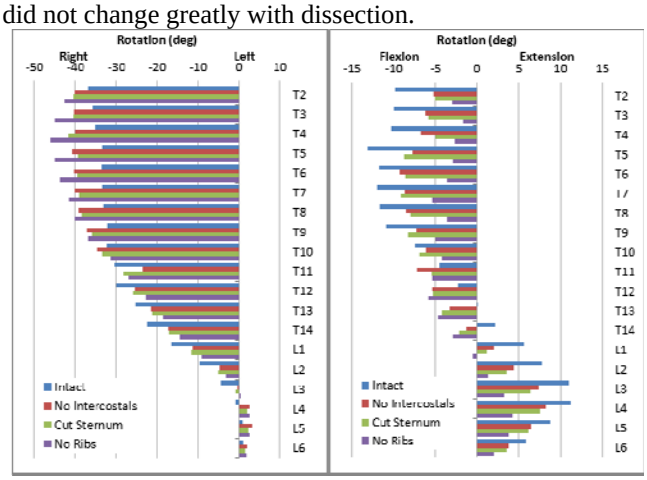

Figure 1: Absolute VB rotations for primary lateral bending. Primary direction of motion (left) and the out of plane flexion/extension direction (right)

In flexion, only very small changes were seen in the distribution of VB rotations in the primary motion direction, for each stage of dissection. However, the out of plane rotations showed progressive increases in coupled lateral bending, with a buckling behavior across the length of the spine - T2-T9 curved to the right and T10-L6 towards the left. In the intact spine the magnitude of this lateral bend peaked at -2.9° (T14), and 2.7° (T3). This approximately doubled with the cutting of the intercostals, and after removal of the ribs was -9.5° (T14) and 10.3° (T3). A coupled axial rotation was also seen, primarily in the upper thoracic spine and most dramatically after cutting the intercostals, peaking at -10.5° at T4 with the ribs removed.

In contrast, primary axial rotation saw only small changes in VB rotation with progressive dissection. Coupled out of plane flexion was seen in the lower thoracic spine and extension in the lumbar spine, but at most levels, this was less than 3° for each condition.

CONCLUSIONS

The soft and osseous tissues of the rib cage play an important part in the movement of the whole spine, both in the primary direction of rotation and in coupled out of plane rotations. In lateral bending, the intact spine showed the largest flexion/extension movements. In direct contrast, removing either soft or osseous rib cage tissues increased the lateral rotations occurring during flexion.

The observed coupled rotations and their changes with dissection are important considerations for computational modelling of the biomechanical behaviour of the spine and have clinical relevance in studying biomechanical aspects of pathologies such as scoliosis, which involve atypical rotation of the spinal VB.

MUSCULOSKELETAL MODEL OF LUMBAR SPINE AND LOWER LIMB

Clément D Favier, Andrew TM Phillips
Imperial College London, Structural Biomechanics
Corresponding author email: clement.favier13@imperial.ac.uk

INTRODUCTION

Low back pain (LBP) is a common debilitating condition [1] related to spinal biomechanics, although there is not a clear pathway between the deformation of spinal structures and pain. LBP is often associated with an unusual lower limb stability strategy [2], which could either contribute to the pain, or be an attempt to protect the spine from injury. Understanding these strategies is essential to develop new treatments, requiring knowledge of the loading experienced by the spine for different types of movement. Computational models are now widely used for predicting loading and deformations of bones. In this study, a lumbar spine and lower limbs musculoskeletal (MSK) model is coupled with a finite element (FE) model of the lumbar spine to predict the deformations of spinal structures. A preliminary validation study of the MSK model was conducted and is presented here.

METHODS

An MSK model was developed in *OpenSim*. This model is composed of five articulated lumbar vertebrae linked proximally to a two-segment ribcage and distally to the sacrum and pelvis. The model also includes head, neck and arms with mass properties only. Bone geometry for the upper body is segmented from the Visible Human Dataset CT-scans. Muscle actuators in the lumbar region are adapted from existing models [3, 4]. Stiffness of intervertebral discs and lumbar ligaments is modeled with bushing elements at each lumbar joint. The lower limbs are adapted from an existing MSK model [5] both for geometry and muscle properties.

To estimate muscle and joint reaction forces (JRF) that can be used later as boundary conditions in a FE model, a pipeline of simulations based on a subject's movement was used. Movement data was recorded with the passive optical motion capture system from *Vicon Nexus*. Inverse kinematics and inverse dynamics simulations were used to compute joint angles, forces and moments. An optimization problem was solved to compute the muscle forces required to produce the calculated forces and moments. This optimization problem consists in minimizing the overall muscle activation with a quadratic muscle recruitment criterion. A JRF analysis was performed to estimate the forces and moments corresponding to the internal loads carried by the joint structures. A preliminary validation study was carried out by comparing JRF in the lumbar spine to *in-vivo* measurements at L1-L2, L3-L4 and L4-L5 [6] joints and simulation results from other MSK models of the lumbar spine [7, 8] in static positions. Three lumbar spine positions are presented: 30° flexion, 15° extension and 20° lateral bending.

RESULTS AND DISCUSSION

Intervertebral JRF in the different static positions were normalized to upright standing results to make comparison between models and subjects possible.

Figure 1 shows results at the L4-L5 joint. The JRF estimated by the model are in good agreement with *in-vivo* measurements from Wilke *et al.* [6]. When compared to other MSK studies [7, 8], the model also gives consistent JRF estimations. Overall, the results are within the range of the different studies. Similar results are found at other vertebral levels.

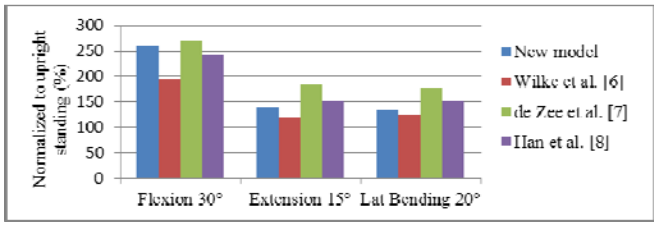

Figure 1: Comparison between JRF at L4-L5 level.

Although dynamic validation is still needed for daily living tasks (walking, sitting down and standing up, climbing and descending stairs), and load carrying activities, the model shows promising results with basic positions of the spine. To increase the consistency of bone geometry and joint locations in the model, new full-body MRI scans are currently being acquired from healthy volunteers. Different cost functions are also being tested by the authors to change the muscle activation pattern depending on the activity. These improvements to the MSK model are hoped to give a more accurate estimation of JRF and muscle forces. This will impact directly the understanding of LBP mechanisms, since these forces are used as boundary conditions in the FE model currently under development.

CONCLUSIONS

A MSK model of the lumbar spine and lower limbs has been developed and statically validated. The combination of this model with a FE model of the lumbar spine is expected to give insights on how the structures of the spine deform under loadings experienced in daily life activities. This will help in the understanding of potential LBP mechanisms.

INTRODUCTION

Low back pain (LBP) is a widespread problem with a lifetime prevalence of 58-84% in western countries [1] and although considered idiopathic, lifting is an independent risk factor [2]. Several models of the spine have been developed to estimate intervertebral joint and spinal muscle forces from kinematic and kinetic data, including two using the modelling software OpenSim [3,4,5]. However, few OpenSim full-body models have been developed [6,7,8] and to the authors' knowledge, none of the publicly available models have been validated specifically for lifting tasks, which involve greater trunk range of motion than walking or running. The aim of this study was to validate muscle activation and intervertebral loads estimated by a full body OpenSim model with a detailed lumbar spine, specifically for lifting tasks. The results for a single subject are presented in this abstract.

METHODS

The OpenSim model used in this study is a modified version of a full-body model [6] that includes a detailed lumbar spine [3] with five articulated lumbar intervertebral joints and 238 muscle fascicles to represent the erector spinae (ES), rectus abdominis (RA), internal oblique (IO), external obliques (EO), psoas major, quadratus lumborum, multifidus, and latissimus dorsi.

Kinematic and kinetic data of three lifting tasks with a load of 5 kg (two-handed squat (SQ), two-handed stoop (2ST), and one-handed stoop (1ST) were collected for one male participant (30 yrs, 81.9 kg), with a 12-camera Vicon motion analysis system (Oxford Metric, UK) and two force platforms (AMTI, USA), with sampling rates of 100 Hz and 2000 Hz, respectively. EMG was recorded at a sampling rate of 2000 Hz using 10 surface electrodes (Delsys, USA) placed bilaterally over the RA, IO, EO, lumbar ES and thoracic ES muscles [8].

The model outputs were verified using two approaches: 1) comparison between the muscle activation patterns estimated by the OpenSim model and the corresponding measured surface EMG signals; 2) comparison between spinal loads estimated by the model and those recorded by telemeterised vertebral body implants during lifting tasks, expressed as a percentage of neutral standing load [9].

RESULTS AND DISCUSSION

The back muscle activation predicted by the model closely matched the activation patterns measured by EMG placed on the thoracic and lumbar ES (Figure 1) for the lifting techniques evaluated. The L1 maximum vertebral compressive loading estimated by the model (592% and 600% of standing load, for SQ and 2ST, respectively) were comparable to the average L1 maximum compression vertebral loads recorded by telemeterised implants for three subjects lifting a 7 kg load (465% and 507% of standing load, for SQ and 2ST, respectively).

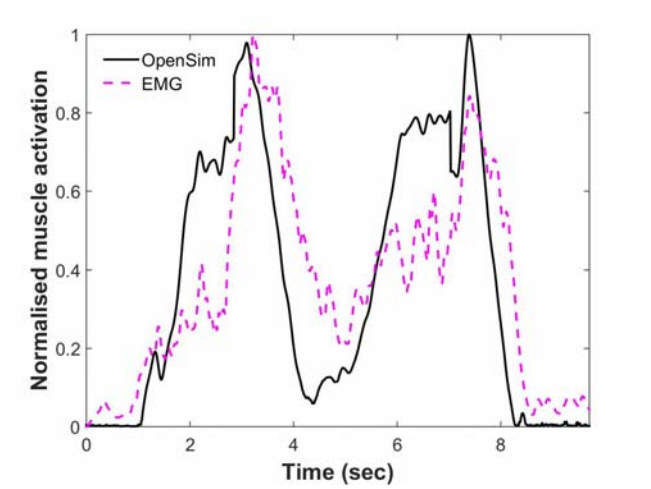

Figure 1: Comparison between the measured EMG and the muscle activation estimated by the OpenSim model for the right lumbar Erector Spinae during a squat.

CONCLUSIONS

The preliminary validation results indicated that the full body OpenSim model evaluated in this study estimates spinal muscle activations similar to the measured EMG and spinal loads of reasonable magnitudes for the lifting tasks undertaken.

A NEW METHODOLOGY FOR THE VALIDATION OF IN-SILICO INTERVERTEBRAL DISC MODELS USING CT IMAGING UNDER LOAD

[1] **Fernando Y Zapata-Cornelio**, [1]Marlène Mengoni, [1]Vithanage N Wijayathunga and [1]Ruth K Wilcox
[1]Institute of Medical and Biological Engineering, University of Leeds, Leeds, UK

INTRODUCTION

Globally, back pain causes more disability than any other condition, with intervertebral disc (IVD) degeneration being a major cause [1]. The development of new interventions for the IVD are currently hampered by the lack of available pre-clinical testing methods, meaning many devices fail at animal testing or clinical trial. Whilst in silico models hold some promise as a testing tool, the validation of these models at tissue level has not yet been fully performed, potentially leading to imprecise predictions of the IVD behaviour. The aim of this study was to develop a methodology to quantify the IVD bulge *in vitro* and use the technique to validate specimen-specific finite element (FE) models of the tissue.

METHODS

Experimental methods. Two sub-adult bovine tails (2 – 2.5 years) were obtained from a local abattoir. A total of four osteodisc (OD) samples from the coccygeal region were harvested, isolating the intervertebral disc from other soft tissues and leaving approximately 15 mm of bone at each end. The samples were potted in PMMA endcaps and forty glass fiducial markers were placed on the surface of the IVD and sub-divided circumferentially in eight different regions (ie five markers distributed axially every 45°).

The specimens were imaged using a HR-pQCT scanner (XtremeCT, Scanco Medical AG, Switzerland) at an isotropic voxel size of 82 µm. Each specimen was compressed axially, using a customized rig designed to fit within the imaging chamber of the CT system. Each individual specimen was scanned at two stages: before compression, and after 1 mm of applied axial compression was held for 1.5 hours, minimising the risk of scanning errors due to the viscoelastic effects in the tissues.

Computational methods. All specimens were modelled with a specimen-specific approach. The geometry of each individual specimen was captured using 3D scan data from the unloaded scan. The CT images were segmented to isolate bone, soft tissues, individual glass fiducials markers, and the cement endcaps in Simpleware ScanIP v7.1 (Synopsys, Mountain View, USA). The mechanical properties of bone and PMMA cement were modelled using isotropic elastic linear materials [2]. The IVD was modelled using non-linear elastic mechanical properties previously derived for an independent set of bovine IVD specimens. Boundary conditions similar to the experimental set up were applied to the FE models.

The coordinates of the center of the glass fiducial markers in the aligned images at all compression stages were extracted using a bespoke script (Python 2.7, www.python.org) and the IVD bulge was derived as the local radial displacement. In the FE model, the mean of the coordinates of the closest nodes to the markers (5-10 nodes) were used to derive the predicted IVD bulge at each marker, and compared against the measured IVD bulge for each individual marker. The agreement between the *in-silico* predicted IVD bulge and the *in-vitro* measured IVD bulge was assessed using concordance correlation coefficients (CCC) [4].

RESULTS AND DISCUSSION

All specimens were successfully compressed and imaged at an applied displacement of 1 mm. The in-vitro IVD bulge at an axial compression of 1 mm were determined from the marker positions (5 markers at each circumferential location for each disc), resulting in a mean bulge of 0.36 mm (st.d.= 0.19 mm). A very good agreement (CCC=0.6458) was observed between the *in-vitro* measured bulge and the *in-silico* predicted bulge (Figure 1).

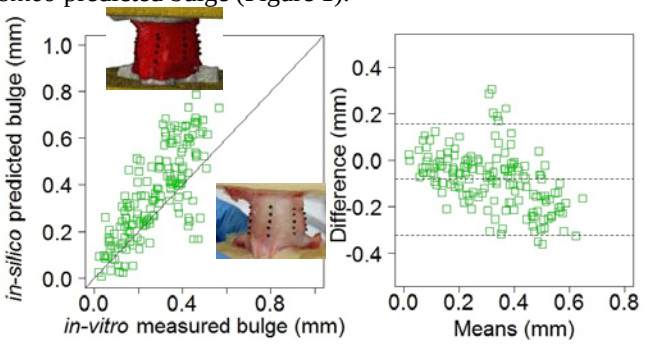

Figure 1: Bland-Altman plot of the *in-silico* vs *in-vitro* measured IVD bulge (n=4).

This study demonstrated that using non-linear elastic material properties derived previously resulted in a good agreement between the experimental and computational approach. The accuracy could be further improved by tuning the non-linear mechanical properties of the FE models to correlate not only the IVD bulge but also the overall load-displacement behaviour using optimisation tools.

CONCLUSIONS

The methodologies presented have introduced new means for the calibration and validation of the non-linear behaviour of the disc not only at a small scale, but as a whole unit in a realistic environment. The latter could be potentially used in the assessment of interventions such as nucleotomy, discography and new therapies that aim to repair the structural integrity of the disc and nucleus.

THE INFULENCE OF THE ROCKER SHOE DESIGN ON SHEAR IMPULSES DURING WALKING IN PATIENTS WITH DIABETIC NEUROPATHY

INTRODUCTION

Rocker outsole shoe is commonly prescribed to diabetic patients to reduce the risk of plantar ulceration. It is well stablished that the primary biomechanical role of the rocker outsole is to offload the plantar aspect of the forefoot [1]. Shear forces have been previously affiliated to the etiology of diabetic foot ulcers [2]. However, there is an obvious paucity of research on the effect of the rocker outsole design on the shear impulse in diabetic patients. While the impulses can be measured during walking [3], the majority of studies concentrated on the vertical component of the Ground Reaction Force (GRF).

Anterior-posterior (AP) shear impulses which are termed positive and negative impulses respectively [4], change the momentum of the body in forward direction. However, Medial-lateral (ML) shear impulses act to push the body away (negative) and towards (positive) the contralateral side [4]. It is envisaged that the rocker outsole design can alter these impulses by changing the contact angles and forces during the shoe-ground interaction. Therefore, the purpose of this study was to investigate the effect of different rocker outsole designs on AP or ML shear impulses.

METHODS

Ten female participants with diabetes aged 55.6±5.25 years, with no history of previous ulceration were recruited to the study after ethical approval was granted by the local university. Three different (A, B and C) designs of toe-only rocker outsoles (with the rocker angle, apex angle and heel height of A:10°, 80°, 2 cm; B: 15°, 95°, 3.5 cm; C: 20°, 95°, 4 cm, respectively) were used. These designs were previously shown to be most effective in plantar pressure reduction in diabetic patients [5]. GRFs were collected while subjects walked with each of the three rocker outsole shoes in a random order with a controlled self-selected speed over a 10-meter walkway. A Kistler force plate was used to record the GRFs of right and left feet at 100 Hz from a total of six trials. AP and ML GRFs of each trial were time-normalized and then integrated to find the shear impulses, and further averaged over left and right trials, separately. Main outcome measures were: the negative, positive and total AP and ML impulses as well as the AP and ML positive/negative impulse ratios. A repeated measures ANOVA followed by an adjusted post hoc with Fisher's Least Significant Difference (LSD) analysis was performed with a confidence interval of 95% using SPSS software.

RESULTS AND DISCUSSION

The positive and total ML impulses of the left foot were both significantly ($P<0.05$) lower in A compared to B and C while there was no significant difference between B and C (Figure 1). This can be mainly due to the different apex angle of the rocker A (80°) compared to the apex angles in the other two rockers (95°).

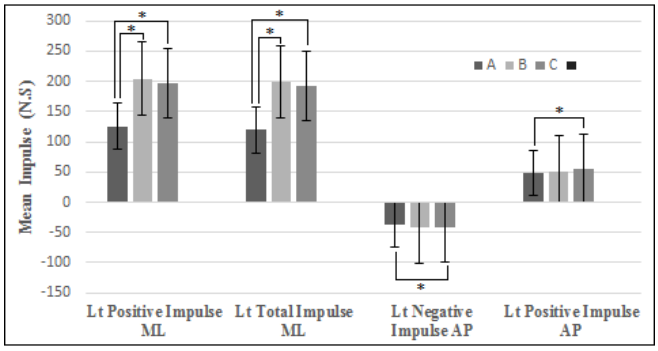

Figure 1: Significant results for three rocker outsoles A, B and C. * indicates statistical significance at $p<0.05$.

The negative AP impulse for the left foot was also significantly ($P<0.05$) lower in A compared to B and C, with no significant difference between B and C. This can be related to much bigger differences in height between A and B/C compared to the height difference between B and C with rocker C having the least height. The positive AP impulse for the left foot was significantly ($P<0.05$) lower in A compared to C, with no significant difference between A and B or between B and C. This finding can be the consequence of a more considerable increase in the rocker angle from 10° in A to 20° in C. No significant difference between different rocker outsoles were found for the right foot.

CONCLUSIONS

The results of this study showed that the outsole design of the rocker can influence the shear impulses. Although it has been frequently demonstrated that the offloading capability of the rocker outsoles increases while increasing the rocker angle, it might have negative effect on the shear impulses. This can influence the effectiveness of rocker by increasing the risk of mechanical trauma/ulceration to the foot during walking.

RELATIONSHIP BETWEEN FOOT MUSCLE STRENGTH AND PLANTAR PRESSURE IN PEOPLE WITH DIABETIC NEUROPATHY

[1]**Karen J Mickle**, [1]Aaron J Melrose, [1]Patrick Mclaughlin, [2]Rajna Ogrin and [1]Rezaul K Begg

INTRODUCTION

The lifetime risk of a person with diabetes developing a foot ulcer is up to 25%, and peripheral neuropathy (PN) increases this risk 4-fold. Foot biomechanics is considered to be a major contributor to the development of plantar foot ulceration in people with diabetes; with high plantar pressures the most commonly cited risk factor. Plantar ulcers typically occur in locations of high plantar pressures, particularly in the forefoot region of people with PN [1].

Limited foot joint mobility and reduced toe strength have been attributed to increased plantar pressures during walking [2, 3]. However, there has not been a comprehensive study that looks at both of these factors and their effect on plantar pressures in people with diabetes or PN. Therefore, the aim of this study is to determine the relationship between muscle strength, range of motion (ROM) of the foot and ankle, and plantar pressures in people with type 2 diabetes.

METHODS

Twenty-four men and women diagnosed with type 2 diabetes over the age of 50 (mean age = 68 ± 8.03 years) were initially recruited for this study. The presence of PN was determined using the Michigan Neuropathy Screening Instrument [4]. Toe flexor strength was assessed while each participant stood on an emed pressure platform (Novel$_{gmbh}$). During each trial, participants were instructed to push down as hard as possible onto the platform under two conditions: i) using their lesser toes (2-5), or ii) using only their hallux. Maximum force under the hallux and lesser toes were calculated and then normalised to body mass (%BW).

The participants then walked across the pressure platform using the second-step method. Pressure data were analysed using Novel Projects (Novel$_{gmbh}$) by dividing each footprint into 10 regions using the Novel mask set. Peak plantar pressures and pressure-time integrals (PTI) were calculated for the metatarsal (MTH) and toe regions. Static range of motion was measured using a goniometer to assess the participant's maximum dorsiflexion range of motion at the first metatarsal and ankle.

Ankle strength (max force, kg) was measured using hand-held dynamometry. The participants were asked to perform the following four movements; dorsiflexion, plantarflexion, inversion and eversion while the examiner held the hand-held dynamometer stationary. Correlation co-efficients were calculated to determine the relationships between the plantar pressure variables and the foot strength and range of motion variables using SPSS ($p < 0.05$). *t*-tests were conducted to compare variables in those with (n=14) or without (n=10) PN.

RESULTS AND DISCUSSION

Strength at the ankle and toes was significantly reduced in the diabetes PN group compared with the diabetes only group ($P < 0.01$; see Figure 1). Hallux strength was negatively correlated with peak pressure under the MTHs ($r = -0.42$ to $r = -0.43$) and lesser toe strength was negatively correlated with peak pressure and PTI under the lateral MTHs ($r = -0.46$ to $r = -0.47$; $p \leq 0.03$). Furthermore, 1MTH ROM was negatively correlated with peak pressure and PTI at the 1MTH, hallux and 5MTH ($r = -0.44$ to $r = -0.53$; $p \leq 0.03$). Ankle strength or ROM did not significantly correlate with any of the plantar pressure variables.

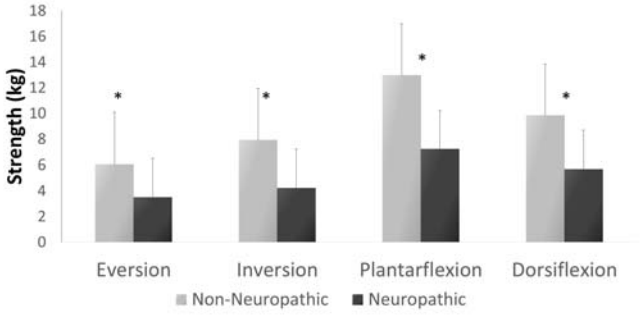

Figure 1: Ankle strength of neuropathic and non-neuropathic diabetes participants; * indicates significant difference between groups ($p \leq 0.01$).

CONCLUSIONS

The results from this study show that the strength of the ankle and toe muscles are reduced in the presence of PN in patients with diabetes. Furthermore strength of the toes and 1MTH ROM moderately correlated with the pressure distribution under the forefoot of older people with diabetes during walking, whereby increased strength and flexibility reduced the peak pressure under the MTH. These findings suggest that older people with diabetes who have stronger toe flexor muscles use their toes more during walking and reduce the loading under the metatarsal heads. Further research is warranted to determine whether interventions designed to strengthen and mobilise the toe muscles and joints may be effective in reducing forefoot plantar pressures in individuals with diabetes at risk of ulceration.

INTRODUCTION

Consequences of alterations of foot biomechanics in the presence of Diabetes and diabetic neuropathy has been studied for decades, and is still a dramatic research issue worldwide [1]. From the specific point of view of foot loading during locomotion, however, an overall agreement is far to be reached in terms of a comprehensive, clinically relevant biomechanical model [2]. In order to shed more light on this controversial topic, a wide study has been designed which relies on an integrated methodology based on pressure and kinematics measurements [3]. Main aim of the study is to detect and quantify the impact of Diabetes-associated modifications on foot function by isolating and modeling the role of each possible confounding factor. This paper reports on phase 1 of the study, i.e. investigation of role of type I and type II Diabetes, prior to the onset of neuropathy and foot deformities, while strictly controlling the remaining relevant biological and clinical variables.

METHODS

From January 2016, a wide sample of diabetic patients and healthy volunteers was examined through integrated pressure-kinematics measurements based on the IORfoot model and 5 foot regions of interest (ROIs) [3,4]. At present, 140 participants have been enrolled and assessed under controlled, self-selected cadence. Five consistent trials have been collected for each foot. Patients were clinically stratified based on the type – I or II - of Diabetes and, within each type, grouped according to: presence/absence of neuropathy; presence/absence of deformities or functional limitations; BMI; age; walking cadence. The hereby reported, preliminary study was conducted on a limited sample of 30 feet, equally distributed among three subgroups i.e. type I diabetics (T1), type II (T2) diabetics, and matched controls (C). Inclusion in the three groups was strictly controlled as for: walking cadence (range 50-55spm); BMI (<30kg/m^2); absence of deformity or functional limitation. Inclusion in the diabetic groups was also controlled as for the absence of Neuropathy. Based on previous correlation studies [4] the range of motion of Shank-Calcaneous joint in the frontal plane (ShCa RoM) was selected as kinematic variable. Being stance phase durations strictly comparable, pressure-time integral (PTI) was preferred to peak/mean pressure to investigate foot loading under the total foot and the 5 ROIs. 1-way ANOVA ($p<0.05$) with Bonferroni-Holm correction was finally applied to all parameters and groups.

RESULTS AND DISCUSSION

Interestingly, T1 and T2 performed differently with respect to C and between them (Table 1). T1, who only differed from C for the presence of long-term Diabetes, however showed a significant shift of loading from midfoot and forefoot to toes, associated with a moderate – not statistically significant - RoM reduction. T2, likely due to Diabetes but also in possible association with older age, showed significant changes in both loading and kinematic variables with respect to C, namely: lower PTI at toes; higher maximum PTI and PTI at forefoot; a significant ShCa RoM reduction. Further, T2 significantly differed from T1 for the lower loading of hindfoot and toes, and the higher loading of forefoot.

Further, deeper investigation is necessary to better characterize the possible role of age (comparable in C and T1, higher in T2) and different duration of disease (higher in T1) which could not be avoided in these preliminary groups. However, the hereby reported findings well highlight the biomechanical changes that Diabetes alone, i.e. without neuropathy or deformity complications, may entail on foot biomechanics according to different types of Diabetes itself.

CONCLUSIONS

Even though preliminary, the results of this study show that when integrated, rigorous analyses of pressure and kinematics over foot segments are performed, valuable classifications of foot biomechanics can be defined also in the complex area of diabetic foot, where a large number of confounding factors affect classes or categories of patients. Particularly helpful resulted, as reasonable, the control of variables which greatly affect ground reaction, like walking cadence and BMI.

INTRODUCTION

High plantar peak pressure is an important risk factor of foot ulceration in diabetes. Custom-made (orthopedic) footwear aims to relieve these high-pressure areas by redistribute pressures to other foot regions. Several innovative orthopedic footwear concepts that use pressure analysis in the design and evaluation of the footwear have been developed for the high-risk diabetic foot. The aim of this study was to evaluate the offloading effect of these different footwear concepts with the ultimate goal to determine the building stones for the best orthopedic shoe for high-risk diabetic patients.

METHODS

Twenty-four diabetic patients (16 male, mean age 65.8 years) at high ulcer risk were included in this cross-sectional comparative study. Four different innovative orthopedic footwear concepts were tested: fully-custom-made (DIAFOS-A) and semi- custom-made (DIAFOS-B) shoes that were designed using a scientific-based algorithm and evaluated and, if indicated, modified based on in-shoe plantar pressure measurements [1,2], barefoot pressure and foot shape based custom-made insoles that were modified, if needed, based on in-shoe pressure measurement (DIABETEC), and barefoot pressure and foot shape based custom-made insoles that were designed and manufactured using automated computer assisted technology (TrueContour) [3]. Concepts 2-4 were tested in Podartis Goodsport shoes that had a stiffened rocker outsole.

These concepts were additionally compared to athletic footwear (ASICS Gel-Nimbus 17) and a standard non-therapeutic shoe (Pulman New Comfort). All concepts were evaluated in random order with Pedar-X (Novel, Munich) during walking at a comfortable speed that was standardized between conditions. Peak pressures were calculated for the metatarsal heads, hallux, midfoot and heel regions and compared across concepts using repeated measures ANOVA ($P < 0.05$).

RESULTS AND DISCUSSION

The four innovative shoe concepts all showed significantly lower peak pressures at the metatarsal heads compared to the standard shoe. At metatarsal heads 1 and 2-3, the lowest peak pressures were present with DIAFOS-A, with significant differences found compared to almost all other concepts (Table 1). At metatarsal heads 4/5, DIAFOS-B showed the lowest peak pressures, significantly lower than for the TrueContour concept and the athletic shoe. Small pressure-reducing effects of the innovative footwear concepts was found for the hallux region.

CONCLUSIONS

The results prove the value of a scientific-based data-driven approach to footwear design.

The lowest metatarsal head peak pressures were achieved with footwear concepts that used in-shoe plantar pressure measurements to guide modifications to the footwear after they were manufactured. In almost all these cases pressures were lower than 200kPa, a level found to indicate some protection against ulceration [1,4].

Lowest pressures were generally found with the shoes that were fully custom-made shoes, which is understandable from the point of view that this type of footwear has most options for incorporating pressure-relieving elements and for modification.

The design and manufacturing principles of in particular footwear concepts DIAFOS A and B may be used for definition of the most optimal orthopedic shoe for the high-risk diabetic foot patient.

INTRODUCTION

Little is known about the gait characteristics and plantar pressures in people with diabetes related foot ulcers during ulcer healing [1]. The aim of this study was to investigate the key gait characteristics and plantar pressures at baseline, three months and six months in cases with foot ulcers compared to diabetes controls without ulcers [2].

METHODS

Standardised protocols for three-dimensional movement analysis were utilised to evaluate ten gait characteristics (angular joint kinematics, ground reaction forces and spatio-temporal characteristics) in cases and controls longitudinally. Mean peak plantar

pressure and pressure-time integral measurements at 10 plantar foot sites (the hallux, lesser toes, metatarsals 1 to 5, mid-foot, medial heel and lateral heel) during barefoot walking were also collected. Measurements

were performed at three study visits: baseline, three and six months. Linear mixed effects random-intercept models were utilised to assess whether gait outcomes and plantar pressures differed between cases and controls after adjusting for age, sex, body mass index, neuropathy status and follow-up time. Standardised mean differences (Cohen's d) were used to measure effect size.

RESULTS AND DISCUSSION

Twenty-one DFU cases and 69 controls commenced the study and 16 cases and 63 controls completed the study. Seven out of ten gait characteristics that were different at baseline remained different between cases and controls during follow-up. These characteristics included a lower pelvic obliquity at toe-off (d =-0.5) and a lower minimum pelvic obliquity during gait (d= 0.69) in cases compared to controls during each study visit. The minimum anterior-posterior ground reaction force (d=-0.40), range of anterior-posterior ground reaction force (d=-0.40), the final vertical ground reaction force (d=-0.44) and the total vertical ground reaction force (d=-0.32) were all lower in controls compared to cases during each visit (all $p<0.05$). Walking speed (d=0.38) was faster in controls compared to cases during each visit (all $p<0.05$).

Cases had a higher mean peak plantar pressure at several foot sites including the lesser toes (d =0.36), and mid foot (d=0.36) and a higher pressure-time integral at the hallux (d= 0.42), metatarsal 1 (d= 0.33) and mid foot (d=0.64) compared to controls at baseline and follow-up.

Perhaps the most important finding of our study is the presence of significantly higher anterior-posterior and vertical ground reaction forces in cases compared to controls throughout follow-up. These findings confirm our earlier suggestion that the combination of these two gait features are likely to not only increase the vertical loading and hence the plantar pressures on ulcerated plantar tissue, but contribute to significant shearing force, especially in the anterior-posterior direction.

CONCLUSIONS

Seven out of ten gait characteristics between cases and controls remained different throughout follow-up and plantar pressures during gait were higher in patients with foot ulcers compared to patients without foot ulcers throughout follow-up. These results support the need for on-going offloading in people with chronic foot ulcers.

3D MODELLING OF THE DIAPHRAGMATIC DOMES IN BREATHING: EFFECT OF LUNG HYPERINFLATION IN PATIENTS WITH CYSTIC FIRBROSIS

INTRODUCTION

Breathing function depends on interaction between the rib cage and diaphragm. In previous studies 3D modelling of the thorax joints during breathing motion was achieved allowing quantification of segmental costovertebral kinematics in healthy subjects [1] and cystic fibrosis patients [2]. Diaphragm muscle shape and kinematics during breathing were shown to be possibly altered in patients with emphysema [3]. In addition, literature reports a radiographic method for measuring inspired volume attributable to diaphragm motion [4]. Therefore the aim of this study was to develop a method based on spiral CT data to determine 3D shape and kinematics of diaphragmatic domes (DDs), and to estimate the part of the change in lung volume attributed to each DD displacement over the inspiratory capacity (IC). A secondary objective was to integrate the DDs model into previously developed thorax joints kinematics model in breathing [1,2]. Finally the effect of lung hyperinflation on DDs shape and kinematics was tested in a group of patients with cystic fibrosis.

METHODS

Data sample and 3D reconstruction: Retrospective codified spiral-CT data obtained at total lung capacity (TLC), middle of inspiratory capacity (MIC) and at functional residual capacity (FRC) were processed following previously published method for determining costovertebral joints kinematics [1,2]. Twelve asymptomatic subjects (AS) and 10 patients with cystic fibrosis (CF) and lung hyperinflation were included in the study. Lungs were reconstructed at each lung volume using segmentation software (Figure 1A).

Shape and volume displacement computation: A series of 92 anatomical landmarks (ALs) were placed on the inferior area of each lung corresponding to the location of the right and left diaphragmatic domes (RDD /LDD). The ALs were then registered in previously developed 3D model of the entire thorax joint kinematics (Figure1B).

Delaunay triangulation was then used to create diaphragmatic domes surfaces at each lung volume (Figure 1C). From these surfaces, various geometrical parameters were computed such as sagittal /coronal radius of curvature. In addition, approximation of the global vertical displacement of each DD (change in cylinder height obtained from volume divided by area of projected surface) and the volume enclosed between two successive surfaces were computed.

Statistical analysis: A mixed model analysis of variance was performed. Laterality and volume level were considered as within-subject factors and the pathology considered as between subject factor. Bonferroni post hoc tests were performed when appropriate.

RESULTS AND DISCUSSION

The pathology had a significant influence on DD displacement ($p<0.01$) and radii of curvature in both sagittal ($p<0.01$) and coronal ($p<0.05$) planes (radii were greater in CF than in AS corresponding to more flattened DD; DD displacement were lower in CF than AS group). The side had no significant influence on DD displacement ($p=0.08$) and coronal radius of curvature ($p=0.16$) but a significant influence on the sagittal radius of curvature and volume displaced by DD. Regardless of the side, the volume displaced by DD did not differ between groups ($p=0.24$) and corresponded to, respectively, 42±10% and 39±11% of their IC. When considering a rib cage-diaphragm ratio (Volume displaced by DDs / Volume displaced by rib cage), no significant difference was observed between groups ($p=0.47$; Mean ratio: 1.54±0.73 in AS; 1.78±0.84 in CF).

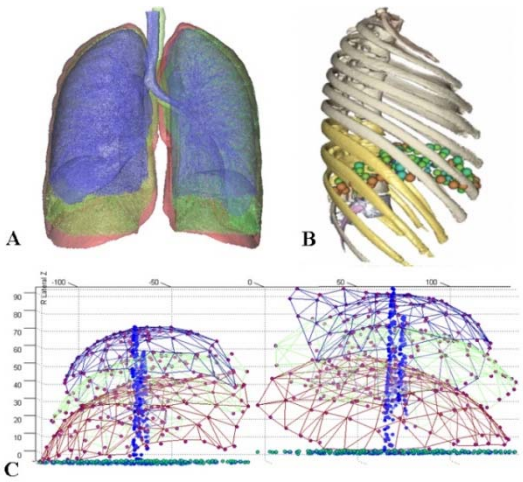

Figure 1: A: 3D lung reconstructions at each breathing pose (TLC in red, MIC in green, FRC in blue). B: 3D model of the entire thorax with diaphragmatic domes. C: Delaunay triangulation of right and left DD at each lung volume. Colors correspond to those of lung reconstructions.

CONCLUSIONS

The present method enables computing various morphometric parameters and the volume displaced by each DD over inspiratory capacity directly from the 3D reconstruction of the lungs. Results have shown that lung hyperinflation observed in patients with CF leads to an alteration of DD radii of curvature and displacement while the volume displaced by DD and the rib cage/diaphragm ratio did not differ between groups. The present method is promising for evaluating effect of other disease or the effect of treatment on DD behavior.

3D MODELLING OF HUMAN THORAX JOINT KINEMATICS IN BREATHING: QUALITATIVE AND QUANTITATIVE ANAYLSIS

[1,2,3]**Benoit Beyer,** [3]Laurence Chèze, [1]Victor Sholokha, [1]Serge Van Sint jan, [1,2]Véronique Feipel

INTRODUCTION

Modelling is a frequently used tool enabling to improve understanding of joint mechanical behavior in various clinical conditions. The kinematics of numbers of joints has been quantified for gait analysis (i.e. upper and/or lower limbs). However, in vivo thorax joint kinematics remains a poorly investigated topic while musculoskeletal structures are among the most common source of chest pain [1]. Moreover, thorax joints are the most solicited joints since the respiratory rate represents between 17000 to 29000 cycles a day and some billions of cycles during lifetime. Recent work have estimated the relation between costovertebral joints (CVJ) kinematics and lung volumes from in vivo CT data [2,3] but no quantified analysis is to date available on the entire close kinematic chain that takes into account the anterior joints of the thorax (i.e. the sternocostal (SCJ) and manubriosternal joints). Therefore, the aim of the present study was to investigate: -the respiratory kinematics of the seven first rib pairs (i.e. "true ribs") relative to the vertebra and sternum by using 3D modelling approach; -the sternal angle variations and the relation between joint kinematics and sternum displacement.

METHODS

CT data and 3D bone models

Retrospective codified spiral-CT data of twelve asymptomatic adults were processed. These CT data were performed at total lung capacity (TLC), middle of inspiratory capacity (MIC) and at functional residual capacity (FRC). 3D reconstruction of each bone of interest was obtained from CT data segmentation techniques.

Anatomical landmarks and kinematics computation

Virtual palpation was used to locate a series of anatomical landmarks (ALs) on each vertebra, rib, manubrium and sternum body at the three available breathing poses. The ALs were then used to define anatomical coordinate systems of the bones of interest (Figure 1) and to compute joint kinematics using rigid body transformations and helical axis method. A fusion method [4] of ALs with 3D models was used to obtain visualisation of both motion and kinematic parameters (i.e. bones motion; mean helical axes (MHA) orientation and position (Figure 1).

RESULTS AND DISCUSSION

Sternum displacement relative to Th7 vertebra occurred mainly anteriorly and superiorly. The mean displacement was 9.6±7.1 mm, 17.8±5.9 mm and 0.8±2.3 mm along x-, y- and z-axis respectively.

The mean sternal angle was significantly decreasing from 16.7°±5.5° at TLC to 14.9°±5.2° at MIC (p=0.016) and to 12.4°±4.9° (p=0.0011) at FRC which confirms a small ROM (4.4° ± 2.7°) available at manubriosternal joint.

CVJ ROMs gradually decreased from 17.4°±7.3° at CVJ1 to 9.7°±2.4° at CVJ7. SCJ ROMs gradually decreased from 15.5°±1.7° at SCJ1 to 7.6±0.8° at SCJ7.

At both SCJ and CVJ, the MHA were oriented obliquely anteriorly, medially and inferiorly at all rib levels. The direction cosines ranged from 0.31 to 0.58 on the x-axis; from -0.49 to -0.58 on the y-axis and from 0.35 to 0.74on the z-axis. No difference was found between the orientations on the x and z-axes at both SCJ and CVJ. A significant positive correlation was demonstrated between CVJ (and SCJ) ROMs and sternum cephalic displacement (Figure 1 right).

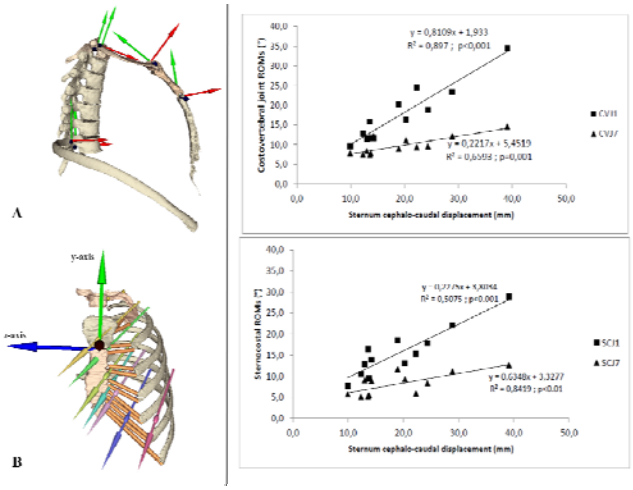

Figure 1: Left: A: 3D representation of bones and anatomical coordinate systems of interest. B: 3D representation of the mean helical axes of the left seven first SCJ and costal cartilages (frontal view).

Right: rib angular displacement as a function of cephalo-caudal displacement of the sternum at CVJ (top) and SCJ (bottom). Results are given for each of the 12 subjects, at rib1 and rib7. ROMs are expressed in degree and sternum displacement in mm.

CONCLUSIONS

This is the first study in humans that achieved quantification of 3D kinematic parameters of both costovertebral, sternocostal and manubriosternal joints in breathing movements. The present 3D modelling approach based on in vivo measurements enables a combined qualitative and quantitative analysis of the thorax joints behavior in breathing. The substantial amount of quantitative data represents a relevant basis that could be integrated into a multiscale model of the entire respiratory system.

RELATIONSHIP BETWEEN INCREASE IN ENDOLYMPHATIC PRESSURE AND LEVEL OF DPOAES: FINITE-ELEMENT ANALYSIS OF HUMAN ACTIVE COCHLEA

Sinyoung Lee, Takuji Koike
The University of Electro-Communications
Corresponding author email: sylee@bio.mce.uec.ac.jp

INTRODUCTION

The endolymphatic hydrops (EH) is a disorder of the inner ear and is associated with abnormal fluctuations in the endolymph fluid. This anomalous flow causes an increase of endolymphatic pressure of the cochlea. Hallpike et al. [1] proposed that EH is a pathogenesis of the Meniere's disease based on autopsy cases in which the volume of the endolymph was larger than that in the normal cochlea. The primary symptom of EH is as follows: Low frequency hearing loss is observed at initial stage. Recovery of hearing level at low frequencies and decrease of hearing level at high frequencies are observed at interval stage. And severe high frequency hearing loss is observed after repeating these stages. We aim to analyze the relationship between hearing level objectively assessed by DPOAEs (Distortion Product OtoAcoustic Emissions) and increase of the endolymphatic pressure using the finite element cochlear model which includes activity of the outer hair cells. DPOAEs (Figure 1 (a)) are one of acoustic phenomena which are considered to be derived from active cochlea, and distortion components $nf_1 \pm mf_2$ (n and m are arbitrary integer constants) are generated when the cochlea was simultaneously stimulated by two pure tones with different frequencies f_1, f_2 ($f_1 < f_2$).

METHODS

The human cochlear finite-element model was constructed following the model of Koike et al. [2]. The model is simplified to avoid complexity of calculation and includes activity of the outer hair cells (amplification mechanism) because the human cochlea under physiological conditions have a motility which amplifies the vibration of the basilar membrane (BM) of the cochlea.

The BM separates the endolymph and the perilymph and is vibrated by the pressure difference between the endolymph and the perilymph. However, increase of the endolymph volume in the case of EH causes pressure unbalance between each surface of the BM. Therefore, EH was represented by applying static pressure on the entire surface of the BM of the active cochlear model. A geometric non-linearity was considered, but a non-linearity of the material properties did not considered. Next, two pure tones with different frequencies f_1, f_2 and amplitude L_1, L_2 ($f_2 / f_1 = 1.2$, $L_1 - L_2 =$ 10 dB, L_2 is equivalent to the sound pressure level of 50 dB at the ear canal) were simultaneously applied to the stapes head of the model, and distortion components on the stapes and the BM were calculated. The effects of applying pressure to the BM was investigated by calculation with changing the static pressures. The range of the static pressure was determined based on the experimental values [3] of the endolymphatic-perilymphatic pressure gradient in guinea pig ears with EH. A calculation with the static pressure of 0 Pa represents the intact cochlea. In addition, a passive model, in which the amplification mechanism was not concerned, was also calculated in the same way of the intact cochlear model for comparison.

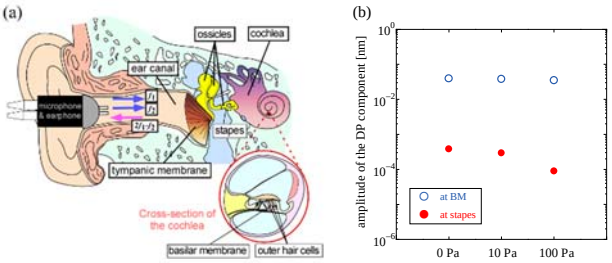

Figure 1: (a) Measurement of DPOAEs and cross-section of the cochlea. (b) Amplitudes of DPOAEs components ($2f_1$-f_2) at the BM and the stapes footplate obtained from the active cochlear models under the different static pressure. Input frequency f_2 was 2 kHz.

RESULTS AND DISCUSSION

The BM was highly-deformed at the apex area by increasing the static pressure load. This result is considered to be caused by the dimension of the BM (thinner and wider at the apical side than the basal side).

DP components ($2f_1$-f_2) were obtained from the active model, irrespective of the static pressure applied on the BM, at not only the stapes footplate but also the BM. By contrast, those were not obtained from the passive model. Figure 1 (b) shows an example of amplitudes of DP components obtained from the active model. The DP component levels at the BM have almost same value regardless of the static pressure. On the other hand, the DP component levels at the stapes footplate decreased with increasing the endolymphatic pressure. These results are matched with the measurement result [4] which shows that the threshold of DPOAEs in the group of late stage of EH was higher than that in the group of early stage. The deflection at the apical side of the BM caused by the EH increases the structural stiffness of the BM and makes the BM difficult to vibrate.

CONCLUSIONS

EH was simulated with applying the static pressure on the surface of the BM of the active cochlear model. The application of pressure caused deformation of the BM and makes the BM difficult to vibrate. These changes are considered to be the reasons for decrease of the levels of DP components at the stapes footplate when the endolymphatic pressure increased.

INTRODUCTION

From physical point of view, breathing process is a flow of air through a system of tubes and other specific parts. During breathing, the direction of the flow changes periodically. Between the turns, the flow is interrupted. During all phases of breathing, respiratory system produces noise which includes specific phenomena depending on properties of the respiratory system and breathing conditions. All this suggests that an appropriate analysis of respiratory sound recordings may prove very helpful in diagnosis in some conditions, when conventional methods do not provide reliable results.

An example of such condition is asthma in small children. Its diagnosis by mean of conventional spirometry requires cooperation of the patient at high level of coordination, which is often difficult to reach in small children (aged 3 years or less). Thus, physicians are often left just with simple auscultatory examination. It is important to note here that early diagnosis of asthma may help significantly reduce symptoms of the disease in higher age. Necessary diagnostic information can, however, be obtained by more sophisticated analysis of the acoustic recordings. How important such possibility can be becomes obvious if we realize that there are about 300 million people worldwide suffering from asthma [1]. These patients live with feeling of constricted chest and physical activity is strongly limited [2] due to difficulties in breathing demonstrated by presence of wheezing in respiratory sounds.

METHODS

In our experiment, 9 volunteers (4 healthy and 5 asthmatic children) aged 8 -12 years were investigated.

All recordings were obtained from examinations done by physicians from Department of pneumology in University Hospital Motol, Prague using commercially available electronic stethoscope (middle price category). Recordings were taken in physical repose of volunteers and after their minor physical activity (10 squats).

Analysis of the recorded signals was performed in MatLab environment using the fast Fourier transform (FFT). The complete data processing consisted of three steps. First, the boundaries between inspiration and expiration were identified. Then the harmonic analyses of each inspiration and expiration were done. Finally, results of both previous steps were organized into graphs to display the time course of identified significant frequencies occurrence in analyzed recordings. Those frequencies are color-coded in the graphs, depending on their amplitudes.

RESULTS AND DISCUSSION

A representative example of obtained results is shown in graphs on Figure 1. Boundaries between inspirations and expirations in both graphs are marked by vertical turquoise lines.

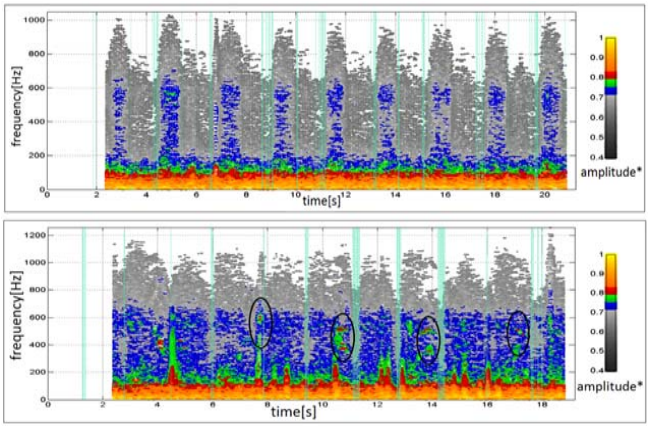

Figure 1: Comparison of healthy volunteer (upper graph) and asthmatic patient (lower graph)

The upper graph presents results from a healthy volunteer. At the first glance, there are well seen significant Differences in inspiration and expiration phases are clearly visible. The bottom graph shows the results from an asthmatic patient. The noise at frequency range from 150 to 700 Hz is highly expressed here. Noise at that frequency region is present in inspiration phases of a healthy volunteer, too, but it is missing during expiration phases. The asthmatic patient exhibits repeatedly significant wheezing at cca 400 – 600 Hz (marked by white ovals).

There were only minor deviations from the pattern shown in Figure 1 in all other recorded healthy and asthmatic volunteers.

CONCLUSIONS AND FURTHER INVESTIGATION

The results obtained so far suggest that automated breathing sound analysis should be feasible and applicable in clinical practice. At present, a more extensive study is being started which should already have sufficient statistical power.

As the above described approach is very sensitive to the FFT setup, we started using wavelet analysis as an alternative in a hope that it may eliminate this problem and make the method more robust.

INSIGHTS INTO FREEZING OF GAIT FROM WEARABLE SENSORS

[1,2] **Martina Mancini**, [1] John G Nutt and [1,2] Fay B Horak

INTRODUCTION

Freezing of Gait (FoG) in people with Parkinson's disease (PD) is an environmentally sensitive, intermittent problem that occurs most often during turning, gait initiation, and passing through doorways [1]. Due to its intermittent nature, this phenomenon has been difficult to study in the laboratory, and its pathophysiology is still controversial. A typically observed feature of FoG is the trembling of the legs, that has been objectively quantified with high frequency (3-8Hz) oscillation measured with inertial sensors on the legs [2,3]. We hypothesize that FoG is due to lack of release of hip abductor muscle activity for lateral anticipatory postural adjustments (APAs) in preparation for a stepping during gait and turning. Here, we characterize the muscle activation patterns and leg movements prior and during freezing episodes to better understand the neural mechanisms responsible for FoG.

METHODS

Nineteen idiopathic PD subjects with a clinical history of FoG (FoG+, MDS-UPDRS III 49±10, Age 66±9) and 18 idiopathic PD subjects without FoG (FoG-, MDS-UPDRS III: 39±14, Age 64±6) were recruited from the Movement Disorders Clinic of the Parkinson Center of Oregon.

The participants performed: - a freezing assessment course with starts, multiple passes through a doorway, and 180° turns, and – a 2 minutes long walk while wearing 8 Opal inertial sensors (APDM.com) mounted on the posterior trunk, on each shin, each foot, each wrist and on the sternum. In addition, wireless sEMG (Cometa Wave) were collected bilaterally on the tibialis anterior (TA), gastrocnemius medialis (GM) and at the hip on the tensor fasciae latae (TFL). The wireless EMG system was synchronized to the Opals. Based on shin angular velocities, heel-strike (Hs) and toe-off (To) events for each right and left steps were extracted. sEMG signals were collected with a sample rate of 2000 Hz, then rectified, low pass filtered (20 Hz) in order to obtain the linear envelope, and expressed as a percentage of gait cycle. Onset and duration of sEMG burst of activity were determined by a threshold (20% of the max peak of each muscle) and visually inspected.

The FoG ratio (power spectral density ratio between high and low frequency shank acceleration) was computed for the overall freezing course. Then, for the three steps preceding a turn (in FoG-) or a turn that resulted in a FoG episode (in FoG+), the following variables were calculated: - duration of stance/swing activity for TA, GM and TFL, - onset of activity from Hs for the TA, GM, and contralateral TFL, -offset of activity for the ipsilateral TFL from Hs and successive onset. The same set of variables were computed for 3 steps during straight-ahead gait without FoG. In addition, the medio-lateral acceleration during the course was inspected.

RESULTS AND DISCUSSION

All FoG+ subjects exhibited FoG during the assessment. The FoG ratio was significantly larger in FoG+ compared to FoG- (1.25±0.3 vs 0.5±0.3, p=0.007). We observed that: i) FoG+ showed increased co-contraction of the TFLs during straight-ahead gait, but not prior to a FoG episode, compared to FoG-; ii) FoG+ showed a reduced activity of the TIB in the swing phase during straight-ahead gait compared to FoG-, and even further reduction prior to a FoG episode; iii) FoG+ showed a reduced activity of the GAS in the stance phase during straight-ahead gait compared to FoG-, but an increase of GAS activity prior to a FoG episode; iv) FoG+ showed reduced AP trunk acceleration compared to FoG- during straight-ahead gait and prior to FoG, while ML trunk acceleration is similar between groups. In addition, the TFL co-contraction was significantly associated with the FoG Ratio during the freezing course in the FoG+ group, and not during straight-ahead gait (r=-0.62, p=0.005).

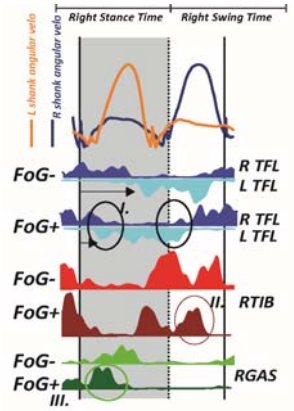

Figure 1: Representative right and left shin angular velocity and respective muscle envelopes during the stance and swing phase in FoG- and FoG+.

CONCLUSIONS

We observed increased ipsilateral TFL activity and reduced contralateral TFL activity in FoG+ compared to FoG-, consistent with impaired APA inhibition and inadequate postural preparation for a step. These observations suggest that abnormal temporal muscle activation patterns during FoG episodes may be due to abnormal coupling of anticipatory postural adjustments with stepping rather than a disruption of central pattern generators.

CHANGES IN MOVEMENT VARIABILITY WITH INCREASED MECHANICAL DEMAND MAY BE INFLUENCED BY LIMB PREFERENCE

INTRODUCTION

Typical self-selected hopping rate is 2.0-2.2Hz [1,2]. Minimal changes in mechanical demands occur at faster rates, but notable changes in mechanical demands exist at slower rates [1,3]. Altered demands are likely accompanied by altered neuromotor control strategy to maintain consistent hopping at slow rates [3]. Therefore, this study examines the structure of movement variability – a window into neuromotor control – during hopping at typical & slow rates.

METHODS

23 healthy volunteers (age 31±8yr, 10♂) performed ≥25 unipedal hops at 2.0 & 1.7Hz. Preferred kicking/stance limb for the task of kicking a ball for distance were determined.

The referent joint configuration ($\underline{\theta}$) was calculated at each 1% of stance by averaging sagittal foot-to-floor, and ankle & knee intersegmental angles across trials. A forward kinematic model linked changes in these angles to changes in vertical leg length. The Jacobian matrix ($J(\underline{\theta})$) of this linkage was computed at each 1% of stance. Elemental variance projected onto the $J(\underline{\theta})$ null space is task-irrelevant variability (V_{UCM}), which allows consistent vertical leg length across hops. Elemental variance projected onto the $J(\underline{\theta})$ null-orthogonal space is task-relevant variability (V_{ORT}), which hinders vertical leg length consistency across hops [4]. The index of motor abundance (IMA), the normalized difference between V_{UCM} & V_{ORT}, measures the degree of vertical leg length stabilization.

Only stance phase was analyzed, as control of vertical leg length during flight is not an expected goal of the control system. Stance was normalized to 100 frames then divided into 7 equal bins (S1-S7). S1-S3 represent early, mid- & late impact absorption (ABS), S4 the most crouched position, and S5-S7 early, mid- & late propulsion (PROP) toward flight. V_{UCM}, V_{ORT} & IMA were averaged per bin. Repeated measures ANOVAs (2 limb x 7 bin, α=0.05) were run on bin-average differences in V_{UCM} (i.e. $V_{UCM\text{-}1.7Hz} - V_{UCM\text{-}2.0Hz}$), V_{ORT} & IMA between hopping rates. If limb*bin interactions were found with repeated measures ANOVA, 1-way ANOVAs were run per bin.

RESULTS AND DISCUSSION

1-way ANOVA indicated kicking (vs stance) limbs tended to increase V_{UCM} more during late-ABS (S3, p=0.15), seen in Figure 1 (left). Kicking limbs tended to increase V_{ORT} more from mid-ABS through mid-PROP (S2-S6, $0.10 \leq p \leq 0.15$), seen in Figure 1 (center). While hopping at 1.7Hz generally increased both task-irrelevant (V_{UCM}) & task-relevant (V_{ORT}) variability, this tendency was exaggerated in kicking limbs for V_{ORT}. There was no difference in IMA shifts, as seen in Figure 1 (right). Kicking & stance limbs similarly increased IMA during early-ABS & late-PROP (bins S1 & S7) and decreased IMA from mid-ABS through mid-PROP (bins S2-S6) when shifting from typical to slow hopping.

The self-stabilizing properties of musculotendinous units contribute to the attractor state of ~2Hz for hopping and thus likely cannot be exploited by the control system during 1.7Hz hopping [3]. This may explain the bilaterally similar decreases in IMA throughout most of stance (S2-S6). Transitions from flight to stance (S1) & stance to flight (S7) may entail more performance consistency if greater control effort is exerted (i.e. when the neuromotor control system cannot exploit musculotendinous unit properties) during more demanding slow hopping.

CONCLUSIONS

V_{UCM}- & V_{ORT}-response to altered mechanical demands may differ with limb preference. However, both limbs achieve similar behavior in terms of stabilization of vertical limb length in response to altered demands.

INVESTIGATING GAIT VARIABILITY AND MOTOR CONTROL IN KNEE OSTEOARTHRITIS

[1] **Gwenllian F Tawy**, [2]Leela C Biant, [3]Michiel Simons, [1]Philip J Rowe

INTRODUCTION

Knee osteoarthritis (OA) causes pain, reduced muscular strength and stiffness to the affected joint [1]. In response, the motor control mechanism is altered, potentially compromising stability during acts of daily living [2]. Reduced walking stability can be quantified in terms of increased gait variability [3]. The Uncontrolled Manifold (UCM) method has previously been used to quantify gait variability by calculating combinations of elemental variables (joint degrees of freedom) that successfully stabilise ('good variance') or compromise ('bad variance') the stability of the centre of mass (COM) [4]. Successful COM stability is said to have been achieved when the 'good variance' outweighs the 'bad variance'.

Improving our knowledge of the relationship between gait variability and COM stability in lesser-abled populations may enable us to investigate the possibility of using the UCM method as a biomarker for gait instability. The aim of this study was therefore to use the UCM method to quantitatively evaluate sagittal and frontal plane variability from cycle-to-cycle during normal walking in an osteoarthritic population.

METHODS

Fifty adults (25 males/25 females) with end-stage OA of the knee walked on a self-paced treadmill for 2 minutes. A motion capture system was used to record 50 consecutive gait cycles from each patient. Kinematic variability of gait was then analysed using the UCM method in MATLAB. The position of the COM was chosen as the task variable for the analysis, and sagittal and frontal plane kinematics of the hips, knees and ankles were defined as the elemental variables. Balanced ratios of 'good' to 'bad' variances were calculated. A ratio > 0 suggests that the task in question (COM stabilisation) was successful.

RESULTS AND DISCUSSION

Results showed that our patient cohort were able to maintain a stable COM whilst walking, as the 'good variance' outweighed the 'bad variance' throughout the gait cycle. This suggests that the patients adopted variable combinations of hip, knee and ankle kinematics to stabilise the COM whilst walking. This is known as kinematic synergy. The greatest magnitudes of instability (reflected by low balanced ratios) occurred during initial contact and terminal stance. Active extension of the knee joint to approximately 5° is required during these gait cycle events, meaning that the events are highly quadriceps dependent. These results suggest that stability during gait could be improved in knee OA patients through strengthening the quadriceps.

CONCLUSIONS

Overall, this study identified and quantified components of the gait cycle where patients with knee OA are most unstable. Employment of this technique may therefore allow specific personalised prescription for prehabilitation and rehabilitation.

BIOMECHANICS OF MEDIAN NERVE COMPRESSION AND DECOMPRESSION

Zong-Ming Li

Hand Research Laboratory
Departments of Biomedical Engineering, Orthopaedic Surgery, and Physical Medicine & Rehabilitation
Cleveland Clinic, Cleveland, Ohio, USA liz4@ccf.org

The median nerve is prone to compression neuropathy at the wrist, leading to carpal tunnel syndrome. Carpal tunnel syndrome is currently the most common hand disorder in the general population, and the number of cases continues to rise with the increasing amount of work that demands use of the hands and upper extremities. Symptoms associated with carpal tunnel syndrome include pain, paresthesia, numbness, weakness, and loss of sensory/motor function in the hand. If left untreated, carpal tunnel syndrome can lead to irreversible degeneration of the median nerve, debilitating the hand.

While the etiology of carpal tunnel syndrome is multifactorial, pathomechanics associated with the carpal tunnel is one of the main contributors to the development of this hand disease. Many biomechanical factors can cause the compression of the median nerve in the confined space inside the carpal tunnel. The size of the carpal tunnel can be reduced by hypertrophy of the transverse carpal ligament, bony deformation, and wrist positional deviation; the contents of the carpal tunnel can be expanded by a number of space-occupying factors such as muscle intrusion and synovium thickening. In addition, carpal tunnel pressure elevation is known to impair the physiological function of the median nerve.

Decompression of the median nerve is routinely achieved by carpal tunnel release surgery to transecting the transverse carpal ligament. While carpal tunnel release is effective in reducing carpal tunnel pressure and improving symptoms, the invasive procedure of transecting the transverse carpal ligament disrupts the biomechanical and physiological integrity of the wrist. Surgical complications include inflammatory reactions, hypertrophic scarring, adhesion, edema, injuries to unintended structures, post-operative grip weakness and pillar pain, and symptom recurrence. Attempts have been sought for alternatives that decompress the median nerve while preserving the transverse carpal ligament. In our research to understand carpal tunnel mechanics and to search for alternative treatments of carpal tunnel syndrome, we found novel mechanisms of increasing the cross-sectional area of the carpal tunnel by biomechanically manipulating the carpal tunnel. Through cadaveric experimentation, human subject studies, geometrical modeling and finite element analysis, we have shown that shortening the carpal arch width and/or elongating the transverse carpal ligament are effective in increasing the arch area and reducing carpal tunnel pressure, and therefore potentially decompressing the median nerve and relieving carpal tunnel syndrome symptoms.

COMPLIANCE MEASUREMENTS OF THE CARPAL TUNNEL COMPLEX

INTRODUCTION

Carpal tunnel syndrome (CTS) is multifactorial and the most common peripheral neuropathy affecting the median nerve. It has a prevalence of 3% - 4% of the general population [1, 2]. Signs and symptoms associated with CTS include swelling, pain, tingling or numbness in the thumb, index, middle and half of the ring fingers. In severe cases these signs and symptoms can result to muscle weakness and atrophy along with sensory loss to the affected fingers [3].

Various biomechanical studies have evaluated the compressive and tensile properties of the carpal tunnel complex. However, more recently Ugbolue and colleagues have investigated the biomechanical properties of the transverse carpal ligament (TCL) and carpal tunnel complex by method of indentation [4] and using a Maillon Rapide Delta setup [5] respectively. This study reports the compliance measurements of the TCL and overlying soft tissues after running laboratory compressive biomechanical tests.

METHODS

Ethical approval was obtained from the Laboratory of Human Anatomy, University of Glasgow and from the Department of Biomedical Engineering, University of Strathclyde, ethical committees. Six embalmed cadaveric specimens amputated at the mid forearm and aged 82 ± 6.29 years were tested. The biomechanical properties of the TCL and the overlying soft tissue layers were tested by indentation using a BOSE Electroforce 3200 materials testing machine [4]. The indenter was attached to the BOSE 450N dry load cell (Model: 10-32 THD) and fitted to the upper actuator of the machine. The cadaveric hands were placed and secured on a custom made aluminium specimen platform and adjusted until the indenter was aligned and perpendicular to a defined central location on the palmar surface directly above the TCL. The experimental procedure entailed performing four indentation trials for each specimen at the following different levels of dissection: (a) Intact hand, (b) Skin removed – epidermis, dermis, subcutaneous adipose and palmar aponeurosis removed, (c) Removal of one muscle group – Thenar or Hypothenar muscle, (d) TCL exposed with carpal tunnel contents intact. The test protocol started with a preconditioning cycle where indenter was lowered to 0.5N preload with the specimen. Ten sine wave preconditioning cycles of -4.5mm displacement at a rate of 2Hz were performed. The specimen was allowed a 10s recovery period before performing a displacement ramp of -4.5mm at 2mm/s and held at constant displacement (constant strain) for 1800s. Each specimen was allowed a one hour recovery period between the different indentation trials. Compliance was expressed as the reciprocal of the stiffness measurements. Descriptive statistics and t-tests were performed to compare the difference between the dissection levels. P value was set to 0.05.

Table 1: Compliance (mm/N) and peak load (N) measurements at different hand dissection levels

Dissection Level	Mean Compliance	STDEV	Mean Peak Load	STDEV
Intact	0.179	0.11	68.02	42.87
Skin Removed	0.074	0.04	121.79	64.33
Thenar Removed first	0.039	0.02	228.15	101.18
Hypothenar Removed first	0.077	0.03	115.71	64.90
TCL Exposed	0.043	0.02	179.64	56.35

RESULTS AND DISCUSSION

All other dissection levels produced lower compliance values and higher peak loads when compared to the intact dissection level. The removal of the hypothenar muscles first showed an increase in compliance compared to the 'Skin Removed' level of dissection. There were no significant differences between the 'Thenar Removed' and 'Hypothenar Removed' conditions, P = 0.13.

Previously published work by Zong-Ming Li (2005) has investigated gender differences in carpal tunnel compliance using healthy participants [6]. Our compliance measurements on average are close but slightly higher by 0.078 mm/N.

CONCLUSIONS

Our results provide useful carpal tunnel complex compliance information of potential biomechanical changes that occur at the different levels of dissection. The reported carpal tunnel complex compliance measurements benefit clinicians and provide biomechanical data that could improve current hand and wrist models.

INTRODUCING AND VALIDATING A MUSCULOSKELETAL MODEL OF HAND AND WRIST

[1] **M.Mirakhorlo ,** [1] H.Maas , [1] H. E. J. Veeger , [2] I. Jonkers
[1] Vrije Universiteit Amsterdam

INTRODUCTION

To improve our understanding of the neuro-mechanics of finger movements, a comprehensive musculoskeletal model is needed. The aim of this study was to build and test a musculoskeletal model of the hand and wrist comprising all muscles, the carpo-radial, metacarpal and phalangeal joints.

METHODS

We built a 3D dynamic model comprising the segments of hand and wrist as well as the muscles of forearm and hand in OpenSim (3.3 Stanford, USA). In total, the model comprises 19 segments (the carpal bones were modeled as one segment) with 23 degrees of freedom and 43 muscles.

All required anatomical input data, including bone masses and inertias, joint axis positions and orientations and muscle morphological parameters (i.e. PCSA, mass, optimal fiber length and tendon length as well as muscle origins, insertions and via-points) were obtained from a cadaver of which the data set was recently published [1].

Model validity was investigated by first calculating model moment arms for the following muscles:

- The index finger's extrinsic muscles (flexor digitorum profundus (FDP), flexor digitorum superficialis (FDS) and extensor digitorum communis (ED))
- The index finger's intrinsic muscles (dorsal interosseous (DI), lumbricals (Lu), palmar interosseous (PI))
- The wrist muscles (extensor carpi radialis longus (ECRL), extensor carpi radialis brevis (ECRB), extensor carpi ulnaris (ECU), flexor carpi radialis (FCR), flexor carpi ulnaris FCU)

And compare them with experimental measurements [2,3].

Secondly, using static optimization muscle forces during thumb-index pinching (2-10 N) were computed and compared with those measured intraoperatively [4]. The square sum of muscle activation was used as cost function. To compare model and experimental moment arms correlation coefficients (r) and root mean square deviation (RMSD) over the whole range of motion were calculated using Matlab (2014a, Mathworks, Natick, USA).

RESULTS AND DISCUSSION

Correlation coefficients were high for all intrinsic and extrinsic muscles (r>0.83 and >0.93, respectively). The magnitudes of moment arms were quite similar for the extrinsic muscles as RMSD ranged from 8 to 15 %. However, moment arms of intrinsic muscles predicted by the model and those measured experimentally differed to a greater extent, as indicated by a higher RMSD (19, 27 and 61% for PI, Lu and DI), but their patterns were comparable (Fig. 1).

For ECRB, ECRL, FDP and FDS, patterns of moment arms at wrist flexion-extension (data not shown) were similar to experimentally measured data (r>0.97). The deviations from experimental moment arms for ECRB and FDS were relatively small (RMSD = 19.4 and 15.4%), but were higher for ECRL and FDP (31.2 and 34.7 %). The level of similarity was less for ECU, FCR and FCU; correlation coefficients were 0.75, 0.69 and 0.51 respectively. The deviations for FCR and FCU were relatively small (RMSD<15.4 %), but was rather high for ECU (41.6 %).

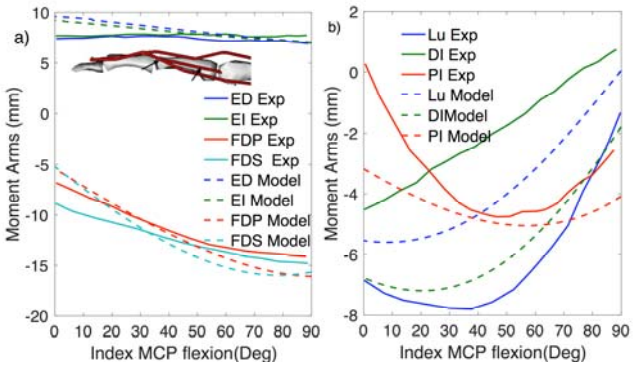

Figure 1: Comparison of experimentally measured (Exp) [2] and computed flexion/exertion moment arms of MCP joint of index finger during MCP joint movement. (a) Extrinsic muscles; (b) intrinsic muscles. For muscle abbreviations see the text.

Computed FDS and FDP forces of index finger during the pinch task were within one standard deviation of those measured in-vivo forces. In both cases, a linear relationship between muscle and finger-tip forces were found. The model estimates of the ratios of FDP and FDS forces to fingertip force were 2.52 and 2.31. Intraoperatively assessed ratios were 2.2±0.8 and 1.5±1.0 for FDP and FDS, respectively [4].

CONCLUSIONS

Good agreement between experimentally measured and computed moment arms as well as the FDS and FDP muscle tendon forces during pinch was found, providing a first indication of model validity.

INTRODUCTION

Anatomical structure affects function in joints. This morphology likely dictates the way forces travel through the joint. Since the wrist is composed of multiple joints, with complex ligamentous structures, the anatomical structure of the wrist remains incompletely understood, affecting our ability to understand wrist joint biomechanics.

The structural intricacy is increased by differences between wrists in regards to the bony shape of the joints. We believe that these morphological patterns provide the basis for variations in the biomechanical behaviour of distinct wrists.

Most studies have evaluated the structure of the midcarpal joint. In a previous study we described two wrist structural types centered on the morphology of the midcarpal joint. The purpose of this study was to further describe these two wrist patterns using multiple measurements performed on plain wrist radiographs. We hypothesized that we will be able to better describe the two distinct anatomical patterns using radiologic measurements independent of the midcarpal joint.

METHODS

A database of 171 normal adult wrist posteroanterior (PA) radiographs was created. Radiographs that were read by the radiologist as “normal” then underwent further scrutiny by two hand surgeons for quality and the quality of wrist positioning.

Radiographs were evaluated for: radial inclination, radial height, radial length, ulnar variance, volar tilt, d2/w2, lunate and capitate type. Two lines of reference were used: a continuation of the line of the anatomical axis of the radius into the metacarpals (3 points in the middle of the radial shaft) and a continuation of the anatomical axis of the index metacarpal (3 point in the middle of the shaft in its narrowest area). We measured the distance between the 2 lines and the angle between them. We measured and calculated the percent of the distal capitate facet that articulates with the lunate, the percent articulation with the scapholunate ligament and scaphoid bone. The percent articulation of the radial capitate that articulates with the scaphoid and the trapezoid was also measured. Wrist type 1 was defined as a lunate type 1 and a spherical distal capitate articulation. Wrist type 2 was defined as a lunate type 2 and a flat distal capitate articulation.

Statistical analysis included Chi square and t-tests as well as logistic regression analysis

RESULTS AND DISCUSSION

Type 1 and 2 wrists differed significantly in the length of the capitolunate joint within the midcarpal joint. Specifically type 1 wrists were positively associated with a larger distance of the facet between the capitate and the distal lunate ($p=0.01$), a shorter articular facet (line) between the lunate and proximal hamate ($p=0.004$).

The wrist types differed in the measurement of the middle carpometacarpal (CMC) joint. Specifically the length and percent circumference (of capitate) of the articular line between the distal capitate and the base of the middle metacarpal base was longer in type 1 wrists ($p=0.004$).

In type 1 wrists we found a positive association between the lengths of the articulation between the capitate and the base of the third metacarpal and the articulation between the capitate and the lunate ($p=0.03$) and a negative association with the articulation between the capitate and the hamate ($p=0.02$).

In type 2 wrists we found a positive association between the lengths of the articulation between the capitate and the hamate and the articulation between the capitate and the scaphoid, the facet between the capitate and the base of the ring and index metacarpals. There was also a positive association between scaphoid-capitate facet length and the index CMC articulation. Other measured parameters did not differ between the two wrist types. Based on these observations, two distinct wrist patterns could be estimated assuming that a longer facet indicates a larger contact area.
Figure 1: 1=contact line between capitate-base middle metacarpal, 2=line between capitate-base metacarpal 4, 3=capitate-hamate, 4=capitate-lunate, 5=capitate-scaphoid, 6=capitate trapezoid line, 7=capitate-index metacarpal.

FIGURE 1:

CONCLUSIONS

1) We were able to describe the two wrist patterns not only within the midcarpal joint but also by differences in the CMC joints as well as the facets between the capitate and the hamate and scaphoid bones.
2) These findings should next be translated into 3 dimensional structures to evaluate the true contact areas.
3) These findings may be used in finite analysis to estimate the transfer of forces in different wrist functions.

GENDER DIFFERENCES IN CRICKET FAST BOWLING

[1] **Paul J Felton**, and [1]Mark A King
[1]Loughborough University
P.J.Felton@lboro.ac.uk

INTRODUCTION

Previous research has investigated the influence of technique parameters on ball release speed almost predominately using male fast bowlers with ball release speeds in excess of 85 mph (135 km/h). Despite females having known differences in anthropometry and strength compared to males, the coaching of female fast bowling is based on the knowledge acquired on their male counterparts. Biomechanical comparisons between male and females in other throwing motions (baseball pitching and javelin throwing) have shown that there is a gender difference evident[1,2]. Since female athletes generate less muscle torque and power it is hypothesized that gender differences exist in the kinematics of cricket fast bowling.

METHODS

Twenty elite female (age: 19.8 ± 3.2 years; mass: 64.48 ± 8.8 kg; height: 1.67 ± 0.07 m) and male (age: 20.1 ± 2.6 years; mass: 81.5 ± 8.3 kg; height: 1.88 ± 0.08 m) fast bowlers were tested. Kinematic data were collected at the England and Wales Cricket Board (ECB) National Cricket Performance Centre, Loughborough University which provides an indoor practice facility allowing fast bowlers to bowl using their normal run-up on a standard artificial cricket wicket. An eighteen camera Vicon MX motion analysis system (OMG Plc, Oxford, UK) operating at 300 Hz was used to collect three-dimensional kinematic data of six stock deliveries. Forty-seven 14 mm retro-reflective markers were attached to the subject and an additional marker was attached to the ball in order to calculate ball speed. All marker trajectories were filtered using a fourth-order low pass Butterworth filter with a cut-off frequency of 30 Hz. The best three trials were averaged and 14 kinematic parameters previously associated with ball release speed were determined for each trial. Gender differences were tested for each variable using Independent Samples t tests within SPSS v.23 (SPSS Corporation, USA).

RESULTS AND DISCUSSION

Females displayed significantly slower ball release speeds (Table 1). Five of the 14 kinematic variables showed significant differences between genders (Table 2).

In this study, female fast bowlers were found to have significantly slower run-up speeds than their male counterparts. Previous research has indicated that a faster run-up is linked to fast ball speeds by increasing the amount of linear momentum which can be converted to angular momentum at front foot contact[3]. This difference may explain the difference in ball release speed and is likely a consequence of gender differences in anthropometry and lower limb strength to support increased run-up speeds during back foot and front foot contact. Although there was no significant difference in the delivery stride as a percentage of standing height, the plant angle of the front leg was significantly different, indicating that female fast bowlers lack the strength to drive off the back leg into front foot contact.

The lack of kinetic energy from the run-up appears to change the kinematics of the upper body. In previous research[3] using male bowlers, the linear momentum is converted to angular momentum via a straight front leg at front foot contact. This angular momentum then drives the trunk forward and coupled with a delayed bowling arm at release increases ball speed. The female fast bowlers in this study however may use a kinematic chain more typically associated with throwing mechanics (Chu et al., 2009) since significant differences were found in the timing of the minimum separation angle between the pelvis and shoulders, the increase in trunk flexion and a reduction in the delay of the bowling arm.

Table 1: Kinematic comparison between genders

Variable	Female	Male	p
Ball speed (m/s)	28 ± 1	35 ± 2	<0.01*
Run-up speed (m/s)	5.3 ± 0.5	5.8 ± 0.6	0.01*
Delivery stride (% of height)	76 ± 8	79 ± 7	0.36
Front Foot Contact (FFC)			
Knee angle (°)	167 ± 7	164 ± 6	0.21
Shoulder angle (°)	-23 ± 17	-29 ± 22	0.32
Plant angle (°)	40 ± 3	36 ± 4	<0.01*
Ball Release (BR)			
Knee angle (°)	172 ± 25	167 ± 19	0.46
Shoulder angle (°)	-126 ± 18	-140 ± 15	<0.01*
Ball height (% of height)	110 ± 3	113 ± 4	0.01*
FFC to BR			
Knee flexion (°)	21 ± 13	18 ± 11	0.37
Knee extension (°)	18 ± 13	12 ± 7	0.07
Shoulder forwards rotation (°)	122 ± 18	116 ± 18	0.29
Thoracic flexion (°)	36 ± 7	31 ± 8	0.08
Pelvis-Shoulder separation angle			
Minimum (°)	-45 ± 13	-40 ± 10	0.14
Time (s)	0.5 ± 0.02	0.3 ± 0.02	0.02*

* Female and male groups significantly different ($p<0.05$).

CONCLUSIONS

This study indicates that gender differences may exist within the kinematics of cricket fast bowling. Coaches should be aware of the differences but more research is required to investigate the optimal female fast bowling technique.

ELECTROMYOGRAPHIC AND KINEMATIC STUDY OF TRACK CYCLISTS IN A VELODROME: A FIELD STUDY

[1]Cristian Riveros Matthey, [1]Claudio Montejo Soler, [2]Felipe P Carpes
[1]Escuela de Kinesiología Universidad Católica Silva Henríquez, Santiago, Chile

INTRODUCTION

Field studies in biomechanics of cycling are important for sports scientific community, but performance of track cycling still lacks information [1]. Different of road cyclists, track cyclists change vertical body orientation with respect to the frontal plane to make possible the bend trajectory [2], and the straight phase of the velodrome may impose different demands to the athlete compared to the bend phase [3]. These moments are fundamental in the competitions, because they represent acceleration and need for control of the bicycle to maintain the speed during the curve. For these reason this study determine the electromyographic and kinematics characteristics of lower limbs in track cyclists during the bend and straight trajectory in the velodrome.

METHODS

Four professional track cyclists from the national team of Chile were recruited for this study. Each athlete used a standard discipline bicycle, with a front/rear gear ratio of 50x14. They performed a standardized warm-up for 10 minutes and then completed 250 m laps by maintaining three different paces: 16, 18 and 20 s per lap [1]. Bilateral muscle activation was recorded through wireless surface electromyography (Noraxon Inc., USA) from rectus femoris, vastus lateralis, biceps femoris, semitendinosus, anterior tibial and lateral gastrocnemius. The onset-offset and amplitude of the signal [2,4] and the co-contraction index for the rectus femoris/biceps femoris (pair 1) and vastus lateralis (pair 2) were determined. Inertial sensors (Noraxon Inc., USA) were used to obtain bilateral sagittal hip and knee angles. Data were compared between bend and straight trajectory, as well as between the lower limbs though analysis of two-way variance (ANOVA) considering a significance level of 0.05. The local ethics committee approved this study.

RESULTS AND DISCUSSION

Both lower extremities (except for vastus lateralis at pace of 16 s) present a greater activation time and amplitude in the bend; furthermore, these variables were higher in right lower limb during the curve ($p<0.05$). Regarding the muscle co-contraction index, the results show a significant increase in right lower limb in both muscle pairs, being greater in pair 2, during the bend, for all lap times evaluated ($p<0.05$). Moreover, during the straight trajectory, it was observed a similar behavior for 16 and 18 s time lap ($p<0.05$) (Table 1). The kinematics data show higher left knee extension during the bend ($p<0.05$). The circular trajectories in track cycling induce changes in muscular physiological behavior when the athletes are exposed to centrifugal forces [5], this phenomenon is maintained despite of changes in exercise configuration like lap times or workload and cadence [6].

Table 1: Mean and standard error of the variables amplitude muscle activation, timing muscle and co-contraction index, for the lower limbs during the bend and straight trajectory in the lap times 16, 18, 20 s.

*Significant difference ($p<0.05$) between right and left lower limbs.

CONCLUSIONS

Our results suggest that there is more muscle work in the lower right limb during the curve phase in the velodrome, which may induce the greater pattern of co-contraction in the muscles surrounding the knee joint, aiming to stabilize this joint as a result of the work generated. In addition, this asymmetric work can be considered as a motor strategy to control laterality to counteract the centrifugal force that the cyclist undergoes during the bend.

ACKNOWLEDGEMENTS

Authors would like to thanks the track cyclists from the Chilean Federation for their participation in this study.

INFLUENCE OF THORAX-PELVIS SEPARATION ON FOUR TURN HAMMER THROW PERFORMANCE

[1]**Sara M Brice**, [1]Kevin F Ness and [3]Doug Rosemond
[1]James Cook University
[2]Australian Institute of Sport
Corresponding author email: sara.brice1@jcu.edu.au

INTRODUCTION

Hammer throw is an athletic throw discipline where performance is measured by distance thrown. Due to its projectile nature, hammer speed at release has the greatest influence on distance thrown. It has been suggested within coaching literature that thorax movement strongly influences the development of speed within the throw [1]. Angle between thorax and pelvis (thorax-pelvis separation angle) has been previously used to describe thorax motion in the hammer throw. It is recommended thorax-pelvis separation angle should increase during the single support phase of each turn and decrease during double support [1,2]. Quantitative assessment of the impact of this coaching recommendation on performance has not been undertaken.

The purpose of this study was to assess the impact of thorax-pelvis separation on performance. Specifically, the impact of reducing separation angle during double support. Behavior during double support was focused on as throwers are at their most stable during this time and probably capable of making technique adjustments if found to be beneficial.

METHODS

Six four turn hammer throwers (two male, four female) participated. Each participant performed ten throws with a competition standard hammer. All throws were performed at an outdoor throwing facility after twilight conditions. Retro-reflective makers were positioned on the hammer's cable at known distances from the hammer's head. Markers were also positioned on the sterno-clavicular notch, xiphoid process, spinous process of the C7 vertebra, spinous process of the T10 vertebra, left and right anterior superior iliac spine, and left and right posterior superior iliac spine of each participant.

Throughout each throw positional data of each marker were recorded using a 21 infra-red camera system (Oxford Metrics, Oxford, UK) sampling at 250 Hz. Distance thrown was also measured using competition measurement protocols. All recorded video footage were post-processed in Vicon Nexus (Oxford Metrics, Oxford UK). Anatomical marker data and Vicon-Nexus modelling functions were used to determine thorax-pelvis separation angle. Hammer marker data were used to determine hammer speed [3].

Thorax-pelvis separation angle at its smallest within each turn of each throw was determined. This discrete data point was chosen as it occurs during double support [1] when the thrower is at their most stable. Performance was measured using distance thrown and hammer release speed. Speed was examined in addition to distance as throwers may have utilized non-optimal release angles and heights which may have negatively influenced throw distance. Data were grouped for each turn and Pearson's correlation was determined to measure the strength of the relationships between minimum separation angle within each turn and the two performance measures. Scatterplots were used to confirm linearity and check for influential observations. Significance was set at $p < 0.05$ and post hoc power analyses were performed to assess statistical power.

RESULTS AND DISCUSSION

Very large negative correlations were observed between release speed and minimum separation angle within each turn (Table 1). These associations indicate throwers attained higher release speeds when thorax-pelvis separation was reduced to a smaller amount during double support. The same was observed in the first two turns for the relationship between throw distance and minimum separation angle (Table 1). This relationship was weaker in the final two turns however, these correlates were not significant. Post-hoc power analyses indicate there was adequate saturation (power > 0.80) for most significant associations.

These findings have important implications as they indicate throwers may be able to increase release speed by reducing the angle between thorax and pelvis to a smaller amount during double support. This in turn could improve throw distance. While the same strength of association was not observed for throw distance it is hypothesized other aspects such as release angle and height may have been non-optimal for this cohort which could have negatively impacted throw distance regardless of the release speeds attained.

CONCLUSIONS

For this cohort a strong relationship exists between thorax-pelvis separation angle and performance. Throwers may be able to improve performance by focusing on reducing thorax-pelvis separation angle during the double support phases. Future work to assess if throwers are capable of adjusting technique in the manner should be done.

DETERMINING INSTANTANEOUS IMPACT CHARACTERISTICS IN CRICKET BATTING

[1]Chris Peploe, [1]**Stuart McErlain-Naylor**, [1]Fred Yeadon, [2]Andy Harland and [1]Mark King
[1]School of Sport, Exercise and Health Sciences, Loughborough University, Loughborough, UK

INTRODUCTION

In cricket, the impact location of the ball on the bat face has a substantial effect on the subsequent post-impact ball trajectory, with impacts further from the sweetspot or longitudinal axis of the bat resulting in lower ball speeds [1], and often causing the bat to twist and the ball to depart on unintended trajectories [2]. Evidently, the impact location has a considerable influence on the success of the batting stroke, and thus is an important measure of success in cricket batting. Despite this, there has been minimal research investigating methods for determining an accurate measure of ball impact location during a dynamic hitting motion. The purpose of this study was to develop and validate a methodology for accurate determination of bat-ball impact location, as well as the timing of impact and instantaneous post-impact ball velocity using motion capture data in a whole body kinematic data collection environment.

METHODS

Data were recorded using an 18 camera Vicon Motion Analysis System (OMG Plc, Oxford, UK) operating at 250 Hz. Five 15 x 15 mm squares of Scotchlite 7610 reflective tape were attached to a standard size adult cricket ball and four 14 mm spherical reflective markers were positioned on the back corners of the blade of a short-handle adult cricket bat. A participant (26 years, 1.88 m, 93.2 kg) of premier league club standard performed three forward drives and three pull shots against a bowling machine with inbound velocity of 24.1 ± 0.7 $m \cdot s^{-1}$. Measured impact location was derived from the impression left in a fine powder coating on the bat face and digitised using Image-Pro Analyser software (Media Cybernetics Inc., MD, USA).

Logarithmic ball displacement equations were derived for the anterior-posterior and medio-lateral directions from knowledge that the drag force acting on a body is proportional to the squared velocity of that body, and that the deceleration of a body is proportional to the force acting on it (Eq. 1). Vertically, the addition of acceleration due to gravity led to the derivation of a second equation (Eq. 2).

$$x = \frac{1}{k} \cdot \ln(1 + k \cdot v_0 \cdot t), \quad (1)$$

$$x = \frac{1}{2k} \cdot \ln \cdot \frac{(g - k \cdot v_0^2)}{\left[g - ka^2 \cdot \frac{\left(1 - \frac{a + v_0}{a - v_0} \cdot e^{2 \cdot a \cdot k \cdot t}\right)^2}{\left(1 - \frac{a + v_0}{a - v_0} \cdot e^{2 \cdot a \cdot k \cdot t}\right)^2} \right]} \quad (2)$$

where x = displacement; t = time; k and v_0 are constants; and $a = \sqrt{g / k}$

Curves were fitted in MATLAB (Version 8.0, The MathWorks Inc., Natick, MA, 2012) utilising a Trust-Region-Reflective Least Squares algorithm to determine separate values for k and v_0 for individual trials in each of the three directions, both pre- and post-impact. Separate one-term Fourier models of displacement in the time domain were fitted to the four corners of the bat face in each direction for 36 ms prior to the frame before impact. Time of impact was determined as the mean time at which the pre- and post-impact ball curves, plotted against time, intersected in the vertical and anterior-posterior planes. Impact location of the ball centre relative to the local coordinate system of the bat was then calculated from the ball centre and bat face marker positions at the estimated impact time (calculated from the curve equations) using global to local coordinate system rotation matrices.

RESULTS AND DISCUSSION

R^2 and RMSE values for the goodness of fit of the pre- and post-impact ball curves averaged 0.99 ± 0.04 and 7.5 ± 2.6 mm, while those for the bat curves averaged 1.00 ± 0.00 and 0.8 ± 0.2 mm respectively. Comparison of the calculated and measured ball impact locations on the bat face resulted in mean absolute differences of 6.4 ± 4.2 and 7.1 ± 4.4 mm in the medio-lateral and longitudinal planes of the bat respectively. Comparison of instantaneous post-impact ball velocity from the curve equations with velocity via differentiation of post-impact ball position over ten frames revealed an absolute difference of 0.4 ± 0.6 $m \cdot s^{-1}$.

The high mean R^2 and low mean RMSE values for all pre- and post-impact ball curves justify the use of the logarithmic equations, and demonstrate that such equations are appropriate for modelling cricket ball trajectories shortly before and after impact. Measured errors in calculated impact location on the bat were found to be similar in magnitude to the RMSE values found in the pre- and post-impact ball curve fitting stages of the methodology. This indicates that no major additional errors were generated through the calculation of curve intersection timing, or the transformation of position data from a global to local coordinate system; therefore suggesting that the largest absolute errors are found in ball tracking and ball centre calculation.

CONCLUSIONS

This study has successfully developed and validated a methodology for the accurate determination of impact location of a cricket ball on the bat face, as well as the identification of bat-ball contact timing and post-impact instantaneous ball velocity, allowing researchers to more accurately determine shot success and precisely estimate joint and bat kinematics at the point of impact.

A MECHANISM OF KNUCKLEBALL PITCHING

[1] **Ryo Sanogawa**, [1]Yuji Ohgi
[1]Keio University
ohgi@sfc.keio.ac.jp

INTRODUCTION

A knuckleball is the most mysterious pitch in the baseball pitching. A fundamental knuckleball behavior is slow speed with very low numbers of spins. It is known that the airflow around the seam causes unpredictable turbulent flow behind the ball during the flight. For this phenomenon, low spin rate is necessary for the fluctuation (3). However, a knuckleball throwing skill is still unknown and there are several types of the pitching and ball holding styles. Theoretically, it is obvious that for the non-spin ball, the time integration of the angular moment must be zero during the pitching motion. However, at the final moment of the ball release, the pitcher's fingers usually roll on the ball surface. This causes torque for the ball by the outer product between the contact force and the moment arm. Normally, it makes back spin for the ball. Therefore, the knuckleball pitcher must have their special skill for the knuckleball pitch. The purpose of this study was to investigate the mechanism of the knuckleball pitching using the inverse dynamics.

METHODS

Twelve motion capture cameras (VICON MX-T20) were set up around the pitcher with 500Hz sampling rate. 14mm diameter reflective markers were attached on the subject's upper margin of sternum, shoulder, elbow and wrist joints and 6mm hemisphere markers were attached on the hand, fingers for the identification of the anatomical landmarks. Eight 6mm hemisphere markers were on the ball surface as well. In order to identify the ball release, two high speed video cameras (Phantom Ltd., Miro M110 and Miro ex4) were set up at the sampling rate of 2kHz from the side and behind the pitcher. A subject was an amateur knuckleball pitcher (22yrs, 176cm, 68kg). The subject threw sixteen knuckleball pitches and his motion and the ball trajectory were captured. The authors conducted kinematical and kinetical assessment on both the pitchers dominant upper extremity and the ball. A rigid body linked segment model was adopted for the knuckleball pitching motion (Fig.1). The fingers were modeled as a single link as the hand. As shown in Fig.1, the upper extremity was simplified as three links. In order to estimate the joint reaction forces and torques, the authors solve the Newton-Euler equations for these three links from the distal end of the segments. Using the visible ball markers, the center of ball was calculated by the equation of the spherical surface. The authors calculated the spin rate of each pitch. In this study, four successful knuckleball pitches which had very low spin rate (< 4.0 rps) were analyzed. Kinematical and kinetical parameters, including joint forces and the torques ($\mathbf{F}_1$-$\mathbf{F}_4$, τ_1-τ_4) were obtained. For the calculation, the contact free moment on the ball surface was assumed to be zero.

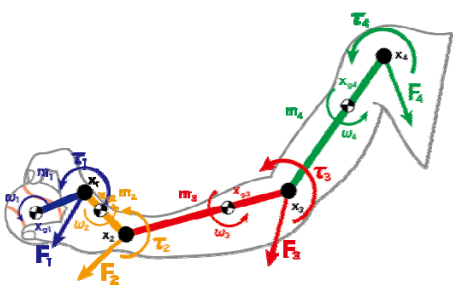

Figure 1: A linked segment model of the ball-hand.

RESULTS AND DISCUSSION

As for the kinematical parameters of the upper extremity, the flexion angle of the elbow was about 40 degree at the release, on the contrary, 20 degree for the fastball in the previous studies (1, 2). The maximum angular velocity of the pronation was 4398.2 deg/s for the knuckleball, 6483.7 deg/s for the fastball in the previous study (4). A significant characteristic of the knuckleball pitching can be seen on the wrist torque (Fig.2). The magnitude of the radial/ulnar torque was remarkably larger than that of the fastball (4). For the fastball, curve, change-up and any other pitch, the palmar/dorsal wrist torque is always dominant. On the other hand, the knuckleball pitch showed a different tendency. It was thought that the large ulnar torque makes wrist stiffen at the late phase of the pitch, which is similar to the cock of the golf swing.

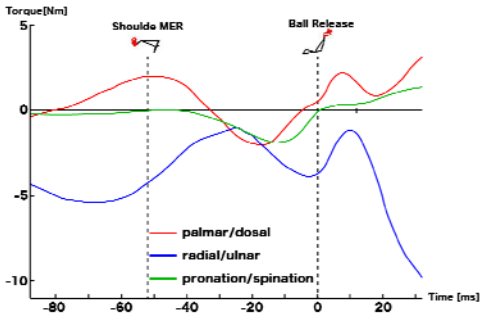

Figure 2: The wrist torque during the knuckleball pitching.

CONCLUSIONS

The authors examined a knuckleball pitching motion by the inverse dynamics. Results showed that the knuckleball pitching motion requires the wrist cock at the release by the ulnar large torque for the non-spin ball release.

INFLUENCE OF FOOTSTRIKE PATTERN ON MID-FOOT BIOMECHANICS AND INTRINSIC FOOT MUSCLE ACTIVATION DURING RUNNING

[1] **Luke Kelly**, [1]Dominic Farris, Glen Lichtwark and [3]Andrew Cresswell

INTRODUCTION

The orientation of a runner's foot at the instant of ground impact can have a profound influence on lower limb biomechanics. It has been suggested that a forefoot running technique is mechanically advantageous as it affords the runner greater opportunity to recycle the energy associated with foot-ground impact via elastic stretch and recoil of the tendons and ligaments of the ankle and foot [1]. Consequently, the popularity of running "re-training" programs that promote a forefoot landing technique to improve running performance and reduce injury risk have surged [2]

While the influence of foot-strike technique on knee and ankle mechanics has been well described, the influence foot-strike technique has on the biomechanics of the foot, in particular the longitudinal arch, remain largely unknown. Therefore the aim of this study was to investigate the influence of foot-strike technique on longitudinal arch mechanics and intrinsic foot muscle function during running.

METHODS

Thirteen healthy participants ran barefoot on a force-instrumented treadmill at 10 km/hr with a fore-foot (FFS) and rear-foot (RFS, preferred) strike running technique, while kinetic, kinematic and electromyographic (EMG) data were collected simultaneously.

Three-dimensional motion of the foot and shank was captured at 200 Hz while ground reaction force (GRF) and EMG data were captured simultaneously at 4000 Hz. Intramuscular EMG was recorded from the two largest intrinsic foot muscles: abductor hallucis (AH) and flexor digitorum brevis (FDB). Analysis of kinetic, kinematic and EMG data was performed using custom written software in Matlab (Mathworks, USA). Marker trajectories and GRF data were digitally filtered with a recursive 20 Hz low pass Butterworth filter. EMG signals were high-pass filtered using a recursive Butterworth filter at 35 Hz.

The longitudinal arch was modelled as a single "mid-foot" joint representing motion of the rear-foot (calcaneus) relative to the forefoot (metatarsals). A decrease in mid-foot angle is indicative of mid-foot dorsiflexion, or a reduction in LA height. Mid-foot plantar flexion is represented by an increase in mid-foot angle, and indicates an increase in arch height.An inverse dynamic analysis was performed to estimate joint moments generated about the mid-foot. Mid-foot joint moments were calculated during the stance phase after the centre of pressure had progressed distal to the axis of the mid-foot joint.

Root mean square (RMS) EMG signal amplitude was calculated using a moving window of 50 ms. Mean EMG RMS amplitude was calculated during the stance and swing phase for each stride cycle.

A one-way repeated measures analysis of variance (ANOVA) was used to describe the influence of foot-strike technique on running mechanics and intrinsic muscle activation.

RESULTS AND DISCUSSION

The mid-foot was more plantar flexed (higher arch) at foot contact when running with a fore-foot running technique (RFS 0.2º ± 1.8º v FFS 6.9º ± 3.0º, ES = 2.7, $P \leq 0.05$), however there was no difference in peak mid-foot dorsiflexion in stance (RFS -11.6º ± 3.0º v FFS -11.4º ± 3.4º, ES =0.06, P = 0.63, Figure 1).

Moments generated about the mid-foot were substantially greater when running with a fore-foot running technique compared to a rear-foot technique (RFS 2.1 ± 0.4 Nm/kg v FFS 2.6 ± 0.4 Nm/kg, ES = 1.3, $P \leq 0.05$).

Stance phase muscle activation was greater for both FDB (RFS 31.6 ± 11% max v FFS 37.8 ± 11% max, ES = 0.7, $P \leq 0.05$) and AH (RFS 32.8 ± 8.9% max v FFS 38.5 ± 9.3% max, ES = 0.63, $P \leq 0.05$) when running with a fore-foot technique. Swing phase activation was also greater when running with a fore-foot technique in AH (RFS 8.5 ± 5.8% max v FFS 14.2 ± 10.6% max, ES = 0.67, $P \leq 0.05$).

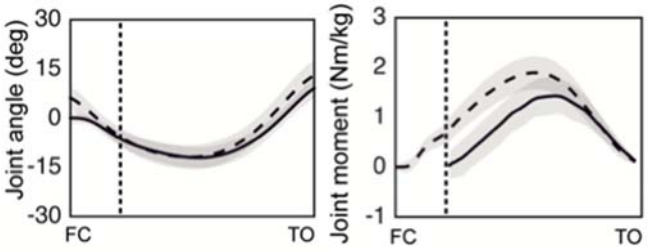

Figure 1: Mid-foot angle (left) and mid-foot plantar flexion moment (right) when running with a forefoot (dashed) and rear-foot (line) running technique.

CONCLUSIONS

Foot-strike technique substantially influences the mechanical function of the mid-foot during running. When running with a fore-foot technique an increase in intrinsic foot muscle activation is observed, presumable to aid in generation of the larger plantar flexion moment that is generated when running in this manner.

COMPARISON OF IN-VIVO TIBIOTALAR AND SUBTALAR KINEMATICS DURING TREADMILL AND OVERGROUND GAIT: A DUAL FLUOROSCOPY STUDY

[1]**Koren E. Roach,** [1]K. Bo Foreman, and [1]Andrew E. Anderson
[1]University of Utah
Corresponding author email: Koren.Roach@utah.edu

INTRODUCTION

Although instrumented treadmills are becoming more common in gait analysis, there is still controversy surrounding potential differences in kinematics and kinetics between these two modes of gait. Most studies have modeled the ankle as a single joint [1], often with motion restricted to one plane of motion [2]. These simplifications, combined with other factors (e.g. soft-tissue artifact), have made it difficult to definitely determine differences between overground and treadmill gait. Therefore, a method that accurately quantifies independent motion of the tibiotalar and subtalar joints is required to fully understand how treadmill and overground gait differ.

We have developed an advanced imaging technique, dual fluoroscopy (DF) that can accurately measure *in vivo* motion of the tibiotalar and subtalar joints in three dimensions (3D) during dynamic activities. The objective of this preliminary study was to quantify and compare tibiotalar and subtalar kinematics during treadmill and overground gait to ascertain whether kinematic differences exist on a per-subject basis.

METHODS

Following ethics board approval (IRB#65620) and informed consent, five healthy adult volunteers (gender: 3M/2F, age: 30.0±3.6 yo; BMI: 24.0±2.7) were enrolled in this study. Subjects walked on a treadmill at a comfortable pace (1.0 m/s) while DF images were acquired. As the motion of the treadmill moved the foot out of the combined field-of-view of the fluoroscopes, heelstrike and toe-off were captured as separate trials and a portion of midstance was not captured. During a separate session, subjects walked at a self-selected pace while DF images were acquired. Subject-specific CT scans were used in conjunction with the DF data to quantify *in vivo* tibiotalar and subtalar joint throughout each activity, as described previously [4]. Joint angles were normalized to the stance phase of gait. The maximum and minimum dorsiflexion (D), plantarflexion (P), inversion (In), eversion (Ev), internal rotation (IR) and external rotation (ER) and their respective locations during stance were compared between treadmill and overground walking. The joint angle differences between treadmill and overground walking were calculated for tibiotalar and subtalar D/P, In/Ev, and IR/ER.

RESULTS AND DISCUSSION

The mean (± standard deviation) difference between treadmill and overground walking D/P angles was 1.85±1.37° and 0.94±0.80° for the tibiotalar and subtalar joints, respectively. The mean difference between treadmill and overground walking In/Ev angles was 7.73±5.27° and 1.57±1.43° for the tibiotalar and subtalar joints, respectively. The mean difference between treadmill and overground walking IR/ER angles was 6.76±6.41° and 1.84±1.33° for the tibiotalar and subtalar joints, respectively.

The most notable trends in joint angles were for tibiotalar D/P. On average, subjects exhibited a maximum tibiotalar ~~D~~/P of 7.2° and 9.7° that occurred at approximately 83% and 78% of stance, respectively, during treadmill and overground gait, respectively (Figure 1). On average, subjects exhibited a minimum tibiotalar D/P angle of -10.7° and -11.5° that occurred at approximately 9% and 10% of stance, respectively, during treadmill and overground gait, respectively (Figure 1). Our preliminary results indicate overground walking may induce higher peak D and P angles compared to treadmill gait. Treadmill peak D occurs later in stance, suggesting that stance between this peak and toe-off is influenced by the motion of the treadmill and occurs quicker than during overground gait.

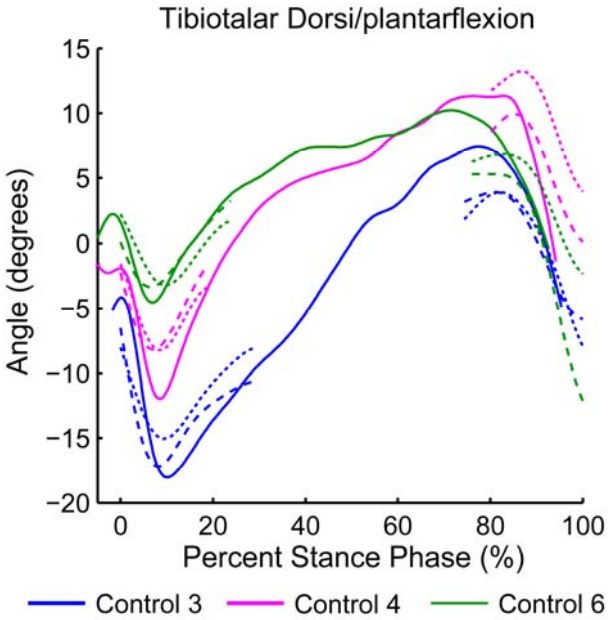

Figure 1: Tibiotalar D/P during 2 trials of treadmill (dashed/dotted lines) and overground walking (solid lines) for three representative control subjects.

CONCLUSIONS

Our results indicate that subjects have altered tibiotalar In/Ev and IR/ER between treadmill and overground gait. Additionally, treadmill locomotion may cause lower peak dorsiflexion and plantarflexion values during gait. These variations should be taken into consideration when evaluating subject gait.

TIBIOTALAR AND SUBTALAR KINEMATICS DURING STAIR ASCENT AND DESCENT: A DUAL FLUOROSCOPY STUDY

[1]Koren E. Roach, [1]K. Bo Foreman, and [1]**Andrew E Anderson**
[1]University of Utah
Corresponding author email: Andrew.Anderson@hsc.utah.edu

INTRODUCTION

Ankle osteoarthritis (OA) is a debilitating condition that can cause pain, diminished quality of life, and is becoming increasingly prevalent in the US due to an aging population. It has been clinically hypothesized that ankle OA is caused by abnormal kinematics (i.e. joint angles and translations) in the tibiotalar and subtalar joints [1]. Despite this proposed connection, kinematics of the tibiotalar and subtalar joints have not been extensively studied, especially during motions that are demanding, such as stair ascent/descent. Often, ankle motion is measured by tracking the trajectories of reflective markers attached to the skin. As there are no reliably palpable bony landmarks about the talus, skin marker motion capture cannot delineate motion between the talus and calcaneus.

We have developed a high-speed dual fluoroscopy (DF) system that can measure three-dimensional *in vivo* bone motion for the tibiotalar and subtalar joints. The primary goal of this preliminary study was to use DF to investigate the kinematic roles of the tibiotalar and subtalar joints during stair ascent and descent.

METHODS

Following ethics board approval (IRB#65620) and informed consent, six healthy adult volunteers (gender: 3M/3F, age: 29.2±3.8 yo; BMI: 23.5±2.7) were enrolled in this study. Subjects completed stair ascent and stair descent activities while DF images were acquired. Model-based markerless tracking was used to determine the positions of the tibia, talus, and calcaneus and tibiotalar and subtalar joint kinematics throughout each activity, as described previously [2]. The rotational and translational range of motion (ROM) was determined for each trial and averaged across subjects.

RESULTS AND DISCUSSION

The most distinct trends were seen in tibiotalar dorsi/plantarflexion (D/P) angles during stair ascent (Figure 1) and descent. Both the tibiotalar and subtalar joints showed decreases in D/P throughout stair ascent (Figure 1). The tibiotalar joint exhibited an increase in D/P during stair descent, while the subtalar joint exhibited a comparatively small decrease in D/P. During stair ascent, the D/P range of motion (ROM) at the tibiotalar and subtalar joints was 37.68±6.14° and 6.63±2.66°, respectively. During stair descent, the D/P ROM at the tibiotalar and subtalar joints was 47.69±6.84° and 6.96±3.88°, respectively.

Throughout stair ascent, the tibiotalar joint exhibited a constant decrease in external rotation, while the subtalar joint exhibited a constant increase in inversion and internal rotation. In fact, the inversion/eversion (In/Ev) ROM was 4.58±0.61° and 8.49±1.49° for the tibiotalar and subtalar joints, respectively. Rotation was similar between the two joints during stair ascent, where the internal/external rotation (IR/ER) ROM was 10.21±3.16° and 10.29±1.47° for the tibiotalar and subtalar joints, respectively.

During stair descent, the tibiotalar joint exhibited a steady increase in eversion and external rotation, while the subtalar joint exhibited a steady increase in inversion and internal rotation. The In/Ev ROM was 9.70±5.96° and 11.73±4.59° for the tibiotalar and subtalar joints, respectively throughout stair descent. The IR/ER ROM was 12.73±1.31° and 8.67±3.19° for the tibiotalar and subtalar joints, respectively during stair descent.

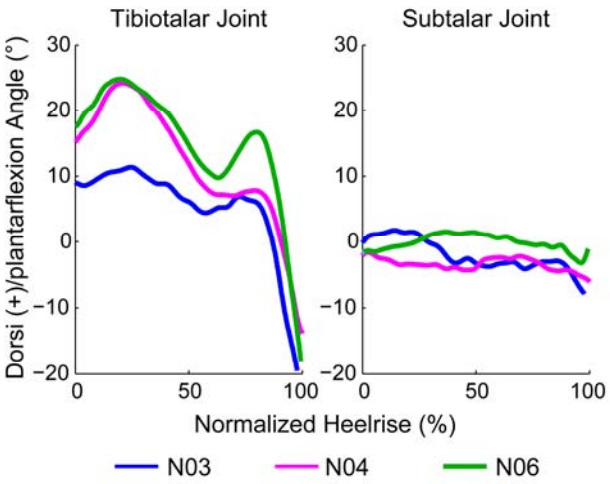

Figure 1: Tibiotalar (left) and subtalar (right) dorsi/plantarflexion (D/P) angles during stair ascent for three representative control subjects who had min, max and average D/P angles. Dorsiflexion = (+).

CONCLUSIONS

These results are in accordance with our previous findings during treadmill walking and single-leg heel-rise that the tibiotalar joint is primarily responsible for D/P while the subtalar joint is primarily responsible for In/Ev [2] and extends this implication to stair ascent and descent activities. The current study provides further evidence that the joint responsible for IR/ER motion may be activity-dependent. As the first study investigating the effect of stair ascent and descent activities on tibiotalar and subtalar joint motion using DF, these data will serve as the foundation to identify how ankle OA and other disorders alter tibiotalar and subtalar joint motion.

AN EVALUATION OF SEGMENT RIGIDITY IN A MULTI-SEGMENT FOOT MODEL

[1] **Po-Hsiang Chan**, [1]Amy B. Zavatsky and [2]Julie Stebbins
[1]Department of Engineering Science, University of Oxford, Oxford, UK
[2]Oxford Gait Laboratory, Nuffield Orthopaedic Centre NHS Trust, Oxford, UK

INTRODUCTION

Multi-segment foot models have become increasingly popular due to the increased accuracy and ease-of-use of motion capture technology. Sub-division of the foot into multiple segments has helped in clinical diagnosis and treatment planning in the case of foot deformities, as well as furthering our understanding of foot biomechanics.

There is currently no consensus on exactly how the foot should be divided, especially in the forefoot region. There is also debate as to whether it is appropriate to consider the whole forefoot segment as a single rigid body, particularly given the anatomical connections of the metatarsals to the bones of the mid- and hindfoot, along with the flexibility of the medial longitudinal arch.

This study aimed to quantify the rigidity of the forefoot (FF) and hindfoot (HF) segments as defined in a multi-segment foot model widely used in clinical work (the Oxford Foot Model [1,2]). It was hypothesized that the FF would be less rigid than the HF and that the deformations of the two segments would differ over the gait cycle.

METHODS

Static (standing) and walking data were collected from 43 healthy adult subjects (22 male, 21 female) using a Vicon Motion Capture System. HF markers were placed on the posterior distal aspect of the heel, sustentaculum tali, lateral calcaneus, and posterior calcaneus (wand marker) [1,2]. FF markers were placed between the second and third metatarsal heads, on the bases of first and fifth metatarsals, and on the head of the fifth metatarsal [1,2].

The rigidity of each segment was quantified using the rigid body error σ_{RBE} [3,4] calculated for each frame of a representative gait cycle chosen from six separate walking trials; σ_{RBE} is a measure of how well the tracking marker configuration at each frame compares to the configuration of the same markers in a reference configuration (here, the static trial).

RESULTS AND DISCUSSION

There was no statistical difference ($p>0.11$) in the average σ_{RBE} over the gait cycle between the male (m) and female (f) participants for either the FF or the HF, although σ_{RBE} values for women were smaller than those for men (mean ± std dev in mm): mFF (2.28±0.43), fFF (2.19±0.70), mHF (0.87±0.46), fHF (0.82±0.33). The FF was significantly less rigid compared to the HF ($p<0.01$).

The patterns of deformation of the two segments differed over the gait cycle (Fig. 1), with HF σ_{RBE} staying relatively constant while FF σ_{RBE} differed between stance and swing phases and changed abruptly near 10% and 50% of the gait cycle.

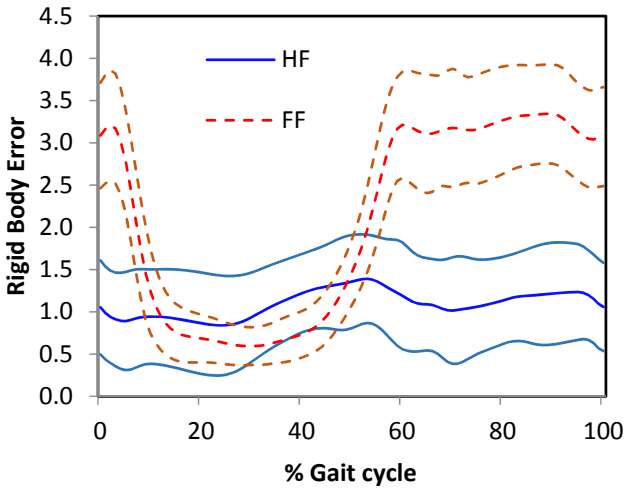

Figure 1: FF and HF σ_{RBE} over one full gait cycle. Means ±1 standard deviation (mm).

CONCLUSIONS

Neither the FF nor the HF segment was perfectly rigid. On average the FF σ_{RBE} was greater than that of the HF. This is as expected since all HF markers are on one bone – the calcaneus, whereas the FF markers are spread across the metatarsals. Both skin-movement error and segment flexibility are captured in σ_{RBE}, and although the latter is likely to be more dominant in the FF, this study is unable to verify how much each effect contributes to the total σ_{RBE}.

The patterns of deformation of the two segments are consistent with our general understanding of how foot shape changes during gait. The FF markers most nearly resemble their static-trial configuration during the single-limb support phase of stance (hence the lower FF σ_{RBE} in this period); this is when load is transmitted through the forefoot and the metatarsals are most spread. Graphs such as Figure 1 could be useful clinically in quantifying the progression over time of a foot condition such as flexible flatfoot.

Further work is required to assess the repeatability of σ_{RBE} and to study how its change during the gait cycle might differ in adults and children and in different clinical populations. It would also be interesting to assess σ_{RBE} to help guide possible sub-divisions of the FF (e.g., medial versus lateral).

INTRODUCTION

Lateral ankle sprains are among the most common injuries in the physically active people and as a consequence to lead to repetitive injuries due to joint instability and neuromuscular control deficits [1]. Manual Therapy, for example, mobilization with movements (MWMs) has proposed as a technique to improve joint range of motion and functional outcome by combining physiological and accessory movements [2].

Dynamic postural control deficits are commonly seen in people with functional ankle instability (FAI) [1,3]. Whether the MWMs could improve dynamic postural control immediately remains largely unknown. We have hypothesized that immediate effects of dynamic postural control and ankle dorsiflexion range could improve after MWMs intervention in active physically people with functional ankle instability

METHODS

A total of 40 participants, which divided into functional ankle stability (FAI) group (age: 21.1 ± 0.8 years; height: 166.1 ± 4.0 cm; mass: 57.2 ± 4.8 kg, mean±95CI) and age- and BMI-matched healthy group (age: 20.7 ± 1.0 years; height: 166.8 ± 4.7 cm; mass: 59.1 ± 4.2 kg), voluntarily involved with the meet of inclusion and exclusion criteria. Mobilization with movements (MWMs) technique [2] was applied to the talocrural joint in the injured side (FAI) and dominant side (healthy control), respectively.

Weight-bearing ankle dorsiflexion lunge test (WBLT) was used to test the range of motion of dorsiflexion. Y Balance test (YBT) was used to examine the dynamic postural control of the lower limb in the anterior (ANT), posteromedial (PM) and posterolateral (PL) directions. Muscle activation of Peroneus Longus (PL), Peroneus Brevis (PB), Tibialis Anterior (TA) and Soleus muscles in the injured leg and dominant leg were examined by surface EMG (Bagnoli™ Desktop EMG system, Delsys Inc. USA). Onset time of muscle activation during the drop landing task was processed by a custom-design program [4] (Matlab R2015a, MathWorks Inc. USA) from raw EMG data transferred from a data acquisition unit (Micro 1401, CED Limited, UK). All measurements were examined in a randomized order before and after MWMs interventions.

All variables in WBLT, YBT and onset time of muscle activation of pre-intervention and post-intervention (within-group, between-group) was examined any significant difference using independent t-test and paired t-test (SPSS 22, IBM Corp., USA). Significance level was set up as 0.05

RESULTS AND DISCUSSION

All variables of WBLT and YBT were significantly increased after MWMs compared to pre-intervention in both groups ($p<0.001$). Interestingly, significant reduced onset time of Peroneus Longus (PL) was found in FAI group after MWMs intervention ($p=0.047$, Figure 1). There was no significant difference of onset time of muscle activation during drop landing tasks in healthy control between pre- and post- MWMs intervention (Figure 1)

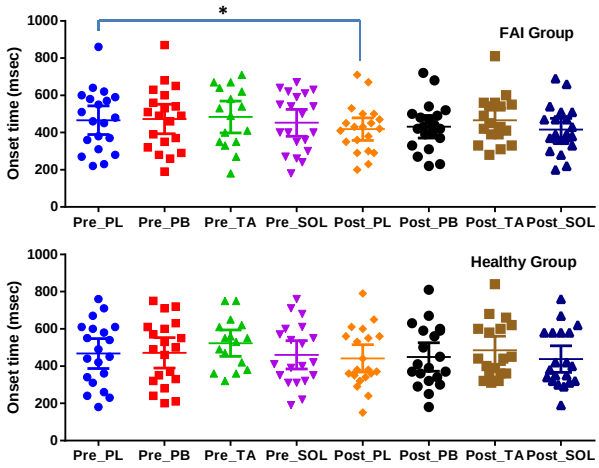

Figure 1: Onset time of muscle activation (Mean±SD) of Peroneus Longus (Pre_PL vs. Post_PL), Peroneus Brevis (Pre_PB vs. Post_PB), Tibialis Anterior (Pre_TA vs. Post_TA) and Soleus (Pre_SOL vs. Post_SOL) in FAI group and healthy control group between pre- and post- MWMs intervention (* indicates the significant difference between Pre_PL and Post_PL).

CONCLUSIONS

The immediately improved effects of dynamic postural control, ankle dorsiflexion range and of ankle eveter muscle activation following MWMs could contribute to reducing the re-injury in people with FAI.

INTRODUCTION

As well as being tensile load-bearers, tendons can also be joint-positioning vs energy-storing. Accordingly, tissue properties, (e.g. biochemical composition and biomechanical properties) may also differ by function. By understanding the relationships between biochemistry, tissue biomechanics and structure in functionally-different tendons, more effective injury-prevention and rehabilitation may become possible.

The aim of this study is to investigate the role of underlying biochemical and structural changes in modulus and ultimate tensile strength of functionally distinct tendons.

METHODS

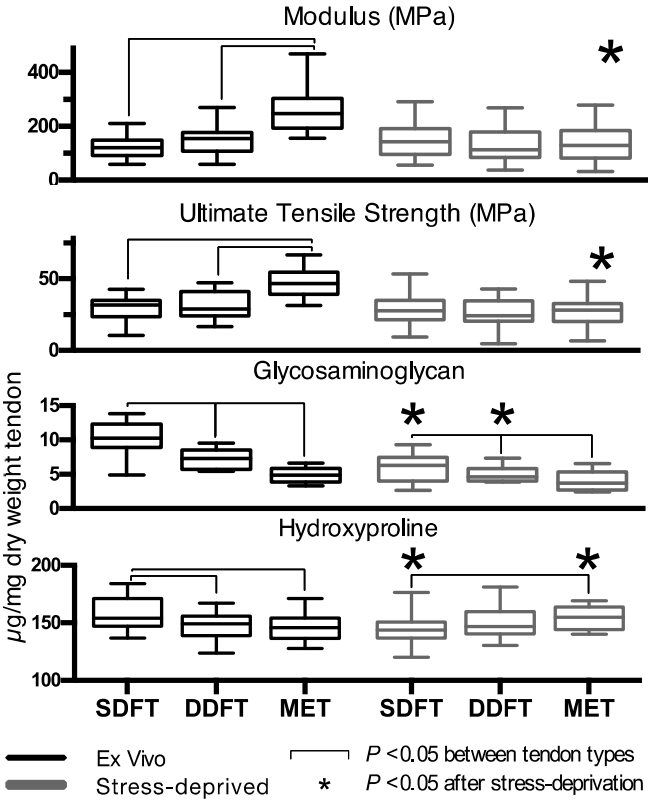
Three tendons were freshly dissected from both forelimbs of n=14 sheep; these were the energy-storing storing tendons of the superficial (SDFT) and deep digital flexors (DDFT) and the positional medial extensor tendon (MET). One limb was allocated to biomechanics/biochemistry, the other for histology. Each tendon was dissected longitudinally to produce; (1) ex vivo "controls"; (2) specimens "stress-deprived" 3 weeks in tissue culture. Collagen alignment was imaged from specimens stained with Picrosirius red. Biomechanics specimens were frozen prior to testing.

Biomechanics specimens were thawed for cross-sectional area measurement, tested in tension to failure (5%/s, Instron 8874, 250N load cell) and measured for glycosaminoglycan (GAG) and collagen by spectrophotometry. By adjusting for cross-sectional area and gauge-length, the stress-strain curves produced from force-displacement data were analysed for elastic modulus (maximum gradient) and ultimate tensile strength (UTS). Effects of tendon type and stress-deprivation were tested by mixed model analysis and associations of biomechanics and biochemistry were tested by pairwise correlations.

RESULTS AND DISCUSSION

Before stress-deprivation (Figure 1), the positional MET had significantly higher modulus (+97% 95%CI[68%,127%]) and UTS (+62% 95%CI[41%,82%]) than the energy-storing SDFTs and DDFTs. Interestingly in biochemistry, the MET had the lowest GAG content (-33%[-46%,-20%] vs DDFT, -53%[-62%,-44%] vs SDFT). In energy-storing tendons, the SDFT was significantly different from the others, having the highest GAG (+53% [45%,62%] vs DDFT) and collagen (+5.2% [0.7%,9.7%] vs DDFT). Compared to the MET, the DDFT also had higher GAG, but was not different in collagen content.

Stress-deprivation (Figure 1) significantly reduced modulus (-55%[-74%, -36%]) and UTS (-48%[-63%,-38%]) in the MET, but not in the energy-storing SDFT nor DDFT. In contrast, GAG was reduced in the energy-storing SDFTs (-37% [-48%, -26%]) and DDFTs (-27% [-36%, -19%]), but not the MET. Total collagen content decreased in the SDFTs (-8% [-13%, -3%]), but increased in METs (+6% [3%, 8%]).



Despite these findings, no significant associations were found between biomechanics and biochemistry, regardless of tendon type or treatment.

In contrast to biochemical composition, histological collagen alignment observations were consistent with biomechanics results. All tendons had highly aligned collagen fibrils at baseline. Consistent with reductions to modulus and UTS after stress-deprivation, the MET's collagen was less aligned and severely disrupted. In contrast, in the energy-storing SDFT and DDFT the structure appeared more intact, with good alignment and less gapping (vs MET). This is consistent with modulus and UTS being maintained after stress-deprivation in these tendons.

CONCLUSIONS

Distinctions between tendon types existed in biomechanics and biochemistry before treatment, however these were disrupted by the immobilising effects of the *in vitro* stress-deprivation. Deterioration of histological structure, but not biochemical composition, was consistent with reductions to modulus and UTS. Further investigation is needed to relate the change in GAG and collagen to the tissue's loading environment and its effect on tissue biomechanics.

MICRO-SCALE DEFORMATION AND RAMAN SHIFTS OF MINERAL AND COLLAGEN PHASES IN BONE TISSUE

INTRODUCTION

Bone has a hierarchical structure at different structural levels and is often regarded as a composite material consisting of mineral particles of apatite crystals ($Ca_{10}(PO_4)_6(OH)_2$) and organic matrix of Type I collagen in microscopic scale [1]. The mechanical properties of bone at macroscopic scale depend on the structural organization and properties of constituents in the microscopic scale. Recent studies found that osteoporosis is not just a simple loss of bone mass or bone mineral content, but involves significant changes in the biochemical and physical properties of the collagen matrix.

Raman spectroscopies have been used to study normal and osteoporotic tissue, as well as to investigate compositional changes associated with various bone diseases [2]. The aim of this study are to observe the mechanical behaviors of mineral and collagen phases in bone tissues by using Raman imaging system and to investigate the relationship between the micro-deformation by X-ray diffraction (XRD) and Raman shifts of both mineral and collagen phases in cortical bone tissue.

METHODS

Raman microscope system (inVia Reflex, Renishaw, UK) and X-ray diffractometer (Nano-viewer, Rigaku, Japan) were used. A continuous laser beam (laser excitation: 532 nm; laser power: 50%) is micro-focused on the specimen through a microscope, and the photons interact with the molecules of the specimen by Raman scattering. Raman shifts of 441 points (observing area with 30×30 μm; 21×21 points with 1.5 μm step) for each specimen were collected in the case of unloading, 5, 10, 15 and 20 N loading by the tensile loading system. The grating was 1800 g/mm and the effective spectral range was 160-1900 cm^{-1}. Each laser exposure time was 1 sec.

In the XRD experiment, the micro-deformation of both mineral and collagen in bone tissue were measured by wide-angle X-ray diffraction (WAXD) caused by the lattice structure of apatite crystals and small-angle X-ray scattering (SAXS) caused by the periodic structure of collagen molecules, respectively. The diffraction images were recorded by imaging plates mounted on 75 mm and 763.5 mm camera length at WAXD and SAXS experiments. The specimens were loaded by the micro-tensile device during XRD. Each X-ray irradiation time was 30 min.

RESULTS AND DISCUSSION

By using Raman spectroscopy, both spectrum of apatite crystals and collagen matrix could be observed as the phosphate ν_1 band at approximately 960 cm^{-1} and the bands associated with collagen (Amide III at 1250 cm^{-1}, CH_2 wag at 1450 cm^{-1}, and Amide I at 1665 cm^{-1}) The most intense peak in the bone spectrum is phosphate ν_1 ($\nu_1PO_4^{3-}$). From all experiments, the Raman shifts of mineral and collagen phases to lower wave numbers were observed with increase of applied tensile stress. Also, the changes in Raman shifts against applied tensile load was distributed as gaussian distribution in the measurement area.

As the results of XRD experiments under tensile loading, the strain of mineral and collagen matrix increased with increasing bone tissue strain. The mineral strain showed lower value than bone tissue strain and collagen matrix strain showed higher value. The collagen matrix strain allowed tensile deformation as compared with mineral phase. Figure 1 shows the relationships between micro-strain measured by XRD and Raman shifts of mineral and collagen phases in cortical bone. This result shows the Raman shifts of mineral and collagen phase in bone tissue were well related to micro-deformation of both constituents.

CONCLUSIONS

This study investigated the relationship between the micro-deformation by X-ray diffraction and Raman shifts of both mineral and collagen phases in cortical bone tissue. The Raman responses of mineral and collagen phase in bone tissue were well related to stress state. It was confirmed that Raman spectroscopy is sufficiently useful to evaluate the stress or strain state based on the microscopic response of constituents in bone tissue.

ROLE OF MECHANICAL FLOW IN THE CYTOSKELETON ORGANIZATION

[1]**Byungjun Kang**, [1]Seunghan Jo and [1]Hyungsuk Lee
[1]Yonsei University
Corresponding author email: hyungsuk@yonsei.ac.kr

INTRODUCTION

The cytoskeleton provides mechanical rigidity to the cell and changes its structure to meet a variety of cellular functions. The change of cytoskeleton is mainly related to the actin which is the most abundant protein in eukaryotic cells. For this reason, researchers have investigated factors that modulate the actin cytoskeletal structure. However, reconstructed actin networks *in vitro* show a random structure, which is not similar to the inhomogeneous and anisotropic cytoskeleton of cells *in vivo* [1]. The origin of such a discrepancy is still unclear. Recently, it was revealed that mechanical flow inside cells called cytoplasmic streaming exists inside cells. The cytoplasmic flow is attributed to dynamic behaviors of the cell such as contraction, external forces applied to the cell, and porous material properties of the cytoplasm [2]. Here, we investigate how the mechanical flow plays a role in determining the structure of the actin cytoskeleton. We develop a computational model of the cytoskeleton network consisting of actin and actin binding proteins formed under the mechanical flow. We analyze the alignment and bundle thickness of actin filaments as a function of kind of actin binding protein as well as the mechanical flow.

METHODS

For modeling of the actin cytoskeleton, actin filaments shaped with a rigid bar are randomly dispersed in a 2D field of view. The structure of the actin cytoskeleton is altered by the drag force produced by flow, crosslinking or bundling of actin filaments by actin binding proteins at each simulation step.

Crosslinking of two filaments occurs when the filaments are intersected with the crosslinking probability depending on the type of actin binding protein. α-actinin and filamin each has a higher probability to form a parallel and perpendicular crosslinking, respectively. Individual filaments are allowed to be translated or rotated in response to the applied flow. Actin bundles are defined as more than two filaments spaced less than the size of actin binding protein.

Filaments orientation is characterized by analyzing 2D FFT of the actin network [3]. Bundling degree is calculated by obtaining the thickness distribution for individual actin bundles.

RESULTS AND DISCUSSION

To validate our computational model, the actin network formed without flow was analyzed. Both the actin/α-actinin and actin/filamin structures were isotropic. However, more actin bundles were observed only in the actin/α-actinin network. Actin/filamin structures exhibited more orthogonal crosslinks of actin filaments as shown in Figure 1. The actin networks shown in the simulation was similar to the fluorescent images of actin/α-actinin network [4] and actin/filamin network [5] synthesized in vitro.

We investigated the effect of flow on the actin cytoskeleton structure depending on the type of actin binding protein. For actin/α-actinin network, the applied flow played a significant role in increasing the alignment of the filament, but little in bundle thickness. In contrast, the flow applied to actin/filamin network enhanced the bundle formation but did not affect the filament alignment. These results indicate that the effect of the flow on the actin network organization depends on the type of the actin binding protein.

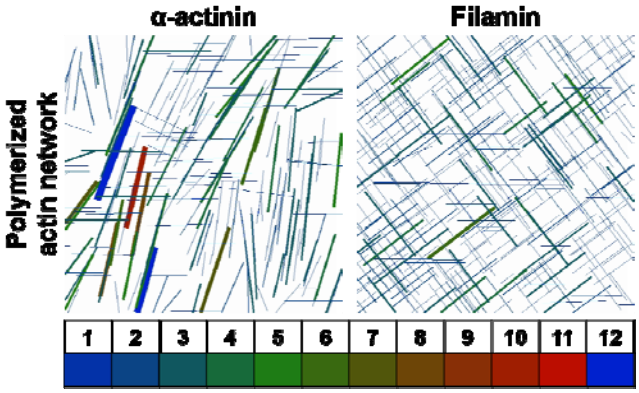

Figure 1: Actin networks polymerized with α-actinin and filamin. The color scale represents the thickness of actin bundle.

CONCLUSIONS

With computational modeling, we investigated how mechanical flow and actin binding protein regulate the actin network organization. The actin/α-actinin network showed enhanced alignment and actin/filamin network exhibited increased bundle thickness when the flow was applied during network formation. Our results may contribute to understanding how the cytoplasmic streaming dictates the cytoskeleton organization in cells.

INTRODUCTION

Articular cartilage tissues found at the bone ends of diarthrodial joints function under variety of physiological loading. It responds to external loading via its specialized structural arrangement of constituents, water swollen proteoglycan macromolecules trapped inside a collagen network. Although proteoglycan is known to facilitate compressive load bearing ability [1], role of proteoglycan when responding to loading from low to high strain-rate has been rarely investigated systematically. Therefore, through chemical degradation of proteoglycans and simultaneous mechanical testing this study aims to establish the proteoglycan contribution to strain-rate dependent mechanical behavior of knee cartilage.

METHODS

Visually normal (ICRS macroscopic score=0), 8 mm diameter, osteochondral cartilage samples (2–3 mm intact subchondral bone) were harvested from the medial femoral of ten adult red kangaroo knee (n=10). Mechanical indentation testing on samples was conducted at four strain-rates, i.e. 10^{-4}/s, $5x10^{-4}$/s, $5x10^{-3}$/s and 10^{-2}/s subjected to 25% engineering strain. In order to reduce potential tissue damage maximum nominal stress on samples was limited to 3.0MPa. After every test, samples were microscopically examined to check the cartilage surface integrity. From the ten samples tested one was identified to be damaged after the first set of mechanical tests and was removed from the testing. The thickness of samples was estimated based on the average ultrasound speed reported for knee cartilage, which is 1627 m/s [2]. The testing was done on Instron testing machine (Model 5944, Instron, Canton, MA, USA) using a 3mm diameter plane-ended, polished indenter with 0.1mm radius rounded edge. The rounded edge was introduced to reduce possible local tissue damage due to stress concentration at the indenter edge. After every test, prior to the next test, samples were allowed to recover in PBS-inhibitor (PBS: P4417-100TAB, Sigma-Aldrich, Castle Hill, NSW, Australia; Inhibitor: 5 mM benzamide-HCL and 5 mM EDTA) solution for approximately an hour. After the first set of mechanical tests, samples were incubated in 0.1 mg/ml Trypsin–PBS solution at 37 ^{o}C for 4hrs and were tested again at the aforementioned four strain-rates.4hrs trypsin-PBS treatment is reported to remove significant portion of proteoglycans without affecting the collagen architecture [3].

RESULTS AND DISCUSSION

Trypsin treatment reduced the stiffness of the knee cartilage significantly at all strain-rates as indicated by the decreases in Young's modulus ($p<0.005$) (Fig 1). The percentage decreases in Young's modulus due to trypsin treatment was 83.7±5.9%, 85.0±3.6%, 64.7±15.4% and 53.6±19.5% for 10^{-4}/s, $5x10^{-4}$/s, $5x10^{-3}$/s and 10^{-2}/s strain-rates, respectively.

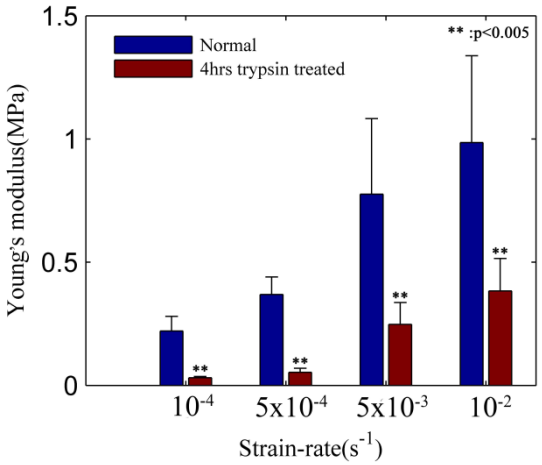

Figure 1: Proteoglycans role on strain-rate-dependent behavior knee cartilage

Percentage decreases in Young's modulus at the lowest two strain-rates (i.e. 10^{-4}/s and $5x10^{-4}$/s) were considerably larger than at the highest two strain-rates (i.e. $5x10^{-3}$/s and 10^{-2}/s), with an average difference of approximately 25%. Further, the percentage decrease in Young's modulus at 10^{-4}/s was significantly higher than percentage decrease in Young's modulus at $5x10^{-3}$/s and 10^{-2}/s ($p<0.05$). However, no significant differences in the percentage decrease in Young's modulus were identified at the two lowest strain-rates ($p=0.512$). Moreover, the percentage decrease in Young's modulus at $5x10^{-4}$/s was significantly different to the decreases at $5x10^{-3}$/s and 10^{-2}/s ($p<0.005$). Also, the percentage decreases in Young's modulus at the two highest strain-rates were not significantly different either ($p=0.403$).

CONCLUSIONS

Together, these results concluded that proteoglycans play a more significant role in tissue behaviour at low strain-rates than at high strain-rates in knee cartilage. It has been noted in the literature that the equilibrium properties of knee cartilage are governed by proteoglycans, while the dynamic properties are governed by the collagen network [4] which is similar to the results of the current study where proteoglycan contribution decreased with increasing strain-rate.

INTRODUCTION

Bone changes in both quality and quantity with ageing and other bone related diseases such as glucocorticoid osteoporosis, and the changes are generally in the direction of affecting the fracture resistance mechanisms at different hierarchical levels of bone tissue [1], and the challenge has been to quantify what these changes are. However, there have been to date relatively few studies on the nanoscale changes in the deformation mechanisms of the mineralised bone matrix in ageing bone. Therefore, it is crucial to apply multiscale imaging techniques that can quantify these alterations in situ. In this study, the deformation of the skeletal tissue at the material level was measured, to quantify how changes in bone quality with ageing (independent of any associated diseases like osteoporosis) and secondary osteoporosis may reduce mechanistic competence at the material level, independent of associated BMD reductions at organ level [2].

METHODS

We combined in situ synchrotron imaging (SAXS/WAXD) with micromechanics to directly measure fibrillar [3] and mineral particle deformation of the bone matrix when subjected to loading. Human ageing was considered as a phenomenon in itself separate from any induced disease phenotype. A mouse model of premature ageing (removal of the klotho gene) [4] was used, exhibiting multiple phenotypes very similar to those observed during human ageing. A most prevalent bone disorder glucocorticoid induced osteoporosis developed in mouse model via ENU mutagenesis. Glucocorticoid induced osteoporosis (GIOP) is the most common form of secondary osteoporosis, affecting 1-3% of the general population. [Lane et al, Weinstein et al.].

RESULTS AND DISCUSSION

Using the nanomechanical imaging method, it was found that the effective fibril modulus was significantly higher (up to ~ 200%) in klotho mice when compared to wild-type mice. Mineralised fibrils in klotho mice deform to lower strain values (~ 0.3 %) before reaching the plastic regime, whereas wild-type fibrils have a larger strain zone over which the stress/fibril-strain plot remains linear (~ 0.85 %).
In osteoporotic specimens, a significant ($p<0.05$) reduction of ~79% of fibril modulus occurs in GIOP bone relative to wild-type. The fibril-to-tissue strain ratio was much higher in GIOP mice (1.25±0.43 S.D.) compared to 0.57±0.2 S.D. for wild-type mice. Furthermore, the maximal fibril strain for GIOP bone specimens (0.63 %±0.22 S.D.) was significantly higher ($p<0.05$) compared to the wild-type mice (0.3 %±0.25 S.D.).

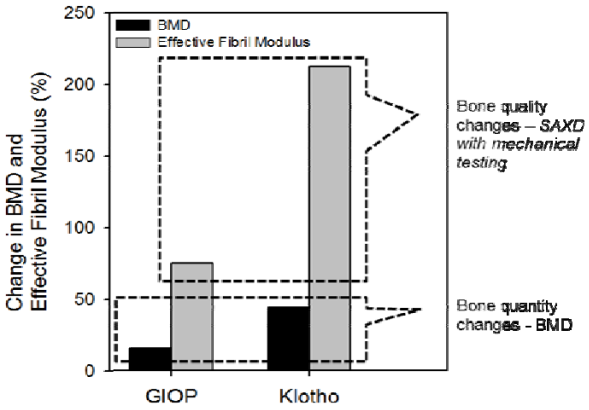

Figure 1: Percentage change in BMD (black) and effective fibril modulus (grey) between GIOP and Klotho mice and their respective wild-type littermates

As an overview of the efficacy and sensitivity of the current synchrotron X-ray technique compared to currently used gold standard for assessing bone fracture risk - DXA - the whole-body BMD changes in the mouse models studied above were plotted against changes in effective fibril modulus in Figure 1. BMD were assessed by DXA analysis for GIOP and klotho mice and their respective wild-type littermates. The percentage changes in BMD from wild-type to GIOP and klotho mice are significantly lower compared to changes in effective fibril modulus.

CONCLUSIONS

In summary, the studies performed here demonstrate that the technique is highly sensitive, compared to BMD determination methods like DXA, and show that small changes in mineral content or collagen deformability in metabolic diseases, when combined with abnormal nano- and microscale mineralisation, altered remodelling and possibly changes in the organic matrix structure, can lead to significant reductions in bone mechanical competence and fracture risk.

JOINT LOADING INDICES AND BONE MICROARCHITECTURE DIFFER AMONG BIOMECHANICAL GAIT PHENOTYPES IN END-STAGE KNEE OSTEOARTHRITIS

INTRODUCTION

Peak joint loads during gait are associated with progression of knee osteoarthritis (OA) [1]. Previously, subgroups with distinct walking gait patterns were identified in a knee OA cohort [2]. However, no study has yet examined whether also joint loading indices (peak knee moments, static alignment) differ among gait patterns in OA.

Subchondral bone (SB) adapts to its local mechanical environment. Comparing proximal tibia SB microarchitecture among gait subgroups may also provide insights into the loading history of the corresponding joints.

The aims of this study, in end-stage knee OA patients undergoing total knee replacement, were (1) to identify subgroups with distinct walking patterns; (2) to compare joint loading indices and proximal tibial subchondral bone microarchitecture parameters among these subgroups.

METHODS

Patients: 25 knee OA patients (age 68±7, BMI 34±4 kg/m^2) scheduled for total knee replacement (TKR) underwent gait analysis.

Gait analysis: Peak knee flexion (KFM), extension (KEM), adduction (KAM) and internal-external rotation moments, were collected using 12 Vicon cameras and 4 force platforms, and analysed with Visual3D v5 (C-motion Inc., MD, USA). The knee adduction moment impulse was also computed and moments normalized by bodyweight. Peak tibio-femoral joint contact force (JCF) was calculated with a musculoskeletal model [3] and the mechanical axis deviation (MAD) obtained from full-length anterior-posterior weight-bearing radiographs.

Cluster analysis: Peak knee moments were input into principal component and k-means cluster analysis, to identify subgroups with relatively homogeneous walking patterns. Analysis was performed with MATLAB (MathWorks, MA, USA).

Micro-CT: Following surgery, entire tibial plateaus were retrieved and scanned with micro-CT. Subchondral bone 3D microarchitecture including bone volume fraction (BV/TV) was analysed in four subregions of interest, in antero-medial (AM), antero-lateral (AL), postero-medial (PM) and postero-lateral (PL) condyles.

Statistics: Differences in joint loading indices and SB microarchitectural parameters among subgroups were assessed (Kruskal Wallis and Mann Whitney U tests).

RESULTS AND DISCUSSION

Cluster analysis revealed three subgroups with distinct walking gait patterns: biphasic (n= 7), flexor (n= 9) and counter-rotators (n= 9) (Fig. 1a). The peak KAM and KAM impulse (Fig.1b) were highest in the biphasic subgroup, followed by flexor and counter-rotators (-0.65, -0.40, -0.21 Nm/kg and 44, 26, 15 Nm.s/kg, respectively). Interestingly, subchondral M:L BV/TV ratio was also significantly higher in biphasic and flexors than in counter-rotators (2.2, 1.9 and 1.0, respectively, Fig. 1b); however, it was not significantly different between biphasic and flexors. MAD was significantly higher in biphasic and flexors than counter rotators (41, 21 and -21 mm, respectively). JCF did not differ between subgroups.

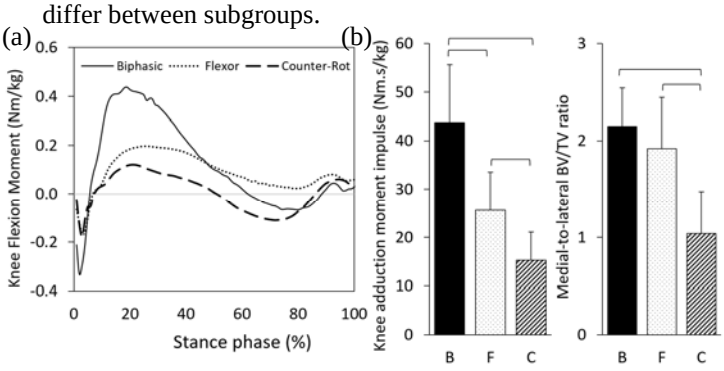

Figure 1: (a) Average knee moment curves, (b) KAM impulse and M:L BV/TV ratios. Lines indicate significant difference ($p < 0.05$) between subgroups

CONCLUSIONS

This study identified three distinct walking patterns in knee OA patients undergoing TKR. Biphasics, compared with flexors and counter-rotators, exhibited significantly higher KAM and KAM impulse and were more varus-aligned, suggesting a higher medial-to-lateral tibiofemoral load ratio during gait. However, despite these higher indices of KAM, the M:L BV/TV ratios did not differ between the biphasic and flexor subgroups. Thus, different loading mechanisms between biphasic and flexor gait subgroups may produce comparable loads upon the tibial plateau and corresponding microarchitectural bony responses, despite lower KAM indices in flexors. Hence, in patients with a flexor gait pattern, conservative treatments designed to reduce KAM indices, may not be appropriate.

Understanding how joint loads vary among gait patterns and are related to bone microarchitecture may be useful for identifying, and improving the management of, persons at risk for development of knee OA.

EFFECTS OF THE IMPACT AND ACTIVE PHASE OF RUNNING ON THE MECHANICAL FATIGUE OF BONE

[1] **Lindsay L Loundagin**, [1,2] Tannin A Schmidt and [1] W. Brent Edwards
[1]Faculty of Kinesiology, [2]Schulich School of Engineering, University of Calgary

INTRODUCTION

The repetitive loading of bone is associated with microdamage accumulation that can reduce the overall quality of bone. This process, known as mechanical fatigue, is an inevitable consequence of physical activity and believed to be the predominant etiology of stress fracture.

Stress fractures account for 15% of all overuse injuries in runners [1]. A typical vertical ground reaction force (vGRF) profile in heel-toe running illustrates a bimodal shape characterized by a low magnitude/high frequency impact and a high magnitude/low frequency active profile. Several case-control studies have observed an association between increased vGRF loading rates during impact and individuals with a history of stress fracture [2].

To assess the mechanical fatigue of bone at the material level, small cadaveric samples are cyclically loaded until failure. However, the waveforms used for these tests are typically sinusoidal and not representative of the loading patterns experienced *in vivo*. The purpose of this study was to use vGRF-like profiles, including those that have been broken down into their respective impact and active phase components, to examine the fatigue behavior of bone.

METHODS

Thirty-eight cylindrical samples, 35 mm in length and 7 mm in diameter, were cored out from fresh-frozen bovine cortical tibiae and femora. Samples were machined into a waisted geometry with a central gauge diameter of 5.25 mm. Mechanical testing was performed on an Electroforce 3000 (TA Instruments, USA) or Electropuls 3000 (Instron, USA) test frame. Prior to fatigue testing, bone apparent density was determined and initial elastic modulus was quantified with a bone-mounted extensometer (MTS, USA).

The vGRF profile was based on ensemble measurements from heel-toe running. Extraction of the impact and active phases of running was accomplished using a previously-reported cubic spline routine [4]. The force applied to the active and raw vGRF profiles were chosen to induce a peak compressive stress of 110 MPa. The ratio between peak loads of the extracted impact and active profiles resulted in a peak compressive stress of 51.6 MPa for the low impact profile (Figure 1). An additional high impact profile with a peak stress of 82.7 MPa was created by scaling the extracted impact curve to match the magnitude of the first peak in the raw vGRF profile. Samples were randomly allocated to the four groups and cyclically loaded in zero-compression under force control using the raw (n=10), active (n=10), low impact (n=10), or high impact (n=8) vGRF profiles (Figure 1). The average strain rate for the active, low impact, high impact and the initial portion of the raw curve was 0.05, 0.10, 0.16 and 0.14 s^{-1}, respectively.

Failure was defined as catastrophic fracture and if the sample survived 10^5 cycles the test was terminated. Statistical differences in material properties and fatigue-life measures were examined using one-way ANOVAs with Tukey's post-hoc tests ($p \leq 0.05$).

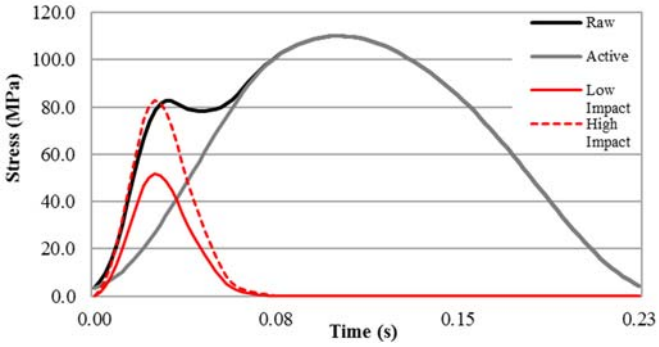

Figure 1: Applied stress as a function of time for the raw, active, low and high impact profiles.

RESULTS AND DISCUSSION

There were no differences in density or elastic modulus between the four groups. Fatigue life was significantly greater for the impact groups when compared to the active ($p<0.001$) and raw ($p<0.001$) groups, with all low impact samples (100,000 ± 0) and 6 of 8 high impact samples (89,081 ± 25,575) surviving 10^5 cycles. The mean cycles to failure for the active and raw groups were 12,133 ± 11,704 and 16,552 ± 29,612, respectively. Fatigue-life was not significantly different between the active and raw groups ($p=0.96$).

From a mechanical fatigue perspective, these findings suggest that the active phase of running is more damaging to the skeletal system than the impact phase. Despite the higher loading rate, both the low and high impact groups demonstrated a longer fatigue life than the active group. Furthermore, the presence of an impact peak and higher initial strain rate in the raw profile did not decrease fatigue life relative to the active profile, suggesting the mechanical fatigue of bone was more influenced by the high magnitude active phase rather than the high frequency impact phase.

CONCLUSIONS

This study employed a novel testing paradigm to demonstrate that the mechanical fatigue of bone was more influenced by the active phase of running, rather than the impact phase. Although there is an established relationship between higher loading rates at impact and risk of stress fracture, the current results indicate loading rate may not be the causal mechanism for the pathogenesis of this injury.

ACKNOWLEDGEMENTS

Some of the mechanical testing was performed at Zymetrix (Calgary, AB).

OSTEOGENIC POTENTIAL OF EXTERNAL MECHANICAL LOADING DURING WALKING IN SEDENTARY AND NON-SEDENTARY ADULTS

[1] **Tina Smith**, [2]Jin Luo and [1]George Metsios
[1]University of Wolverhampton
[2]London South Bank University
Corresponding author email: tina.smith@wlv.ac.uk

INTRODUCTION

Sedentary behaviour is generally regarded as having deleterious effects on cardiometabolic health, although little is known about its specific association with bone health. Impact forces generated as the foot contacts the ground during activity have the potential to act as a stimulus for bone maintenance and development. Therefore, increased sedentary behaviour may reduce the time available to gain osteogenic benefits from impact-based activity.

Peak ground reaction force is commonly used as an estimate of loading intensity when determining the osteogenic potential of activity [1]. Dynamic, high impact, high frequency activities have been shown to be most effective at applying an osteogenic stimulus [1], although low level impacts have been shown to beneficially modify bone geometry [2]. Therefore, differences in the characteristics of low impact activity have potential to influence bone health.

As impact forces are attenuated as they travel up the body, exploration of mechanical loading at regions such as the spine, require further investigation. External force due to impact is related to acceleration; therefore an accelerometer attached to the spine can provide an estimation of the mechanical loading. The aim of this study, therefore, was to investigate associations between sedentary and non-sedentary behavior on the osteogenic potential of walking, and bone mineral density (BMD) of the lumbar spine.

METHODS

Ten sedentary (Female = 9; 43.06 ± 7.91 yrs; 1.62 ± 0.06 m; 66.82 ± 14.51 kg) and ten non-sedentary (Female = 8; 45.30 ± 6.54 yrs; 1.65 ± 0.08 m; 73.19 ± 17.00 kg) adults, who engaged in low levels of physical activity, participated in the study. The International Physical Activity Questionnaire - Short Form (IPAQ-SF) was used to classify sedentary behavior (≥ 8 hours spent sitting on a week-day) and activity levels (low = IPAQ-SF category 1 or 2).

Walking data were collected via a force platform (Bertec, 4060-10; 1000 Hz) mounted along a 10 m runway, and an accelerometer (Biometrics, ACL300; 1000 Hz) attached to the skin at the 4th lumbar vertebrae (L4). Participants walked at a self-selected pace so their dominant foot landed on the force platform, while timing gates recorded velocity.

Vertical force (cut-off 50 Hz) and accelerometer data (cut-off 46 – 63 Hz) were filtered using a 4th order, low pass, Butterworth, zero phase filter. Peak vertical force during the loading response of walking (Fz1 peak) was extracted along with peak vertical acceleration of the corresponding phase of the same step. Force data was normalised to body weight (BW). Data processing was carried out using Matlab 2015a. BMD of the lumbar spine was measured using dual-energy X-ray absorptiometry (Hologic, Discovery W QDR series x-ray Bone Densitometer) by a certified radiographer. Data were analysed using an independent t-test (SPSS, v20).

RESULTS AND DISCUSSION

No significant differences were found between groups for the external mechanical loading measures or DXA data (Table 1). As both groups had similar walking velocity it is likely this contributed to the similarities found in force and accelerometer data, indicating both groups experience similar amounts of whole body and L4 external mechanical loading, and osteogenic benefit from the activity.

Table 1: Kinematic and kinetic variables and 4th lumbar vertebrae bone mineral density (Mean ± SD).

	Sedentary	**Non-sedentary**	***p*-value**
Velocity ($m \cdot s^{-1}$)	1.49 ± 0.12	1.72 ± 0.23	0.11
Fz1 Peak (BW)	1.21 ± 0.11	1.27 ± 0.23	0.37
Acceleration Peak (g)	0.76 ± 0.35	1.07 ± 0.34	0.06
L4 BMD ($g \cdot cm^{-2}$)	1.07 ± 0.18	1.10 ± 0.16	0.71
Lumbar spine total BMD ($g \cdot cm^{-2}$)	1.05 ± 0.14	1.11 ± 0.13	0.31

Acceleration levels recorded at the lumbar spine during walking were low for both groups and below the threshold associated with positive changes in BMD [3]. This indicates higher impact activities may be necessary for improvements in BMD at that site. However, as we still continue to investigate the most effective daily activity regimes on overall bone health it is important studies continue to analyse low impact activities [2] as they may be able to improve BMD and bone strength in other body locations [1].

CONCLUSIONS

In the absence of participation in high levels of physical activity, differences in amounts of daily sedentary behavior are not associated with external loading during walking and BMD at the lumbar spine.

INTRODUCTION

Osteoporosis affects 1 in 3 women and 1 in 5 men and represents a worldwide economic burden. The prevalence of osteoporosis is set to increase substantially as the global population becomes more elderly. Treatments for osteoporosis can be classed as anabolic or anti-resorptive, with the latter predominating treatment options by targeting the osteoclasts to prevent bone resorption. Consequently, there is interest in developing novel anabolic treatments, which promote osteoblast formation, thus promoting bone growth. Lactoferrin, present during periods of inflammation and found in very high concentrations in colostrum and milk, has been shown to promote osteoblast growth while inhibiting osteoclast activity [1]. As lactoferrin has anabolic actions on bone, there is potential in using it as a dietary supplement to improve bone health.

The aim of this work was to assess the influence of lactoferrin and its carrier protein, beta glucan, on murine bone strength by evaluating trabecular bone mineral density from micro-CT phantoms, standard micro-CT indices and mechanical tests.

METHODS

Fifty one 12 week old, female, C3H mice were randomised into five groups. There were two control groups: sham operated (n = 11) and ovariectomised (n = 11). The treatment groups included treatments with: lactoferrin (n = 10), beta-glucan (n = 9) and lactoferrin + beta glucan (n = 10). At 26 weeks, the mice were anaesthetised with isofluorane and morphine and the femurs were excised, cleaned of surrounding tissue and stored in 70% ethanol. Femurs were scanned using a SkyScan 1172 micro-CT scanner. Reconstructions were performed and standard micro-CT indices [2] for trabecular bone were obtained and analysed. Once the bones were scanned, nanoindentation was carried out to determine the influence of lactoferrin on mechanical strength. All experimental work was conducted using a double blinded design to prevent bias.

RESULTS AND DISCUSSION

In trabecular bone, there were significant changes in bone mineral density and percentage bone volume in the beta glucan ($p = 0.01$) and lactoferrin + beta glucan ($p < 0.01$) groups compared to the OVX control (see Figure 1). Significant differences were also observed in the trabecular number and separation. Nanoindentation tests showed no significant differences across the groups, however, there was a trend of increasing hardness moving from the controls to the carrier and lactoferrin.

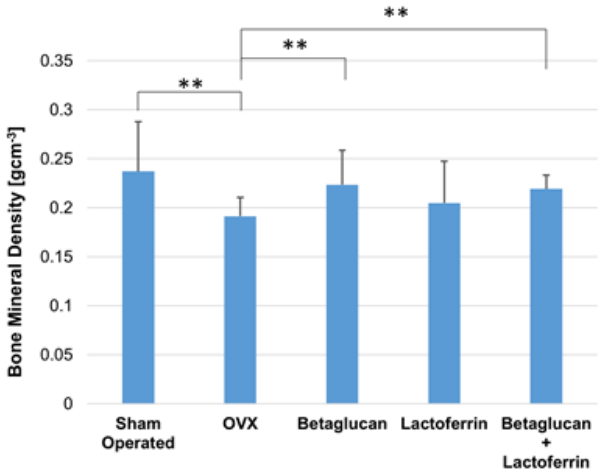

Figure 1: Bone mineral density analysis for trabecular bone across the treatment groups. ** represents significant differences between groups.

CONCLUSIONS

Based on our findings, lactoferrin, when administered within its carrier, beta glucan, has a positive effect on trabecular bone strength, which is primarily due to morphological differences. Mechanical tests, while not significant, also showed a trend of increasing strength. This suggests that lactoferrin, combined with a beta glucan carrier, is a potential anabolic that may be an alternative to current, clinically approved treatments such as parathyroid hormone.

ENHANCED FRACTURE RISK CLASSIFICATION BASED ON FINITE ELEMENT MODELLING OF CLINICAL TIBIA pQCT

[1] **Dale L. Robinson[1],** Qichun Song[1,2] Hongyuan Jiang[1], Martha Hickey[1,3], Peter Vee Sin Lee[1], John D. Wark[1,3] [1]University of Melbourne

INTRODUCTION

Dual-energy X-ray absorptiometry (DXA) is the 'gold standard' for osteoporotic fracture risk assessment. However, many individuals who are not diagnosed as osteoporotic by DXA experience fracture [1]; there remains a need to develop new clinical methods for fracture risk prediction. Peripheral quantitative computed tomography (pQCT) is an imaging technique that provides the density and structural arrangement of the tibia or radius. From these images, bone mineral density (BMD) and stress-strain indices for bending (SSI_x, SSI_y) and torsion (SSI_{pol}) may be derived and these have been widely used for osteoporotic fracture risk assessment [2]. Unfortunately, these properties do not account for 3D stress states associated with transverse shear and volume changes (Poisson's effect).

In this study we proposed a finite element (FE) model that was based on clinical pQCT imaging to derive the compressive, torsional and bending strength of individual cross-sections of the tibia. The diagnostic performance of these variables for predicting fracture risk was determined and compared with standard clinical pQCT variables. Since FE models account for 3D stress-states, it was hypothesized these would offer improved fracture risk assessment compared to existing methods.

METHODS

Tibial pQCT were considered for two cohorts: (1) fracture group: 26 women (age 63.6±9.8 yrs) who had experienced a low-trauma bone fracture at another skeletal site, and (2) control group: 23 women (38.6±7.1 yrs) who had no history of tibial fracture. Considering that individuals who sustain a low-trauma fracture are two to three times more likely to experience a fracture at any location in the body, the intact tibia of the fracture group was assumed to be at a greater fracture risk compared to those of the control group. A Stratec XCT-3000 pQCT scanner was used to obtain axial images at 4% of the bone length, measured proximally from the distal articular surface. The in-plane resolution and slice thickness were 0.4 mm and 2 mm, respectively. Routine pQCT variables such as total density (ρ_{tot}), SSI_x, SSI_y and SSI_{pol} were obtained for each image.

The pQCT images were segmented and meshed with 0.4 mm cubic elements coincident with each voxel. The Hounsfield unit of each voxel was converted into a BMD and an equivalent Young's modulus. The mesh was imported into a commercial FE software (Abaqus) and three loading conditions were simulated: compression, torsion and bending about an in-plane axis that was rotated in 1º increments from 0º to 360º. For each load case, the load was increased until the maximum or minimum principal strain exceeded the tensile or compressive yield strain for tibial bone (0.0065ε and 0.0073ε, respectively). The corresponding reaction loads were taken as the compressive (S_{comp}), torsional ($S_{torsion}$) or minimum bending strength (S_{bend}). These variables were normalized by body mass index (BMI) to account for different body sizes/shapes. The FE model and pQCT variables were used to classify which patients belonged to the fracture and control groups. With the sensitivity set to 100%, the corresponding specificity and accuracy was calculated by standard diagnostic formulas for each variable.

RESULTS AND DISCUSSION

At the 4% site, the FE model property S_{bend}/BMI had the highest specificity and accuracy of 74% and 88%, respectively. With the sensitivity of 100%, these data indicate: (1) 100% of fracture group patients would be correctly classified, (2) 26% of control group patients were classified at risk of fracture, a similar proportion to lifetime osteoporotic fracture risk [3], and (3) the overall accuracy for correctly predicting fracture and controls group patients was 88%. Whilst the pQCT property SSI_{pol} had the highest specificity and accuracy at the 66% site (57% and 80%, respectively), these were lower than those derived at the 4% site using the FE model. Since the 4% site is a trabecular-rich region, these results suggest that changes to trabecular bone provide more sensitive fracture risk diagnosis than cortical bone, a finding supported by others [4].

Table 1: Sensitivity, specificity and accuracy of pQCT and FE model variables for classification between fracture and control group patients.

		4% Site			66% Site		
	Variable	Sens.	Spec.	Acc.	Sens.	Spec.	Acc.
pQCT	ρ_{tot}	100%	52%	78%	100%	0%	53%
	SSI_x	100%	26%	65%	100%	48%	76%
	SSI_y	100%	26%	65%	100%	35%	69%
	SSI_{pol}	100%	26%	65%	100%	57%	80%
FE model	S_{comp}/BMI	100%	52%	78%	100%	17%	59%
	$S_{torsion}$/BMI	100%	48%	76%	100%	26%	65%
	S_{bend}/BMI	100%	74%	88%	100%	17%	61%

CONCLUSIONS

The results of this study demonstrate that FE models based on clinical pQCT tibia imaging provide enhanced predictions of fracture risk compared to clinically-used pQCT variables. These models were constructed from individual cross-sections and, therefore, require minimal radiation doses and scan times and, due to their simplicity, their construction and simulation may be automated for use in clinical fracture risk assessment.

THE USE OF GROOVED AND POROUS COLLARS IN PROMOTING EXTRA-CORTICAL BONE GROWTH: AN EXPERIMENTAL AND FINITE ELEMENT STUDY

INTRODUCTION

Bone cancer occurs mainly in children and adolescents below the age of 20. A reconstruction using massive prosthesis is required to restore limb functions after the removal of the tumor [1]. The long-term survival of the implant depends on the successful osteointegration of the bone with the prosthesis, but mechanical fixation in patients is difficult to predict and aseptic loosening is the primary reason for implant failure [2]. The use of a hydroxyapatite (HA)-coated grooved collar has been demonstrated to encourage extra-cortical bone formation (Fig. 1), leading to an improved survivorship of the implant from 75% to 98% at 10 years [3]. However, osteointegration of the HA collar only occurs in 70% of all cases. Therefore, it is necessary to develop time-dependent simulation models and algorithms to predict the extent of adventitious bone formation in the grooved collar, and to use these algorithms to evaluate the performance of 3D-printed porous collar designs, which is believed to improve fixation.

METHODS

A Finite Element (FE) model was used to approximate the geometry of the femur at the diaphysis, using data from computed tomography (CT) scans. The bone was virtually implanted with different collar designs made of commercial grade titanium and assigned isotropic material properties. A bone remodeling algorithm based on strain energy density, where the rate of bone adaptation is controlled by the difference in the current strain energy per unit mass against a reference value [4], was combined with a new concept of bone osseo-connectivity to determine the external shape changes of bone developing in the soft tissue envelope. Loads associated with typical walking conditions were applied to the model. The algorithm was implemented using custom-written subroutines in a FE solver (Marc 2015). The bone adaption results for the grooved collar designs were verified against clinical studies at different time stages. No patients were recalled specifically for this study; all data was obtained from postoperative radiographs from previous retrospective studies [3].

RESULTS AND DISCUSSION

The FE results for the grooved collar were shown to correspond well with the process of bone growth (Fig. 1). Remodeling occurred primarily at the base of the collar and the bone stock, and bone ingrowth was predicted into the first row of grooves, matching with radiological observations. Bone growth at the shoulder of the implant and the collar was also predicted, due to the presence of high stress concentrations, which is not seen clinically. Soft tissue remodeled to an elastic modulus of about 2GPa, a typical value of trabecular bone.

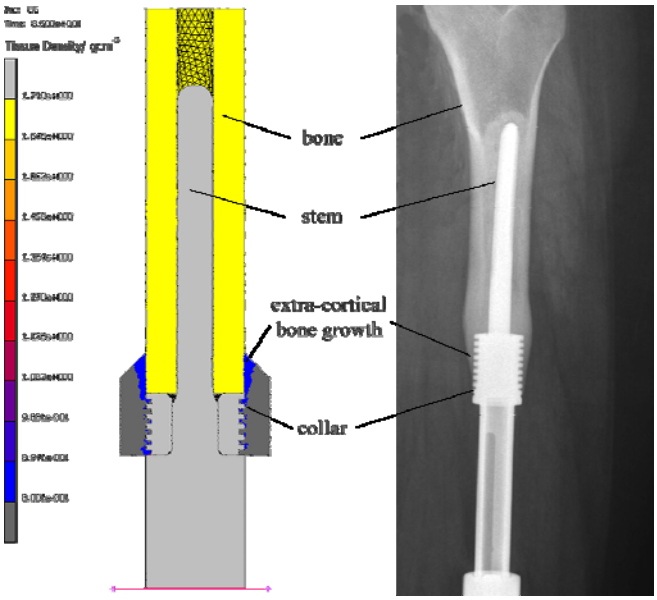

Figure 1: Left: Predicted bone growth (blue) with elastic modulus of approximately 2 GPa around an implanted grooved collar (light grey) and cortical bone shaft (yellow). Right: Good correspondence with X-ray results taken 12 years after implant insertion, where there was adventitious bone formation and good osteointegration with the HA-coated collar.

Comparing the performance of the porous collar design with the grooved collar, the former has a lower overall structural stiffness and promoted the formation of a larger volume of bone with higher elastic modulus within the porous structure.

CONCLUSIONS

The developed simulation algorithm allowed the assessment of the performance of third generation implant designs before they are manufactured, reducing the need for animal testing. The modelling approach thus shows potential to be developed further for the optimization of implant collar designs and for predicting bone ingrowth into porous structures.

QUANTIFYING CERVICAL FUSION USING DIRECTIONALITY STRUCTURAL QUANTIFICATION OF BONE REMODELING

INTRODUCTION

There are an increasing number of spinal fusion procedures being conducted each year (patients increasing by 134% in the USA from 1997 to 2013[1]). Autologous bone harvested from the iliac crest exhibits osteoinductive, osteoconductive and osteoinductive properties and is still regarded as the biologic gold standard for achieving fusion in the spine; however, post-operative morbidity, a limited supply and the economic costs associated with extended surgery time have resulted in an increased adoption of synthetic bone graft substitutes. There is therefore a need for synthetic substitutes for the autograft, and a need to be able to quantify how well they perform, namely how the bone they form remodels.

As bone is a living material it is expected to remodel as the forces on it change, this can be modelled either mechanically in the form of Wolff's law[2] or biologically in the form of Frost's mechanostat[3]. Both these theories imply that the bone will remodel with its trabeculae will align with the forces acing on the bone.

We test the hypothesis that bone graft substitute (BGS) will remodel towards trabecular structure similar to that of normal remote bone. The use of high quality hospital based scanners and powerful GPU based computers the direction of each induvial trabecular will be assed in this study.

METHODS

BGS remodelling was studied in anterior fusion of single and multi-level symptomatic cervical intervertebral discs. Fusion surger was perofrmed in 13 patients (20 spinal levels) using a PEEK interbody cage). Each cage was filled with i-FACTOR™ Peptide Enhanced Bone Graft. Post-operative radiographic follow-up was conducted at 3 and 6 months using Cone Beam CT (CBCT) (NewTom 5G, 0.125 mm voxel size).

For this study only the fused samples were used for the quantification of the bone quality. A remote healthy bone site was used as a control.

The 3D models of the remodeled i-FACTOR™ were created from the CBCT data sets using Mimics software (Materialise, Leuven). A multistage algorithm was used to segment out the bone with higher fidelity in the region of interest while compensating for both beam hardening and x-ray.

Analysis of the trabecular structure were performed on the resultant 3D models using ray casting to determine the central line of each of the trabeculae as well as the volume of each trabeculum. From this the orientation of the trabeculum can be computed.

RESULTS AND DISCUSSION

The results are displayed in circular angle volume histograms with the 3 and 6 months samples being compared against a "healthy" remote bone site Figure 1.

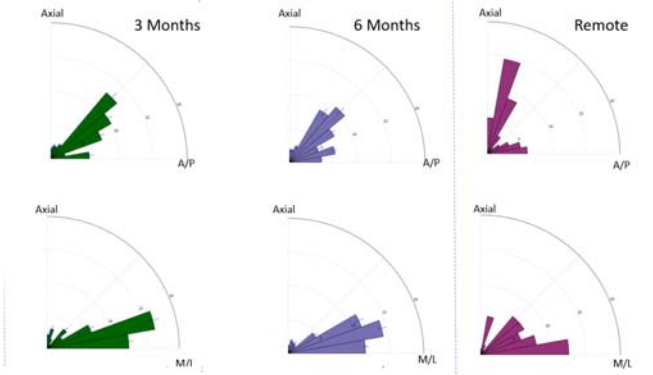

Figure 1: Trabecular orientations at 3 and 6 months and at a remote site with standard error.

For the sagittal plane, the remote bone shows a major alignment towards the axial direction, and a minor direction along the anterior/posterior (A/P) direction. Both the 3 and 6-month time points show a similar minor direction but the major direction is more towards 45-degrees.

In the coronal plane, the major direction is along the medial/lateral (M/L) direction for the remote bone site. With a broad fan shape in the other directions. Both the 3 and 6-month time points show similar fan shapes as the remote bone but with a more compressed shape. With time the graft material remodels to a broader fan configuration towards that of the remote structure.

CONCLUSIONS

The analysis of i-FACTOR™ remodeling shows that there is a clear progression a solid graft towards the structure of healthy bone.

THE EFFECTIVENESS OF ELECTROMYOSTIMULATION AT RAT QUADRICEPS ON INCREASING IN THE MECHANICAL PROPERTIES OF THE LUMBAR VERTEBRAE

INTRODUCTION

Osteoporosis (the decreasing of bone mineral density) has become global bone disease in elderly people because that bone becomes fragile and easy to be broken. Most of osteoporosis impact were experienced at the neck femur and the vertebrae. Like as silent killer “heart attack”, the patients of osteoporosis had never realized that they had osteoporosis until their bones were broken and checked by X-Ray diagnosis. Although usage of the drugs is a promising way to prevent osteoporosis, physical activities such as walking, running is still more feasible to prevent osteoporosis for most of the potential patients. Unfortunately, however, such activities are not always available in elderly people, especially, with disabilities or in bed rest condition [1]. Electromyostimulation is able to involuntarily induce muscle contraction, which causes bone strain and mechanically stimulates bone formation [2, 3]. However, previous researches have investigated the effectiveness of this stimulation only at the stimulated bone. We hypothesize that the osteogenic effect of electro-myostimulation appears even in bones far from the stimulated site through the nerve system. It has been reported that the nerves govern bone remodeling [4-6]. The objective of this study was to investigate the effectiveness of electrical stimulation at rat quadriceps in regulating the mechanical properties of lumber vertebrae.

METHODS

In anesthetized condition, eight-weeks-old female Sprague-Dawley rats were stimulated at left quadriceps using stainless-steel-needle electrodes with electrical pulse train (2 mA, 552 μs duration, 50 % duty ratio) for three days continuously for 30 minutes per day for consecutive three days. The muscle contractions are induced by reversing the polarity of pulse train. Two types of pulse train were tested: periodic pulse train (PrPT, contraction frequency of 20 Hz); and randomly pulse train (RdPT, random contraction frequency in 0-20 Hz). Sham control rats were also prepared and given only the needle electrodes under anesthesia, but without stimulation. Fifteen days after stimulation, lumbar vertebrae were harvested, scanned with μCT to investigate the vertebrae microarchitecture, and tested mechanically under quasi-static compression test at a speed of 1 mm/minute. Maximum load, strain energy, and stiffness were obtained from load-deformation curves, and average values were compared among the groups.

RESULTS AND DISCUSSION

The mechanical tests showed that the RdPT group were larger values than the sham control and PrPT groups in all of the mechanical properties. The significant differences were observed in strain energy (898.96±2.27 N.mm) and stiffness (442.73±88.02 N/mm) results if compared with the sham control group (694.20±23 N.mm and 245.18±89.41 N/mm). On the other hand, the PrPT group did not show any remarkable differences in maximum load and strain energy, except stiffness (380.93±61.41 N/mm) compared with the sham group (Fig. 1).

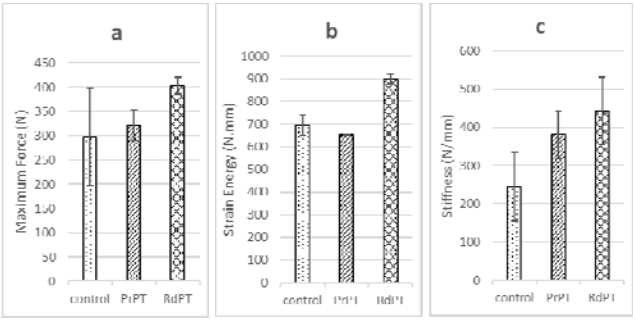

Figure 1: Comparison of mechanical properties of lumbar vertebrae (L2) among the groups. (a) maximum force, (b) strain energy, (c) stiffness. Vertebrae stimulated by RdPT showed the highest values in all of the properties.

This mechanical test results demonstrated that the RdPT at the quadriceps could make vertebrae of rat stronger, tougher and stiffer, even the vertebrae were not the site of stimulation. This results support our hypothesis and imply the possibility of the intervention of nerve system in the osteogenic effect of electromyostimulation. On the contrary, in the PrPT, the remotely-induced osteogenic effect was the limited properties, suggesting that this effect depends on stimulation pattern [3].

CONCLUSIONS

This study showed that electromyostimulation can increase bone strength not only at the stimulated bones, but also at others bones, suggesting its potential as a novel physical therapy of osteoporosis.

VERTEBRAL STRENGTH PREDICTION FROM BI-PLANAR DUAL ENERGY X-RAY ABSORPTIOMETRY UNDER ANTERIOR COMPRESSIVE FORCE USING A FINITE ELEMENT MODEL

[1]**Julie Choisne**, [1]Jean-Marc Valiadis, [1]Christophe Travert, [2]Sami Kolta, [2]Christian Roux and [1]Wafa Skalli

INTRODUCTION

Finite element models (FEM) derived from qCT-scans were developed as a clinical tool to evaluate vertebral strength. However, the high dose, time and cost of qCT-scanner are limitations for routine osteoporotic diagnosis. A new approach considers using bi-planar dual energy (BP2E) X-rays absorptiometry to build vertebral FEM using synchronized sagittal and frontal plane radiographs [1].

The purpose of this study was to compare the performance of the areal bone mineral density (aBMD) measured from DXA, qCT-based FEM and BP2E-based FEM in predicting experimental vertebral strength.

METHODS

11 lumbar spines were scanned on a qCT machine (120 kV, 1489 mA/s, voxel size: 0.39×0.39×0.33 mm) along with a calibration phantom (ESP) to map grey scale values. Low dose BP2E X-rays were acquired for all spine segments using a dual energy prototype of the EOS® system (EOS imaging, Paris, France) which can simultaneously take a pair of X-rays in the sagittal and frontal planes in upright position [2], allowing for 3D reconstruction of the spine [3]. Two levels of energy scans were used to compute the projected aBMD images of the vertebrae, similar to DXA images [1]. DXA measurements were performed with each spine positioned in a 15 cm water bath and scanned in Anterior-Posterior. The 28 vertebrae (8 L1, 11 L2 and 9 L3) were then cleaned from all soft tissue and prepared for destructive anterior compressive tests [4].

FEM were built based on qCT and BP2E images for each vertebra. Subject-specific FEM were built based on 1) the BP2E images using 3D reconstruction and volumetric BMD distribution estimation and 2) the qCT scans using slice by slice segmentation and voxel based calibration. Linear regression analysis was performed to find the best predictor for experimental vertebral strength (Fexpe); aBMD from DXA, modelled vertebral strength (F) and vertebral stiffness (K) from qCT and BP2E models

RESULTS AND DISCUSSION

All results are summarized in table 1. ABMD from DXA was moderately correlated with Fexpe. FEM calculations of vertebral strength were highly to strongly correlated with Fexpe ($R^2 = 0.80$, $p<0.001$ for BP2E model and $R^2 = 0.91$, $p<0.001$ for qCT model). Statistical error in qCT-based model vertebral strength estimation was 78 N ± 381 compared to Fexpe with a Root Mean Square Error (RMSE) of 12 % (382 N) and a Standard Error of the Estimate (SEE) of 11 % (333 N). Statistical error for FBP2E estimation was 112 N ± 629 compared to Fexpe with a RMSE of 20 % (628 N) and a SEE of 20 % (617 N).

CONCLUSIONS

This in vitro study of lumbar vertebral bodies showed that vertebral strength determined from FE models are strong predictors of experimental failure load, highlighting the capability of BP2E X-ray absorptiometry based FE models to predict vertebral body strength. BP2E X-ray absorptiometry allows for fast, low-radiation and minimal cost patient-specific 3D FE model as accurate as qCT-based FE models, currently the gold standard for vertebral strength prediction. These findings support further exploration of the clinical application of BP2E based FE models in vertebral fracture prediction.

INTRODUCTION

The glenohumeral joint is the most commonly dislocated joint in the human body with over 95% of all affected shoulders dislocating anteriorly [1]. The instability of the joint is mostly caused by a tear of the anterior labrum of the joint (Bankart lesion). For therapy, the arthroscopic Bankart technique has been established as the gold standard. However, high recurrence rates of 15.3% are reported after Bankart repair [2]. To address this issue, a new arthroscopic stabilizing technique, the so called "subscapular sling operation" was recently presented in an anatomical cadaver study [3]. Before this new approach can be applied in the clinic, a biomechanical evaluation regarding the biomechanical functionality of the sling technique is needed. The goal of the present study was therefore to investigate the stabilizing effect of the sling operation and to measure the influence of the procedure on the range of motion of the glenohumeral joint.

METHODS

Fresh human shoulder specimens (N=14) were obtained for the study. Furthermore, 14 hamstring tendons were harvested from fresh human knee specimens. Testing of the shoulder specimens was carried out by use of a robot based shoulder simulator. Specimens were tested in four different conditions: intact (I), with Bankart lesion (L), after Bankart repair (R1), and after repair with the sling procedure (R2). All surgeries were carried out arthroscopically: The Bankart lesion was created by releasing the anterior labrum. The Bankart repair was carried out by reattaching the labrum with three anchors. After retraction of the Bankart repair, the sling was created by wrapping the harvested hamstring tendon around the upper part of the subscapularis tendon. Finally, the ends of the hamstring tendon were attached to the anterior rim of the glenoid. For each condition, anterior, inferior and anterio-inferior stability in 0° and 60° of abduction with the arm in 0° and 60° of external rotation was investigated by applying a compressive load of 30 N as well as a dislocation load of 30 N in testing direction. Furthermore, maximum external rotation in 0° and 60° of abduction was measured. Resulting translations and rotations were compared between groups, utilizing a repeated measures ANOVA ($\alpha = 0.05$).

RESULTS AND DISCUSSION

The sling technique significantly increased the stability of the glenohumeral joint compared to the bankart lesion but also compared to the Bankart repair. The sling procedure significantly reduced the translation of the joint in anterior ($p = 0.02$) and anterio-inferior ($p < 0.001$) direction compared to the lesion group, with the arm in 0° of abduction and 0° of external rotation. Similar results could be found with the arm in external rotated position (anterior: $p < 0.001$, anterio-inferior: $p = 0.02$).

With the arm in 60° of abduction and 0° of external rotation, the sling procedure significantly reduced the translation of the joint in anterior ($p < 0.001$), anterio-inferior ($p < 0.001$), and inferior direction ($p < 0.001$) compared to the lesion group (Figure 1). With the arm in 60° of abduction and additional external rotation, no difference could be found between the sling and lesion group in any direction.

After Sling procedure, the maximum external rotation was significantly reduced by 27.0° (SD 11.4°, $p<0.001$) and 11.2° (SD 3.8°, $p< 0.001$) with the arm in 0° and 60° of abduction, respectively (Figure 1).

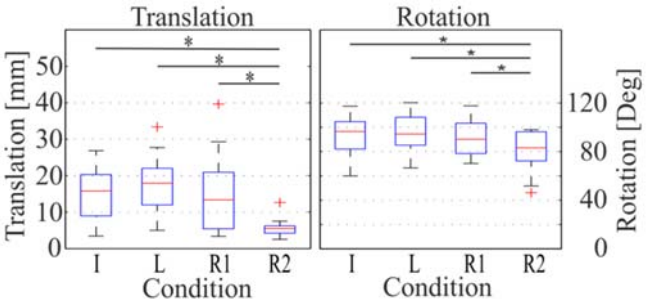

Figure 1: Results of the translation and rotation testing of the glenohumeral joint in 60° of abduction and 0° of external rotation. Shown are the maximum translations (left) and rotations (right) in all tested conditions.

The results of the study show that the sling procedure has a strong stabilizing effect mainly in the anterior and anterio-inferior direction and shows only minor trade-offs regarding the maximum external rotation. Furthermore, the sling procedure significantly increased joint stability in inferior direction, with the arm in abduction

CONCLUSIONS

The aim of the study was to evaluate the stabilizing principle of a new stabilizing technique of the glenohumeral joint. The new sling procedure is a promising alternative to the Bankart repair or the Latarjet procedure, especially for young active patients as well for the treatment of patients after failed Bankart repair.

INTRODUCTION

In 2006 the International Society of Biomechanics (ISB) updated the scapular plane to localise the glenohumeral centre of rotation, and reduce the occurrence of gimbal lock complications. This plane, termed here the 'New ISB plane,' is defined by Trigonum Scapulae (TS), Angulus Inferior (AI) and Angulus Acromialis (AA) points. Prior to 2006, the ISB scapular plane was defined by the TS, AI, and Articular Acomioclaviculare (AC) points – termed the 'Old ISB plane.' The two ISB planes are therefore independent of the glenoid

Clinically, the scapular plane is defined using the same Trigonum Scapulae (TS), Angulus Inferior (AI) points, but uses the centre of the glenoid (GC) as the third point – forcing the scapular plane to be dependent on the glenoid. This provides difficulty in cases of glenoid bone loss in which the glenoid centre point cannot be reliably determined.

This study acts to quantify the relationships between the new and old ISB planes to that of the clinical scapular plane. Additionally, the glenoid centre position is determined using relationships of the two points common to all three planes.

METHODS

Computed tomography (CT) scans were obtained from the shoulders of 50 cadavers (25 male and 25 female). Three-dimensional reconstructions were created for all scapulae (Mimics 17.0®, Materialise, Leuven, Belgium) and the three planes were generated using the built-in medCAD module.

To determine the glenoid centre point (GC) ten points were placed along the inferior border of the glenoid. Custom code (Matlab, Mathworks, Natick, MD, USA) was used to determine the GC using a least-squares circle fit of these ten points.

The intersection of each plane with an axial plane through the mid-glenoid defined each plane as a line. In this plane, the angle between each ISB plane (new and old) and the clinical scapular plane was determined for all scapulae.

To determine the spatial variation in the position of the GC, the angle between a vector pointing from the TS to AI and TS to GC was determined. The Euclidean distance from the TS to GC was also determined.

Comparisons between sexes were determined using t-tests. Institutional review board approval was approved for this cadaveric based study.

RESULTS AND DISCUSSION

The results for the total cohort and by sex are presented in Table 1. There were no significant differences by sex in new ISB ($p=0.28$) or old ISB ($p=0.68$) compared to the clinical scapular plane. The old ISB passes much closer to the clinical scapular plane, being on average 1.3°± 2.3° anterior to the clinical scapular plane. There was no significant difference between sexes in the TS_AI/ TS_GC angle ($p=0.63$), but was a significant difference in the position of the distance of the GC from the TS between sexes ($p<0.001$).

Table 1: Relationships between scapular planes and the glenoid centre

	Male (n=25)	**Female (n=25)**	**Total (n=50)**
New ISB & Scapular Plane Angle	17.3°± 1.7°	16.7°± 2.3°	17.0°± 2.1°
Old ISB & Scapular Plane Angle	-1.2°± 2.5°	-1.5°± 2.1°	-1.3°± 2.3°
TS_AI/ TS_GC Angle	75.2°± 5.5°	74.1°± 4.8°	74.6°± 5.1°
TS_GC Distance	114 ± 6 mm	100 ± 5 mm	107 ± 9 mm

This study demonstrates the relationship between the new and old ISB planes and the clinical scapular plane. Additionally, once the clinical scapular plane has been determined in bone loss cases, the glenoid centre can be determined within 10º in the coronal plane. The medial-lateral position showed greater variability and sex differences; however, this metric in less important than the axial and coronal angles of the GC in bone loss situations.

The results of this study are important in that the angular relationships can be used to determine the clinical scapular plane position and glenoid centre from the new or old ISB plane. This method is independent of the glenoid and can therefore be used in cases of glenoid bone loss. The clinical scapular plane is an important reference for proper implant placement leading to successful long-term clinical outcomes.

CONCLUSIONS

Accurate determination of the clinical scapular plane is important in shoulder arthroplasty to determine optimal implant positioning. When the glenoid has been eroded, glenoid-independent points used in the old and new ISB coordinate systems can be used to reconstruct the positioning of the clinical scapular plane in which implant placement is referenced.

SCAPULA DYSKINESIS IN TOTAL AND REVERSE SHOULDER ARTHROPLASTY: A QUANTITATIVE PRE-POST OPERATIVE PROSPETICE STUDY

INTRODUCTION

Over the last decade, increasing attention has been paid to the analysis of shoulder joint kinematics in patients with Total Shoulder Arthroplasty (TSA) and Reverse Shoulder Arthroplasty (RSA). The clinical evaluation of changes between pre- and post-surgery was mostly accomplished through outcome scores, such as the Constant-Murley Score (CMS). At the same time, biomechanical studies have focused on the alterations of scapula kinematics during arm elevation, i.e. scapula dyskinesis.

To obtain an overall combined assessment, the aim of this study was to assess patients who underwent TSA and RSA using the "Scapula Weighted CMS (SW-CMS)" [1]. This clinical & biomechanical score weights the points of CMS for humerus elevation and abduction, based on a quantitative analysis of scapula dyskinesis. SW-CMS has been already tested in a group of patients treated for rotator cuff tear [1]. For the present work, we formulated two hypotheses: H_1 (technical hypothesis), that scapula kinematics is considerably altered in patients with TSA and RSA, resulting in SW-CMS scores significantly lower than CMS; H_2 (clinical hypothesis), that at 6 months after surgery, shoulder joint recovery is completed, i.e. scapula compensatory movements are recovered in TSA and RSA.

METHODS

This was a prospective comparative study including a sample of 25 patients (25 shoulders) who underwent shoulder replacement either through TSA (12 shoulders, age 62±7) or RSA (13 shoulders, age 76±8). Evaluations were performed at three time points: preoperative (T_0), and postoperative at 6 (T_1) and 12 months (T_2). Only the replaced shoulder was assessed. At each evaluation, the CMS was completed and shoulder kinematics recorded while patients were performing humerus flexion in the sagittal plane (FL) and abduction (AB) in the scapular plane, with 5 repetitions each. The kinematics was recorded with a stereophotogrammetric system (Vicon, UK). Marker clusters were used to track the movements of trunk, scapula, humerus and forearm. Anatomical coordinate systems were calculated with the U.L.E.M.A. software package [2], following ISB guidelines. Joint rotation sequences were defined per Kontaxis et al. [3]. The coordination between each scapula rotation (PRotraction-REtraction, MEdio-LAteral rotation and Posterior-Anterior tilting) and humerus elevation was investigated by means of coordination plots, for both tasks. Each coordination pattern (CP) was compared to reference bands (RBs), calculated on a group of 31 asymptomatic subjects of comparable age (>60), following the method described by Cutti et al. [4]. Results from the comparison of CP and RBs were used to calculate the "scapula weighting factor" of the SW-CMS score. The Lilliefors normality test was used to confirm the normality of data distributions. A two-way repeated measure ANOVA was applied separately for TSA and RSA: Scores (CMS, SW-CMS) and Times (T_0, T_1, T_2) as independent variables. Then, boxplots and paired two-sample t-tests were used to compare data distributions of each Score in each Time.

RESULTS AND DISCUSSION

Kinematic analysis showed that: 1) all distributions were normal; 2) ANOVA was statistically significant ($p<0.05$) for all variables, except for the interaction between Scores and Time in RSA.

By comparing the boxplots (Figure 1) and the outcomes from paired t-tests, we found a statistically different distribution of CMS and SW-CMS. RSA did not show significant changes between T_1 and T_2. TSA patients showed an improved humerus elevation both at T_1 (+20%) and T_2 (+20%), associated with an increased scapula compensatory movement at T_1 and then a lowering at T_2, with ME-LA as the most compensated scapula rotation (more than 30% of incidence). RSA patients showed a significant improvement > 50% in humerus elevation, between T_0 and T_1. At T_2, there was a small improvement in AB but not in FL. For these patients, at T_0 ME-LA had the worst compensation, at T_1 there was a general improvement of scapula compensation (especially for ME-LA), and at T_2 there was an improvement for ME-LA and PR-RE, but a worsening for P-A (71% of incidence in AB, 50% in FL).

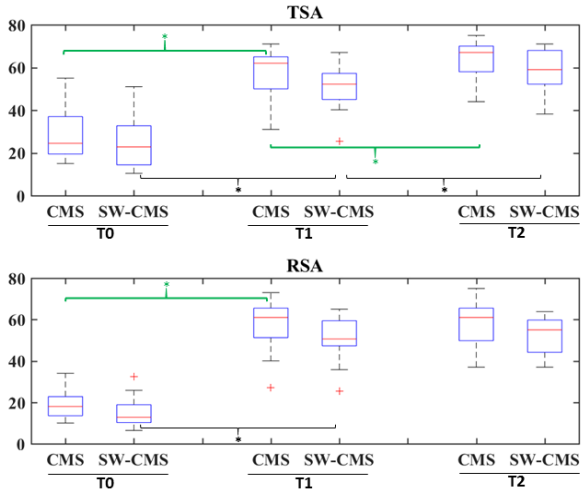

Figure 1: Boxplots of scores distributions at each Time.

CONCLUSIONS

SW-CMS was significantly different from CMS. TSA and RSA present compensatory movement which are not resolved at 6 months and scapula dyskinesis is different between surgical treatment.

INTRODUCTION

Posterior capsule tightness (PCT) is a common tissue adaptation in individuals who perform overhead sports or activities, and has been associated with shoulder pain. Scapular and humeral kinematic alterations have been described in cadaver studies, in those with shoulder pain, and in asymptomatic athletes with PCT, suggesting an interaction among these factors. Considering that PCT and shoulder pain are often related to shoulder biomechanical alterations, studies evaluating the effectiveness of treatment for PCT may help explain these relationships and inform clinical practice. The purpose of this study was to compare the effects of two physical therapy interventions on PCT, shoulder pain, scapular kinematics and humeral translations in individuals with PCT and pain.

METHODS

Fifty-two individuals with shoulder pain and PCT were randomized into 2 intervention groups: experimental (EG) (41.2±12.8yrs; 78.8±13.4kg; 1.72±0.09m; 41.4±55.3 months of pain) and control (CG) (40.1±12.1yrs; 76.1±15.8kg; 1.69±0.08m; 42.4±35.9 months of pain). Shoulder pain was confirmed by a clinical examination and self-reported history. PCT was determined by quantifying a difference between shoulders of at least 7° in the low flexion (LF) test [1]. Pain and function were evaluated by SPADI questionnaire. The Flock of Birds® electromagnetic tracking system was used to evaluate scapular and humeral kinematics during elevation of the arm in the sagittal plane. Local coordinate systems were established for the trunk, scapula, and humerus using the digitized landmarks following the protocol recommended by the International Society of Biomechanics [2]. Three repetitions were recorded with the individual in the standing position. Mean scapula and humeral head translations were analyzed at rest, 30°, 60°, 90° and 120° of arm elevation. All variables were evaluated at pre- and post-treatment. The EG protocol included posterior capsule mobilization (5min), sleeper stretching (3x30s) and external rotator strengthening (3x10rep). The CG protocol included placebo ultrasound (5min), upper trapezius stretching (3x30s) and scapular squeezing exercise (3x10rep). Both protocols were performed 3 times per week for 4 weeks. A mixed model ANOVA was used to compare groups (between factor) over time (within factor) with significance set at $p<0.05$.

RESULTS AND DISCUSSION

There was a significant group X time interaction effect ($p=0.002$) for PCT with the EG demonstrating increased LF values after treatment (22.8°±9.45) compared with the CG (17.52°±6.49). SPADI demonstrated a main effect of time ($p<0.01$) and the questionnaire score decreased 23.47 points after treatment. There was also a group X time interaction ($p=0.02$) for scapular upward rotation. The EG presented more upward rotation than the CG at post-treatment (3.47°) (Figure 1). For humeral translation, there was a significant main effect of time ($p=0.01$), with decreased superior humeral translation (-0.41mm) at post-treatment compared to pre-treatment (Figure1).

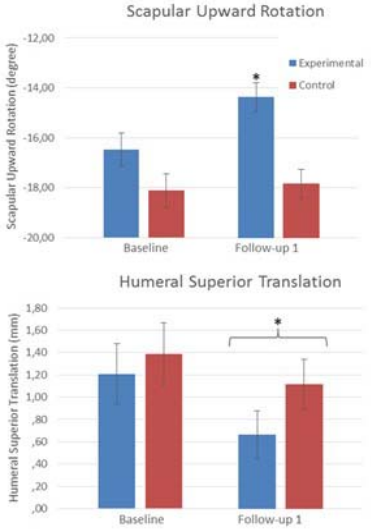

Figure 1: Scapular upward rotation (above) and humeral superior translation (below) during arm elevation for both groups at pre- and post-treatment. Error bars represent standard error. * $p<0.05$

The present study was the first to compare two different physical therapy treatment protocols on PCT, pain and shoulder kinematics in individuals with PCT and shoulder pain. The results showed that a treatment approach more specific to improving PCT was more effective at improving PCT and scapular kinematics, but was not more effective for humeral translations, pain or function. A natural recovery process or a placebo effect might explain the improvements noted in the SG. On the other hand, a real effect of shoulder movement could also justify the positive results for the SG.

CONCLUSIONS

This study showed that a protocol specific to reducing PCT was more effective at improving PCT and increasing scapular upward rotation. Furthermore, both protocols were effective in decreasing pain, improving function and decreasing humeral superior translations during arm elevation in individuals with PCT and shoulder pain.

BIOMECHANICAL ANALYSIS OF ANATOMICAL (TSA) AND REVERSE (RSA) TOTAL SHOULDER REPLACEMENT ON BICONCAVE GLENOIDS

[1]Xiang Chen, [2]Jonathan Glenday, [1]Timothy Wright, [1]Lawrence Gulotta, [1]**Andreas Kontaxis**

INTRODUCTION

Standard management of biconcave (B2) primary shoulder osteoarthritis (OA) with total shoulder arthroplasty (TSA) usually requires substantial eccentric reaming to reduce the high glenoid retroversion and restore glenohumeral (GH) stability [1]. However, TSA on B2 glenoids is often compromised by either joint stability (when retroversion is not reduced) or high risk of glenoid component loosening when excessive eccentric reaming is applied [1].

Reverse shoulder arthroplasty (RSA) was originally proposed for the treatment of rotator cuff arthropathies, but more recently it has been proposed for other challenging pathologies including unstable B2 glenoids [1]. However, no study has compared the biomechanics of TSA and RSA for the management of highly retroverted B2 glenoids. Therefore, we developed three subject-specific B2 musculoskeletal and finite element (FE) models for TSA and RSA, and evaluated GH contact forces, joint stability, and the risks of glenoid component loosening.

METHODS

Subject-specific musculoskeletal and FE models were created from CT scans (n=3) of primary OA B2 patients that had glenoid retroversion of more than 15˚. Each subject received virtual surgeries of TSA and RSA. Biomet Comprehensive Total (TSA) and Comprehensive Reverse (RSA) glenoid components were implanted in 4 positions, simulating eccentric reaming and version correction (VC) of 0˚, 5˚, 10˚, and 15˚ relative to the native glenoid (24 bone-implant models in total).

The musculoskeletal models were used to calculate the GH contact forces during a simulated motion of 'lifting an object to the head height'. The stability ratio was calculated as peak compressive/peak shear forces for the glenoid (TSA) and the humeral (RSA) components [2]. Peak contact forces were then used as input for FE models.

The glenoid component on the TSA FE models was cemented to the reamed glenoid surface, incorporating a fully bonded bone-cement interface and a frictional implant-cement interface [3]. For each RSA FE model, one central and four peripheral screws fixed the baseplate to the reamed glenoid, while frictional contacts between the bone-baseplate and the bone-screw interfaces were considered [4]. For the FE models, the bone material properties were determined by the grayscale values from each CT scan. All other materials were modeled as isotropic elastic [3, 4]. Risks for TSA glenoid loosening was assessed by the volume of the cement mantle that showed principal stresses exceeding the fatigue strength of cement. For RSA, risks of glenoid loosening were assessed by micromotions of the baseplate and the screws.

RESULTS AND DISCUSSION

Increased VC had little effect on the magnitude of the peak GH contact forces in both TSA (520.7±53.2N) and RSA (464.9±66.9N), but did affect the TSA joint stability more compared to RSA (Fig. 1A). The joint stability in the TSA models was comparable to RSA only after 10° of VC, but it showed high critical cement volume (Fig. 1B), suggesting high risk of cement failure indicative of glenoid loosening. This was a result of compromised glenoid bone quality after the excessive reaming. In RSA, peak micromotions of the implants were maintained at a similar level across different VCs for each subject (Fig. 1C), with all values below the proposed critical level for implant fixation (150 µm).

	Micromotion (µm)		
	Subject A	Subject B	Subject C
0° VC	18.4	53.7	8.3
5° VC	12.5	60.3	8.1
10° VC	15.6	58.2	7.7
15° VC	22.0	52.1	5.3

Figure 1: (A) Stability in TSA and RSA in relation to VC. (B) Normalized critical cement volume (to 0˚ VC) in TSA FE models. (C) Peak micromotions in RSA FE models.

CONCLUSIONS

Stability in TSA was improved with increase of VC, but the latter also increased the risk of cement failure. Though VC did not compromise either joint stability or primary fixation in RSA, reverse prostheses are known to affect range of motion due to impingement problems, which was not investigated in this study.

MUSCLE PARAMETER CALIBRATION AND EMG-ASSISTED SIMULATIONS IMPROVE MUSCLE ACTIVATION ESTIMATES IN AN UPPER LIMB MODEL DURING A LOADED DYNAMIC TASK.

[1] **Julie Ellis**, [2]Mohammad Shabani and [1]Joel Lanovaz
[1]College of Kinesiology, University of Saskatchewan
[2]Department of Computer Science, University of Saskatchewan
Corresponding author email: julie.ellis@usask.ca

INTRODUCTION

A bilateral dynamic upper-limb model has been developed using OpenSim [1] and validated for investigating muscle activations and forces during externally loaded tasks, such as push-ups [2] using static optimization (SO). A current limitation of the SO approach is the challenge of predicting agonist/antagonist muscle co-contractions accurately due to an objective function that minimizes activations. It is of particular interest to address this limitation because co-contractions are common in the upper limb for many activities of daily life and exercises. This has also been shown to be an important factor in fall injury mechanisms and fall arrest [3].

A recent sensitivity analysis of the current upper-limb model suggested that the estimations of muscle force were most sensitive to tendon slack length (L_{ts}) and optimal fiber length (L_{opt}) followed by maximal isometric force (F_{max}) [4]. Model performance could likely be improved with better estimates of muscle parameters.

CEINMS, a recently developed neuromusculoskeletal modelling toolbox, provides the capability to optimize muscle model parameters and implement electromyography (EMG) assisted muscle activation estimation [5]. EMG-assisted methods can be particularly useful for predicting muscle co-contraction as the input experimental EMG can encourage the optimizer to turn on muscles which may not normally be activated using standard SO. The purpose of the current study is to explore methods of improving upper limb muscle activation predictions by comparing estimates produced using three different CEINMS simulation configurations:

1. Uncalibrated muscles, static optimization (Uncal-SO)
2. Calibrated muscles, static optimization (Cal-SO)
3. Calibrated muscles, EMG-assisted SO (Cal-EMG)

It is hypothesized that a) muscle calibration will improve muscle activation predictions in all musculotendon units (MTU) and b) that Cal-EMG will further improve activation predictions in all MTU, in particular the antagonist co-contracting muscles (biceps).

METHODS

The data used for this study were collected from a single consenting male participant performing push-up trials using a neutral and wide hand position. Kinematics were collected with a 3D motion capture system (Vicon, Denver, CO). Hand reaction forces were measured using two force platforms (AMTI, Watertown, MA). EMG were collected from the long head of the biceps (BIClong) and the medial head of the triceps (TRImed) (Noraxon, Scottsdale, AZ).

An isolated elbow joint model was created based on the dynamic upper limb model [2]. It included a single degree of freedom (elbow flexion) and eight MTUs crossing the elbow; **Elbow Flexors**: Biceps long head, biceps short head, brachialis & brachioradialis, **Elbow Extensors**: Triceps long head, triceps medial head, triceps lateral head & anconeus.

OpenSim was used for model scaling, inverse kinematics, muscle analysis (MTU lengths and moment arms) and inverse dynamics (external joint moments). These data were used as inputs to the CEINMS simulations. Muscle parameter calibration was performed for all MTUs using 3 push-up trials with hands in a neutral position with L_{ts} and L_{opt} constrained to within 10% of their initial values, and the strength coefficient used to scale F_{max} limited to a range of 1-5. CEINMS was used to predict muscle activations for all MTUs for Uncal-SO, Cal-SO and Cal-EMG for a wide hand position push-up trial. Root mean square error (RMSE) and coefficient of determination (R^2) were used to compare predictions of muscle activations of the triceps and biceps muscle groups to EMG between configurations.

RESULTS AND DISCUSSION

For the agonist muscle group (triceps), both the Cal-SO and Cal-EMG greatly improved muscle activation predictions, even in MTUs without EMG data. In the antagonist muscle group (biceps), BIClong (the muscle with experimental EMG) predictions improved only with Cal-EMG (Table 1).

Table 1: RMSE and R^2 comparisons between experimental EMG and estimated muscle activations.

	Uncal-SO		**Cal-SO**		**Cal-EMG**	
	RMSE	R^2	RMSE	R^2	RMSE	R^2
TRIlong	0.27	0.38	0.22	0.42	0.12	0.55
TRImed	0.19	0.56	0.11	0.61	0.04	0.79
TRIlat	0.21	0.49	0.16	0.56	0.08	0.67
BIClong	0.66	0.18	0.65	0.19	0.24	0.53
BICshort	0.54	0.22	0.52	0.21	0.48	0.19

CONCLUSIONS

This study demonstrates that using muscle parameter calibration and EMG-assisted optimization techniques can significantly improve estimations of upper limb muscle activations during externally loaded tasks and with co-contracting muscle groups.

INVERSE KINEMATICS AND DYNAMICS SOLUTIONS DURING WALKING GAIT: SCALED-GENERIC VS SUBJECT-SPECIFIC MODELS

[1]**Simao Brito da Luz**, [1]David J. Saxby, [2]Luca Modenese and [1]David G. Lloyd
[1]Menzies Health Institute Queensland, Griffith University, Australia

INTRODUCTION

Inverse kinematics (IK) and inverse dynamics (ID) respectively determine joint angles and moments, which are important to normal and pathological gait [1]. Gait analysis software OpenSim [2], uses pre-defined generic rigid-body models based on measurements from cadavers [3], including body segment inertial parameters (BSIP) and joint models. Tibiofemoral (TFJ) is a 2D sagittal planar joint, talocrural (TCJ) and subtalar (STJ) joints are hinges, and the hip joint is a ball-and-socket. Moreover, not all joint degrees of freedom (DOFs) are permitted, e.g. no TFJ or TCJ Int-External (IE) or Abd-Adduction (AA) rotations. For each subject, model's features are linearly scaled, using skin-placed 3D motion capture (3DMOCAP) markers, which can be misplaced [4]. Consequently, generic models can misrepresent the subject, leading to inaccurate joint angles [5] and net moments [6]. Alternatively, subject-specific rigid-body models improve the reliability of gait analysis [5,6] so they should be developed.

A subject-specific OpenSim model was developed from MRIs [7]. TFJ and TCJ mechanisms estimated 3D kinematics [8], hip joint centre (HJC) and STJ were determined from bone surfaces. Personalised BSIPs can be estimated from external skin surfaces off MRIs [9].

For 13 healthy participants, we aimed to compare joint angles and moments, during gait, using scaled-generic and subject-specific models in OpenSim.

METHODS

3DMOCAP, ground reaction forces (GRFs) and full lower-limb MRIs were acquired from 13 participants. 3DMOCAP markers' positions scaled the generic models' features [3]. Subject-specific models were created using 3D surfaces from MRI. 1-DOF mechanisms estimated the TFJ and TCJ 3D kinematics, coupled to Flex-extension (FE). Mechanisms were solved with geometric parameters measured from MRIs and then optimized [8]. STJ hinge axis and HJC were created from spheres fitted to the talus and femoral head surfaces. BSIPs were determined, using NMSBuilder, with assigned density values to bone and soft tissues [9].

Participants performed standing postures and 2-3 gait trials. For both models, hip, knee and ankle joint FE, and the scaled-generic knee AA and IE angles, were estimated using OpenSim IK analysis. Scaled-generic ankle IE and AA rotations were locked to prevent motion. Subject-specific model's mechanisms estimated knee and ankle IE and AA angles. From combining joint angles and GRFs, joint moments were computed via OpenSim ID analysis.

The two models were compared in terms of joint angles and moments using coefficient of multiple determination, i.e. R^2.

RESULTS AND DISCUSSION

Joint angles were generally different between models (Figure 1). Joints' IE and AA angles had low correlations ($R^2 \leq 0.2$), except for the hip AA. However, FE angles had high correlations ($R^2 \geq 0.7$). Joint moments were similar between models, most had moderate or high correlations ($R^2 \geq 0.5$).

Different joint modelling definitions potentially contributed to altered IE and AA angles, but not joint moments, as previously suggested [10]. FE angles were similar between models as previously reported [7].

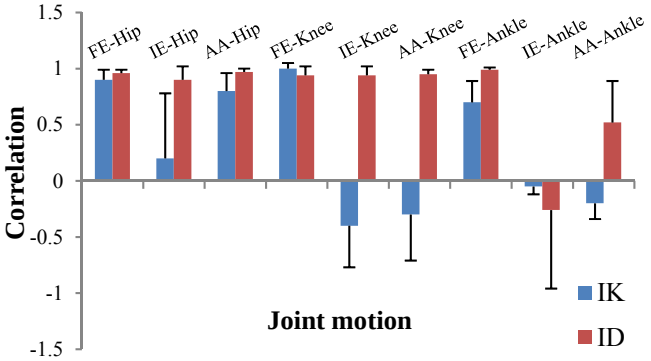

Figure 1: Joint angles (IK) and moments (ID) correlation values between scaled-generic and subject-specific models.

CONCLUSIONS

We presented gait angles and moments for 13 participants using scaled-generic and subject-specific models, which included personalized features. Models presented similar joint moments and FE angles, but different IE and AA angles due to modelling differences. Our ongoing research suggests subject-specific models should be used since they avoid scaling errors, although *in vivo* validation has not been done.

INFLUENCE OF PHYSIOLOGICAL CONSTRAINTS ON A SUBJECT-SPECIFIC BSIP CALIBRATION

INTRODUCTION

Calibration of body segment inertial parameters (BSIP) is crucial in biomechanical studies. To avoid strenuous protocols, identification methods based on rigid body dynamics laws have been proposed [2,3]. Thanks to a motion capture system and force platforms, these methods optimize BSIP by minimizing errors in the equations of motion. These errors arise from estimated BSIP but also from kinematics and force plate measurements that may introduce overfitting in the calibration. To prevent this, [3] added physiological constraints in the calibration. On one case study, the goal of this current work is to analyze the influence of added physiological constraints in a BSIP calibration on results. The different calibration results are compared to the widely used anthropometric data proposed by [1].

METHODS

For this study, one male participant (183 cm, 80kg) performed a range of motion-type motion which activates sequentially each degree of freedom. 47 motion capture markers were placed on standardized anatomical landmarks and captured thanks to a Vicon® motion capture system (125 Hz). Two force platforms (1000 Hz) were used to access external forces applied on each foot. The motion is reconstructed thanks to a whole body model. Then, the BSIP calibration method consists in minimizing the dynamic residuals as proposed by [2]. To improve the results consistency, each limb is assimilated to a stadium solid [4]. So, the calibration finds the better stadium solid characteristics of each limb to minimize the dynamic residuals.

Three different BSIP are compared:

- anthropometric data proposed by [1] (**C0**);
- results of the BSIP calibration computed without any constraint on solids geometry (**C1**);
- results of the BSIP calibration computed with physiological constraints close to those used by [3] (**C2**). They consist in limiting the asymmetry and in limiting the BSIP variation from **C0**.

RESULTS AND DISCUSSION

Figure 1 shows the results of the different calibrations compared to the anthropometric data **C0**. First, it is easy to see that results of **C1** are completely inconsistent (the mass of the torso is very low compared to the other limbs, the symmetry is not respected). Results of **C2** seem more consistent with anthropometric data and correspond to the trends obtained by [3] (i.e. masses of torso and arms slightly lower than **C0** and masses of pelvis, head and legs slightly higher than **C0**).

Thus, even if the optimization is better in **C1** (in terms of cost function value), it appears to lead to overfitting. Additional physiological constraints are therefore essential in this BSIP calibration. Complementary studies have to be achieved to support these results. First, the BSIP calibration has to be tested with different morphologies especially with those distant of the 50th percentile. It allows to refine the choice of the physiological constraints to be added to the optimization problem. Secondly, obtained calibrated BSIP has to be compared with a ground truth estimation, for example with 3D scanning technologies.

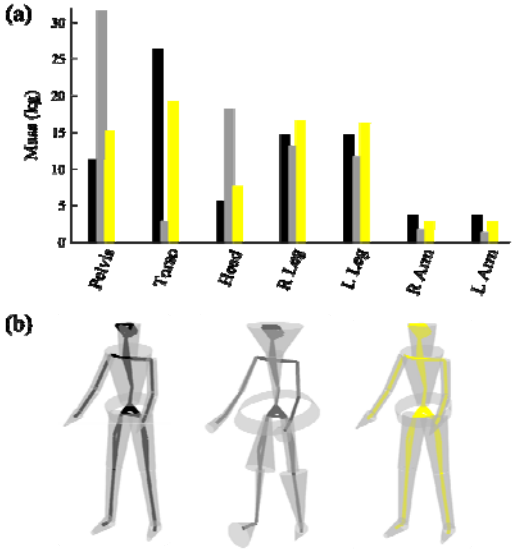

Figure 1: Results of BSIP comparison. (a) shows the mass of the different body parts; (b) represents the limbs BSIP, each assimilated to the close cone frustum in terms of BSIP. 1st result (black) is **C0**, 2nd result (grey) is **C1** and 3rd result (yellow) is **C2**.

CONCLUSIONS

The purpose of this study was to analyze the influence of additional physiological constraints on a BSIP calibration, based on an identification method. Results obtained without any additional constraint turned out to be inconsistent, revealing overfitting. Addition of physiological constraints, close to those used by [3], yields to more consistent results that have be thereafter validated with more accurate approach like 3D scanning.

ARE DYNAMIC MEASUREMENTS NECESSARY FOR PARAMETER ESTIMATION OF THE HILL MODEL IN A SUBJECT-SPECIFIC MUSCULOSKELETAL MODEL?

INTRODUCTION

Musculoskeletal models have now reached a state where we see a transition from more fundamental research towards applications within the clinical field and the industry. In particular models applied within the clinical field, a high level of subject-specific detail is required. Using imaging technology, it is nowadays possible to get a precise model of a specific person's bone geometry. However, it is much more difficult to obtain person-specific parameters of the Hill muscle-tendon model typically used in musculoskeletal models.

Imaging is not sufficient to measure an important parameter like tendon slack length; and even if it were possible, there is no direct relationship between the real anatomy and the parameters in the phenomenological Hill model. Heinen et al. [1] gave an overview of different methods to scale the parameters of the Hill model to an individual person. Using isometric and isovelocity measurements obtained from a dynamometer is one of the few options to get subject-specific parameters of multiple muscles crossing multiple joints, e.g. the muscles of the lower extremity. The disadvantage is that dynamometer experiments require much effort from the subject. This is especially the case for the isovelocity measurements. The aim is therefore to investigate if it is necessary to obtain a full isometric and isovelocity dataset of the joints of the lower extremity.

METHODS

One male long distance runner (height: 1,85 m, weight: 66,5 kg) was included in this study, which was carried out in accordance with the Loughborough University Ethical Advisory Committee guidelines. The isometric and isovelocity experiments were conducted for the ankle, knee and hip (flexors/extensors) of the dominant leg using a Contrex multi-joint isovelocity dynamometer (CMV AG, Switzerland) using a similar protocol as by Lewis [2]. A total of 21 isometric measurements were performed at different joint angles at the three joints. And a total of 22 isovelocity measurements were performed with different velocities at the three joints.

A lower extremity model was used based upon the TLEMsafe 2.0 model [3] using the AnyBody Modeling System (AnyBody Technology A/S, Denmark). The model was scaled based on anthropometric measurements. Each experimental condition was mimicked in the model to evaluate the joint strength of the model after which two optimization procedures were conducted using the SNOPT optimizer.

The first procedure (Isom-opt) minimized the difference between the experimental and simulated isometric joint strengths. The second procedure (Dyn-opt) minimized the difference between the experimental and simulated isovelocity joint strengths based on the results from the first optimization.

RESULTS AND DISCUSSION

Firstly, adjusting the Hill parameters using only the Isom-opt on the isometric experimental data resulted in a much better subject-specific model compared to a general scaling algorithm (Ref-model). The average RMS value between the isometric experimental data and the model decreased from 112.4% (Ref-model) to 15.5% (Isom-opt). Moreover, only using isometric data also leads to an improvement of the dynamic muscle characteristics of the subject-specific model. The average RMS percentage difference value between the isovelocity experimental data and the model decreased from 256.2% (Ref-model) to 192.3% (Isom-opt). Using the isovelocity experimental data together with the Dyn-opt procedure, the latter RMS value could be further improved to 157.6%. Figure 1 gives an impression of the effect of the different procedures on the hip extensors in the concentric phase.

The additional improvement using Dyn-opt is relatively small especially if one considers the extra experimental time, the extra computation time and the considerable load on the subject.

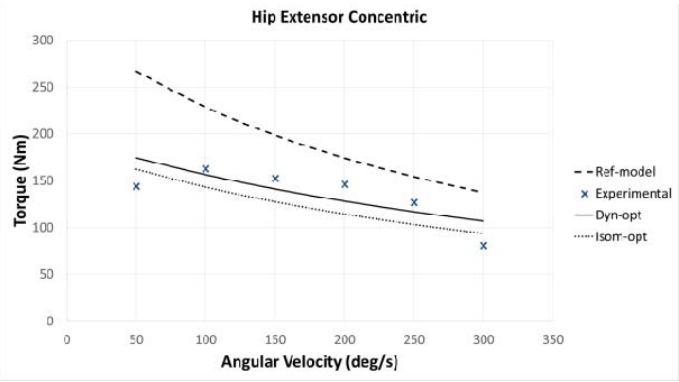

Figure 1: Concentric isovelocity joint-torque for the hip extensors experimental, Isom-opt predictions, Dyn-opt predictions and the reference model.

CONCLUSIONS

For general use, isometric measurements to obtain subject-specific parameters of the Hill model can suffice. This is particularly advantageous when dealing with patients. Highly dynamic applications with subjects who can tolerate the isovelocity experiments would would benefit from the use of the Dyn-opt procedure.

AN EFFICIENT COMPUTATIONAL MODEL FOR PREDICTING THE STRAIN DISTRIBUTION DURING COMMON PHYSICAL ACTIVITIES: SURROGATE MODELING VS FE SIMULATIONS

Hamed Ziaei Poor, Saulo Martelli, Rami Al-Dirini, Dermot O'Rourke, Mark Taylor
Medical Device Research Institute, School of Computer Science, Engineering and Mathematics, Flinders University

INTRODUCTION

The ability to calculate femoral strain during a broad range of physical activities is essential to study the risk of fracture for the elderly population. Strain prediction using the current Finite Element-Musculoskeletal (FE-MS) models is computationally expensive [1]. Surrogate Modelling (SM) offers a unique alternative for predicting the strain field over the femur in a fraction of the time needed by FE-MS models. The objectives of this research were (i) to develop a surrogate model than can accurately and efficiently predict the strain distribution for five different activities, and (ii) to assess the effect of increasing the number of samples on the accuracy of the results.

MATERIALS AND METHODS

The VICON motion capture system were used for obtaining the marker trajectories and ground reaction force of a female subject (68 years, 53kg) during five different activities (walking (5 rep), fast-walking (5 rep), stairs up (5 rep), stairs down (4 rep) and rising from and lowering into a chair (1 rep)). Twenty four different muscle and joint reaction forces were calculated using a developed musculoskeletal model [2, 3]. The obtained forces were applied to an FE model of the subject's femur [2, 3].

Surrogate models of the strain distribution were developed using four different training samples (N = 50, 100, 200 and 300). For this purpose, muscle and joint reaction forces of the entire activity cycles were pooled into a single matrix, from which samples were generated using Latin hypercube sampling (LHS). Different levels of training were performed using a multi-linear regression model based on the generated data sets. Training the surrogate models returned the coefficients, which can be regarded as a link between the forces and the induced strain field. In other words, by showing the training data set to each element (as input variable) and the strain (as output), the response of each element was (the coefficients) obtained. The full field of microstrain for each element were predicted by multiplying the forces and the associated coefficients for different repetitions using the below equation (F_{Mi} = muscle force, F_{JR} = joint reaction force).

$$\text{Microstrain} = \text{Constant} + C_1F_{M1} + C_2F_{M2} + \ldots + C_{25}F_{JR}$$

To assess the accuracy of the technique, the SM prediction was compared to the FE prediction of strains using linear regression. This was repeated for each activity cycle. Furthermore, element-to-element comparisons were performed by finding the difference between FE and each SM.

RESULTS AND DISCUSSION

The study found that increasing the number of samples from 50 to 300, changed the peak RMSE from 200 με to 150 με. Out of the considered activities, and fast-walking had the greatest local error, with the peak and average value of 95% of the absolute error being less than 600 and 300 με, respectively. It was noted that the accuracy is high within the stance phase of a gait ($R^2 > 0.8$), but it falls significantly in the swing phase of a gait ($R^2 = 0.29$). The worst prediction was for rising-from and lowering-into a chair when LHS50 was used (peak RMSE = 200 με), followed by LH100-300, ranging from 175-165 με, respectively. In terms of efficiency, the running time for FE simulations was 55min, compared with 13 seconds for the surrogate models.

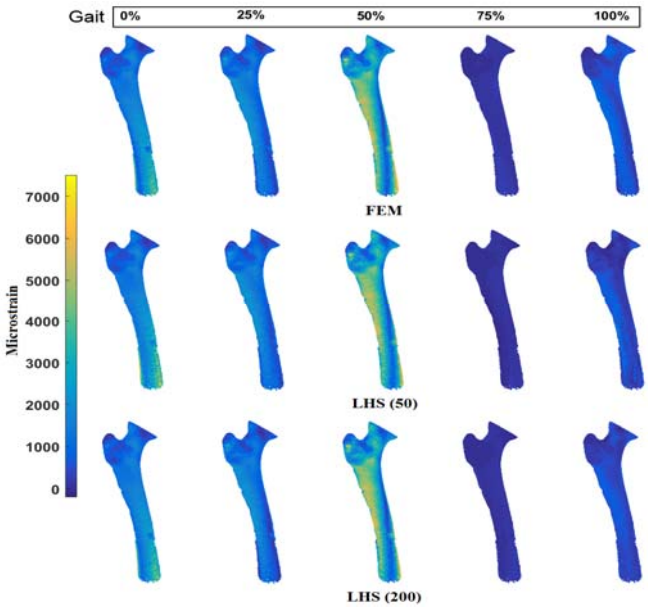

Figure 1: The strain prediction during a gait (in percent) using FE and SM (fast-walking, for LHS50 and 100)

CONCLUSIONS

This study demonstrated the development and validation of an efficient surrogate model of the femoral strain field based on data for five different physical activities. Also, while the accuracy improved by increasing the number of samples from 50-200, not that much difference observed by further increase in the number of samples.

INVITED TALK: INDIVIDUAL MUSCLE FORCES AND MUSCULO-SKELETAL MODELS OF HUMAN MOVEMENT

[1]**John H. Challis**, [2]Zachary Domire, and [1]Benjamin Infantolino
[1]The Pennsylvania State University
[2]East Carolina University
Corresponding author email: jhc10@psu.edu

INTRODUCTION

David Winter claimed "*One of the most valuable biomechanical variables to have for the assessment of any human movement is the time history of the moments of force at each joint*." [1]. While these resultant joint moments have provided insights into human movement they have not necessarily revealed the motor control at the root of the tasks, and Vaughan has argued that they do not represent the "Holy Grail" of human movement analysis [2]. Increased insight into motor function arises if the time histories of the muscle forces producing a movement are known. The direct measurement of these muscles forces [3] is problematic as not all muscles can be easily accessed, and due to other methodological issues [4]. Musculo-skeletal models provide a means of non-invasively estimating muscle forces. The purpose of this study is to examine two musculo-skeletal models to understand the insights which are available from these models, but also the problems which arise with these models.

METHODS

Model 1: a previously validated model of jumping was used to examine the influence of squat depth on jump performance [5]. The model consisted of four rigid links (foot, shank, thigh, and a combined head, arms, and trunk), with the simulated jumps assumed to be bi-laterally symmetrical and therefore simulations of motion were in the sagittal plane only. The model was actuated by models of eights muscles of the lower limb, which each had a series elastic component representing the tendon, and a contractile component representing the function of the muscle fibers.

The model was an optimal control model where the sequence of muscle activations was determined so that the model jump height was maximized. Jumps were simulated from a variety of initial squat positions, and the model kinematics, muscle force time histories, and jump heights examined.

Model 2: muscle models are used in many models of human movement. These models require a number of parameters with a common source of these parameters being cadaver data. The question arises of the sensitivity of these models to their parameters; to examine this question a muscle model was investigated using muscle architectural parameters measured from eight First Dorsal Interosseous (FDI) muscles removed from cadavers [6]. The parameters measured for each muscle were: optimum fiber length, tendon slack length, physiological cross-sectional area, pennation angle, and muscle moment arm thus providing a means of characterizing a model of each of the muscles. For simulated static conditions the cadaver-specific results were compared against different representations of the group data. The FDI was selected because in humans it is a rare instance of only one muscle being responsible for a particular joint motion: it abducts the index finger about the metacarpophalangeal joint.

RESULTS AND DISCUSSION

Model 1: jump kinematics for the simulated jumps compared favorably with those of experimental subjects. The results revealed that jump height increased with increasing squat depth. The model demonstrated that to accommodate increasing depth of initial squat required different coordination the muscles propelling the jumps.

Model 2: for each muscle simulations were run to predict the maximum isometric abduction moments produced by the FDI, the variation in individual muscle properties meant each muscle produced different strength curves. Comparisons were made, for example the properties for muscle 1 were used to predict the activity of muscle 2, and so on for each possible combination. Generally the percent root mean square differences between the actual muscles joint moments and those predicted using parameters from the other muscles were high, even when means of the data set were used. For example, if the mean of the data set was used to simulate the individual muscles the smallest percentage root mean square error between original and estimated muscle moments was 26%.

CONCLUSIONS

The first model provides insights into how muscles should be coordinated to produce movement. Models of this type provide biomechanists with insights into muscle force time histories, but have the problem that while the nature of the movement (kinematics and kinetics) can be used to validate the model, data are not available validate the estimated muscle forces. The second model highlights the problem arising for musculo-skeletal models of providing the appropriate muscle model parameters. As Panjabi has highlighted "*The basic dilemma in the process of validation may be stated in the following manner: a mathematical analogue can be validated only in a given number of known situations. Yet the main purpose of an analogue is to predict behavior in unknown situations. Thus, no perfect validation is possible*." [7]. The state of the art in biomechanics has provided understanding of human motor control, but there are issues with providing models with the appropriate parameters if we are to move closer to the "Holy Grail".

DETECTING THE RELEVANCE OF EACH MOTION COMPONENT IN WHOLE-BODY MOTION TO PERFORMANCE

[1] **Ken Takiyama** and [1]Daisuke Furuki
[1]Tokyo University of Agriculture and Technology
Corresponding author email: takiyama1106@yahoo.co.jp

INTRODUCTION

Goal-directed whole body movements are fundamental in our daily life, sports, music, art, etc. However, the nature of these movements have not been sufficiently investigated because of the complexities inherent to these movements, such as high-dimensional, non-linear dynamics and redundancy [1]. A question that needs investigation is how to overcome these complexities to achieve the desired performance. One approach to the question can be quantifying how each motion component (motion of each body part at each time point) contributes to the movement performance. However, high-dimensional nonlinear dynamics and redundancy make it difficult to quantify the relevance of each motion component to performance.
Here, we propose a data-driven approach to detect the relevance of each motion component to performance.

METHODS

General framework: We measured both whole body motion trajectory data, $\boldsymbol{x}_k = (p_{1,1,k}, v_{1,1,k}, \ldots, p_{N,T,k}, v_{N,T,k})$ using a motion capture system (Optitrack, flex 13, 120fps) and performance data, d_k, at the k^{th} trial (k = 1, ..., K); where, $p_{i,t,k}$ and $v_{i,t,k}$ indicate the position and velocity data of the i^{th} marker at the t^{th} time frame (i = 1, ..., N, t = 1, ..., T). We quantified how each motion component (i.e., $p_{i,t,k}$ and $v_{i,t,k}$) is relevant to performance by using a linear regression method:

$$y_k = \boldsymbol{w}\boldsymbol{x}_k = w_0 + w_{i,t}^{p} p_{i,t,k} + w_{i,t}^{v} v_{i,t,k} \quad (1),$$

where, y_k is predicted performance, w_0 is bias term, and weight values $w_{i,t}^{p}$ and $w_{i,t}^{v}$ indicate how $p_{i,t,k}$ and $v_{i,t,k}$ are relevant to predict performance, respectively. A larger |w| indicates greater relevance of the corresponding motion component to the performance. To estimate w and w_0, we used ridge regression and cross validation [2]. The same results could be obtained by LASSO and Gaussian process regression [2]. If it is impossible to predict performance, all the w and w_0 are estimated to be 0 and ($\Sigma\, d_k$)/K, respectively.

Experiments: Nine subjects performed ring throwing (100 trials per session, 34 sessions in total). Subjects threw a ring (133g) towards the center of a 2 m distant target (target board was 0.2m square).

Data Analysis: We analyzed 60 time frames before the ring release. To discuss how motion at each time point is relevant to the performance, 60 time frames were divided into 12 time bins (5 frames/bin). The 12th time bin includes the time frame of ring release. We separately analyzed data in each time bin.

Performance was defined as a two-dimensional deviation of the measured ring center from the target center, horizontal deviation in x-axis and vertical deviation in y-axis.

RESULTS AND DISCUSSION

Figure 1a indicates the representative predicted performance using equation (1), showing that the linear regression enabled to predict performance and discuss the relevance allows the prediction of performance and the discussion of the relevance of each motion component to performance based on weight values.

Figure 1a also indicates how motion at each time point is relevant to the performance. Prediction error for the 9th – 12th bin was significantly lower than that with $w_0 = (\Sigma\, d_k)/K$ and $w_{i,t}^{p} = w_{i,t}^{v} = 0$ ($p < 0.01$, Wilcoxon signed-rank test), indicating that motion not only at the time of release, but also at 160 ms before release is relevant to performance.

Figure 1b indicates representative weight values estimated at the 12th bin (mean ± s.e.m., 34 sessions): How the motion of each body part is relevant to performance.

The linear regression also could work well for ball throwing while being seated (N = 5) and 30-cm jumping (N = 7).

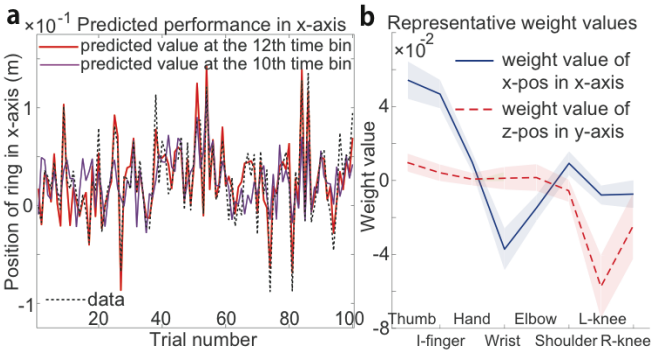

Figure 1: (a) Predicted performance. (b) Weight values.

Despite the high-dimensional, non-linear dynamics of whole body motion, it remains unclear why linear regression is able to clarify the relation between whole body motion and performance. Whole body motion trajectory data, $\boldsymbol{x}$, includes information about the movement performance in a non-linear manner; $\boldsymbol{x} = \mathbf{f}(d)$. When $\boldsymbol{x}$ is a high-dimensional, nonlinear function, it is possible to represent an arbitrary function of d through linear regression [2]. The linear regression thus utilized high-dimensional, non-linear dynamics, embedded in $\boldsymbol{x}$ to find an explicit relation between movement and performance.

CONCLUSIONS

To understand the nature of goal-directed whole body movements, we proposed a data-driven method to quantify how each motion component is relevant to the performance. Our method would make it possible to discuss quantitatively, not only how we control each body part to overcome high-dimensional dynamics and redundancy but also how we should modify our movements to increase performance.

COORDINATION OF MOTOR UNIT FIRINGS DURING CYCLIC ACTIVITIES OF THE UPPER-LIMB

[1]**Joshua C. Kline**, [1]Paola Contessa, [1,2]Serge H. Roy and [1]Gianluca De Luca
[1]Delsys, Inc. and Altec, Inc, Natick, USA
[2]Sargent College of Health and Rehabilitation Sciences, Boston University, Boston, Massachusetts, USA

Corresponding author email: jkline@delsys.com

INTRODUCTION

Investigations into the firing behavior of motor units have begun to improve our understanding of how groups of muscles are coordinated to generate force. Findings such as the "common drive" for example have revealed that motor unit firing rates within and across muscles are regulated with varying degrees of correlation depending on whether the muscles are acting as synergists or antagonists during different contraction tasks [1]. But such work has been limited to studies of isometric contractions or to the use of intramuscular sensors that are not practical for studying motor control during normal human movement. The mechanisms used by the central nervous system to control voluntary movements remain unknown. Therefore, we developed a non-invasive system for measuring motor unit firing behavior during dynamic activities and used this system to investigate the activation of motor units in groups of muscles during movements of the upper-limb.

METHODS

Experiments were conducted on 6 subjects (3 male and 3 female; 40±16 yrs.) with no known history of neuromuscular health conditions. Non-invasive sensors were placed on the extensor digitorum, flexor digitorum, pronator teres and biceps brachii muscles to record the surface electromyographic (sEMG) signals produced during voluntary dynamic activities including: flexion/extension of the fingers, pronation/supination of the forearm and object grasping. The finger force, the joint angle and the inertial measurements of the fingers, hand and arm were measured during the execution of each task using the Trigno™ sensor system (Delsys, Inc. Natick, MA). The sEMG signals recorded during the different movements were processed by sEMG decomposition algorithms to extract the firing times of the active motor units [2]. The measured motor unit data were validated for accuracy and analyzed to investigate the firing behavior during voluntary movement activity.

RESULTS AND DISCUSSION

Throughout the cyclic movements, the motor unit firing behavior in all muscles was governed by the same underlying control mechanisms: 1) the firing rates were ordered in an inverse hierarchical relationship relative to the motor unit action potential amplitude as previously described by the "onion-skin" phenomenon; and 2) the firing rates of motor units within each muscle were correlated with respect one-another and with the output movement in accordance with the common drive [2]. When comparing motor unit firing behavior across muscles, we observed that the firing rates maintained a relatively high correlation but the latency of the correlation shifted depending on the activity being performed. Specifically, when two muscles acted as antagonists, the correlation of the firing rates across the muscles manifested a relatively greater latency (Figure 1) compared to when the muscles were coactivated in other more synergistic tasks.

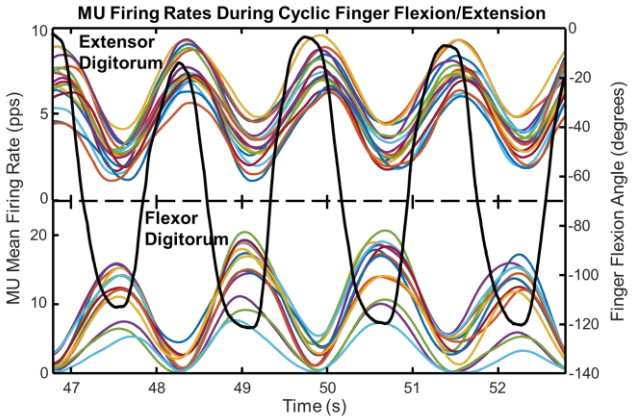

Figure 1: Motor unit (MU) mean firing rates (colored lines) measured from the finger extensor and flexor muscles during four cycles of opening and closing of the hand.

CONCLUSIONS

As excitation from the central nervous system drives the motoneuron pools of a group of muscles to generate force or movement, our data indicate that motor units within the different muscles are all governed by the same underlying control properties of the onion-skin and common drive that have been well documented and established in the literature [2]. Our findings also indicate that to regulate multiple muscles during different movement activities, motor units are controlled in a manner that shifts the latency of the correlation of the firing rates across muscles, depending on whether the muscles are acting as antagonists or synergists.

INTRODUCTION

Human participants can learn to move in novel environments despite an immense number of variables in the musculoskeletal system. However, how the central nervous system (CNS) modifies motor commands controlling the high-dimensional system to adapt to novel environments remains unclear. As the concept for reducing the musculoskeletal variables, previous researchers proposed that the CNS retain several motor repertories in muscle synergies, which modularly organize a lot of muscles [1, 2]. In the present study, therefore, we examined the regulation of musculoskeletal variables during the adaptation to the environment exposed to a velocity-dependent force field, based on the concept of muscle synergies.

METHODS

The participants performed horizontal reaching movements holding robotic handles by their right hand. They sat in an adjustable chair to which their trunk was strapped. They were instructed to move cursors representing the hand positions from a start position located at approximately 30 cm in front of their body to one of the 8 equally placed targets by 45° on a horizontal display (**Figure 1A**), as straight as possible. For the training, the participants performed reaching movements under the presence of a velocity-dependent curl force field (**Figure 1B**, center) [3]. To equalize the endpoint kinematics, we randomly used the error-clamp trials, with which the movement trajectory of the handle was constrained to a straight path from the start position to the target by a virtual force-channel (**Figure 1B**, right) [4]. The experimental tasks were composed of null field, force field (FF) and washout (WO) trials. During the tasks, surface electromyograms (EMGs) were recorded from 14 muscles spanning wrist, elbow and shoulder joints (**Figure 1C**). Muscle synergies were extracted from the EMGs in all error-clamp trials using a non-negative matrix factorization [5].

RESULTS AND DISCUSSION

The lateral deviations due to the velocity-dependent force field were exponentially reduced and stable approximately half in the FF trials. Throughout the trials, at least 3 muscle synergies across each participant were needed to perform the reaching movements. Most of the muscle synergies were grouped into 3 clusters using a hierarchical cluster analysis (**Figure 1D**). The preferred directions (PD) of the muscle synergies relevant to accelerating a hand were rotated to the directions corresponding to the force field during the adaptation (**Figure 1E**). At the same time, a percentage of EMG variance explained by each muscle synergy increased in $W_{1, 2}$ and decreased in W_3 (**Figure 1F**). The relation of activation traces among 3 synergies was changed in FF trials and close to the baseline during WO trials (**Figure 2**). The results indicate that the CNS modulates the spatiotemporal recruitment of muscle synergies to learn to move in the environment exposed to a velocity-dependent force field.

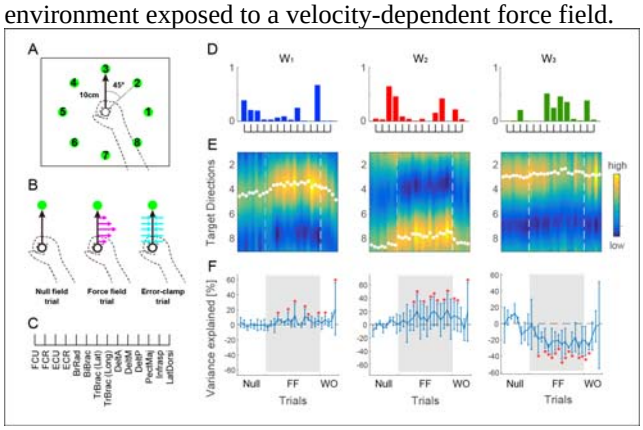

Figure 1: Experimental setup (A-C), mean muscle weights in muscle synergies (D), peak synergy activation across each target direction and trial (E; white dots represent PDs.), and change in % of EMG variance explained by each muscle synergy from null trials (F; *$p < 0.05$).

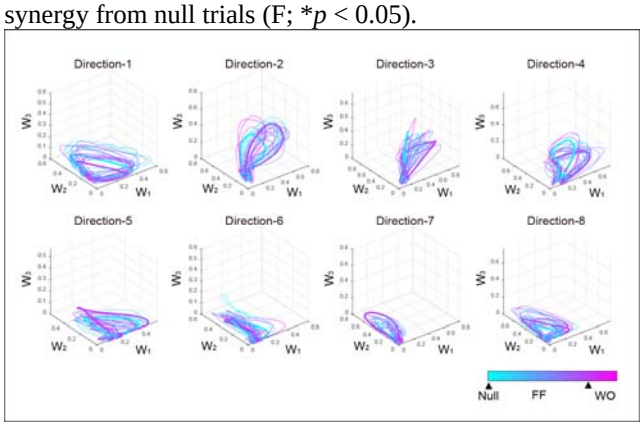

Figure 2: Spatiotemporal relationship of activation traces during movements among 3 muscle synergies across trials.

CONCLUSIONS

The change in the PD and contribution ratio of each muscle synergy enabled the participants to adapt to a velocity-dependent force field. The CNS would reduce the high-dimensional musculoskeletal variables modified in the motor adaptation by modularly regulating spatiotemporal recruitment of relevant muscles.

INTRODUCTION

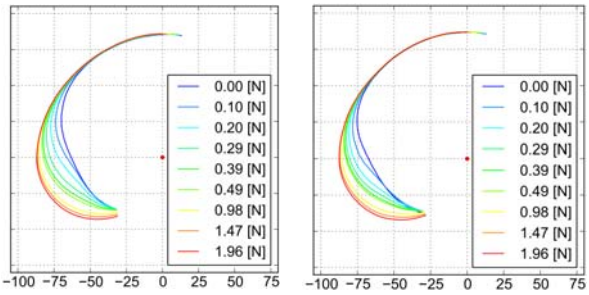
Zancolli's lasso procedure is one of the most popular operations for intrinsic muscle deficiency. Omer also modified this procedure to loop the FDS tendon around the A2 pulley. The differences between the fingertip trajectory in these procedures had not been clarified, however. Our hypothesis is the trajectory of the fingertip forms larger in the A2 pulley insertion group than the A1 pulley insertion group.

METHODS

Six fresh-frozen cadaver hands were used. We exposed six tendons (FDP, FDS, EDC, EIP, IOD, IOV) that contribute to the index finger motion, and tied a silk string into each tendon so that we can pull each tendon independently by our computer-controlled apparatus. Two stainless steel pins were drilled vertically into the dorsal side of the second metacarpal bone and were clamped parallel to the ground with the apparatus. Five tendons except FDS were pulled by our apparatus to make the reference position. We cut the FDS tendon just distal the A2 pulley and sutured itself around the A2 or A1 pulley. FDP tendon was pulled by 2mm per second separately; two seconds after the other tendons were made slack. The FDP was pulled from full extended position until the index finger becomes fully flexed. Threaded stainless steel wires with diameter of 1.6mm were drilled into each bone in order to support a triangular platform where three optical markers with diameter of 4mm were glued. The optical markers were also attached to the base of the apparatus. The motions of these markers were recorded by a motion capture system. The 3D-CT were obtained to calculate the positional relationship between the markers and bones. Surface geometries of the markers and bones created from the CT images were fit into the marker trajectories from the motion capture data to reconstruct the bone motion. We measured the finger motion under nine different FDS activation levels, 0.00N, 0.10N, 0.20N, 39N, 0.48N, 0.96N, 1.47N and 1.96N achieved by a static weight. First we performed this experiment around the A2 pulley, and then performed around the A1 pulley.

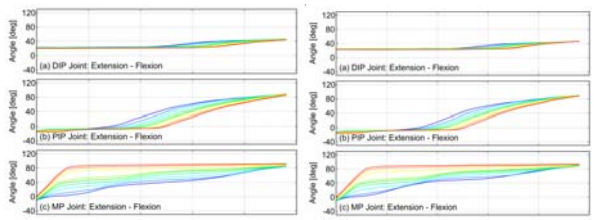
RESULTS AND DISCUSSIN

Figure 1 show the fingertip trajectory in the A1 and the A2 group in one specimen. The fingertip trajectory forms larger arc in the A2 group (Omer modification) than in the A1 group (original Zancolli) with the lower activation levels. In the A1 group, the PIP and DIP joint start flexing faster than in the A2 group with lower activation levels (Fig. 2). These findings suggest that Omer modification may indicate better results to enlarge finger trajectory than original Zancolli's procedure in a weaker FDS muscle power.



A1 A2

Fig. 1: The fingertip trajectory under nine different FDS activation levels



A1 A2

Fig.2 The joint angles of each joint

CONCLUSIONS

The arc of fingertip trajectory is larger in the A2 group the in the A1 group especially with lower activation levels. In the A1 group, the PIP and DIP joint start flexing faster than in the A2 group with lower activation levels. Omer modification is superior for finger trajectory than original Zancolli's procedure in a weaker lumbrical muscle power.

INTRODUCTION

Osteoarthritis (OA) of the basal thumb joint is a very disabling degenerative joint disease. It stands among the most common types of arthritis and can lead to severe articular pain and loss of mobility and strength. Such symptoms are usually caused by the degradation of the articular cartilage, whose primary function is to distribute load and avoid excessive peak pressure on the subchondral bone [1]. While it is known that cartilage thickness diminishes with OA progression, the mechanical properties of healthy human trapeziometacarpal (TMC) cartilage have not yet been assessed. Such information is, however, important to improve our understanding of TMC joint mechanics in the context of OA development.

The objective of this study was to assess the mechanical properties of first-metacarpal (MC1) and trapezial cartilage using a protocol combining indentation testing with contrast-enhanced computed tomography (CECT).

METHODS

The TMC joint of 16 fresh-frozen cadaver hands (10 female, 6 males, age: 66-101 years) was excised and the stiffness of the articular cartilage was assessed at nine articular sub-regions using a standardized indentation testing device (Mach 1, Biomomentum Inc, Laval, Quebec, Canada) with a spherical indenter (1 mm diameter). Indentation parameters were kept constant for each specimen (indentation depth: 0.1 mm, velocity: 0.5 mm/s, relaxation time: 10 s). This novel indentation protocol automatically detects cartilage orientation and moves the spherical indenter perpendicularly to the articulating surface. The compressive Young's modulus was calculated using an elastic model based on the force-position data [2].

A CECT imaging method was used to enhance cartilage visualization and to facilitate cartilage thickness measurement. Each sample was immersed in a cationic contrast-agent solution (CA4+, concentration of 12 mg of iodine/mL) mixed with protease inhibitors for 48h to allow a complete diffusion [3]. CECT images were acquired using a High Resolution peripheral Quantitative Computed Tomography (HR-pQCT) scanner (Xtreme CT, Scanco Medical, Zurich, Switzerland) with an isotropic voxel resolution of 41µm. Each scan was reconstructed as DICOM format, and segmented using a medical imaging processing software (Mimics Research 18.0 x64, Materialise, Leuven, Belgium). Cartilage thickness was manually measured perpendicularly to the direction of the subchondral bone at each testing location. The differences between bones and between articular sub-regions (Young's modulus and thickness) were tested with a Welch two sample t-test.

RESULTS AND DISCUSSION

The cartilage layer of the MC1 had a significantly higher Young's modulus than the trapezium ($p = 0.002$) (Figure 1). In terms of cartilage thickness, no statistical differences were found between the MC1 and trapezium. No significant changes were observed while comparing between articular sub-regions.

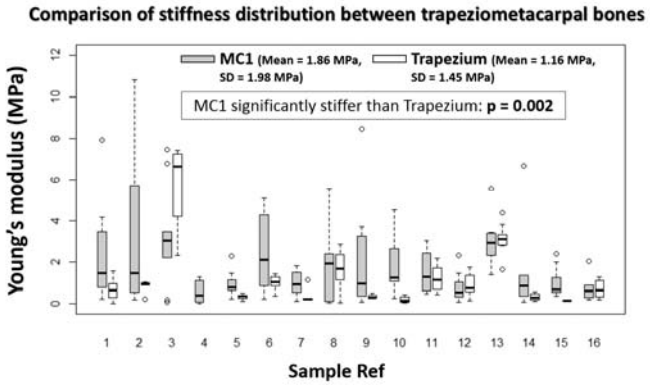

Figure 1: Comparison of cartilage Young's modulus.

CONCLUSIONS

This study is, to our knowledge, the first to report the mechanical properties of TMC joint cartilage. Such data might lead to more accurate computational simulations and therefore improve our understanding of TMC joint mechanics and OA development. The results show that cartilage stiffness differs between opposing articular facets of a single joint. This could imply a higher risk of cartilage eburnation at the trapezial facet, as reported by Pellegrini [4].

INTRODUCTION

Widespread trapeziometacarpal (TMC) joint osteoarthritis (OA) [1] can impair the upper extremity by up to 50 % [2]. Although its etiology is unclear, biomechanical factors are implicated in its pathogenesis [3]. Morphology is an important biomechanical factor that plays a role in contact mechanics, kinematics, and is hypothesized to play a role in the development and progression of TMC OA. Providing clinicians with tools to identify early onset of OA would enable better management and treatment of the disease.

Statistical shape models can efficiently describe morphological variation across a population, and may detect subtle differences in bone morphology. Here we present a statistical shape model classifier to differentiate morphological differences between healthy and early OA TMC joint bones and test the efficacy of this model to automatically classify degenerative changes in the joint.

METHODS

The dominant wrists and thumbs of 49 asymptomatic volunteers, consisting of 23 men aged (35.6 ± 13.7) years and 26 women aged (42.9 ± 15.3) years, and 75 patients with early osteoarthritis (EOA) (modified Eaton stage I [4], symptomatic but not radiographic), consisting of 30 men aged (59.3 ± 6.5) years and 45 women aged (53.1 ± 6.0) years, were imaged with a clinical CT scanner at 0.4 mm × 0.4 mm × 0.6 mm. Age and shape $R^2 = 0.4$ [5].

The 3D reconstructed images were segmented with Mimics v12.11 (Materialise, Leuven, Belgium), exported as data clouds, and a custom piecewise parametric template mesh was constructed. The template mesh was subjected to a series of coarse to fine fits that was followed with principal component analysis (PCA), and repeated until a training set of maximally correspondent meshes were obtained. This training set was used to train the statistical shape model.

Linear discriminant analysis (LDA) was performed on the mode weights between healthy and EOA subjects to create an LDA classifier. Using the classifier, mean healthy and early osteoarthritic TMC joint bones were reconstructed and a pointwise-distance map was calculated. A leave-one-out sensitivity and specificity of the classifier was evaluated.

RESULTS AND DISCUSSION

The first ten principal components of the statistical shape model accounted for over 90 % of the total variance in morphology present in the training set. The leave-one-out RMS error was 0.39 mm, smaller than the voxel dimensions, indicating that sufficient training was performed. The absolute pointwise-distance plot (Figure 1) indicated that local morphology varied by as much as 2.5 mm ($p = 0.0015$). The articular surface was, on average, 1.5 mm deeper in EOA trapezia than in healthy trapezia. Protrusions along the ridges of the articular surface were present in early osteoarthritic subjects, with the volar beak of the metacarpal exhibiting 2.5 mm protrusions. Such bony changes have been previously reported and are believed to be a result of volar beak ligament degeneration. Protrusions of a similar size were also identified on the scaphoid facet of the trapezium. These protrusions may be early stage osteophytes that may not be visible on x-rays.

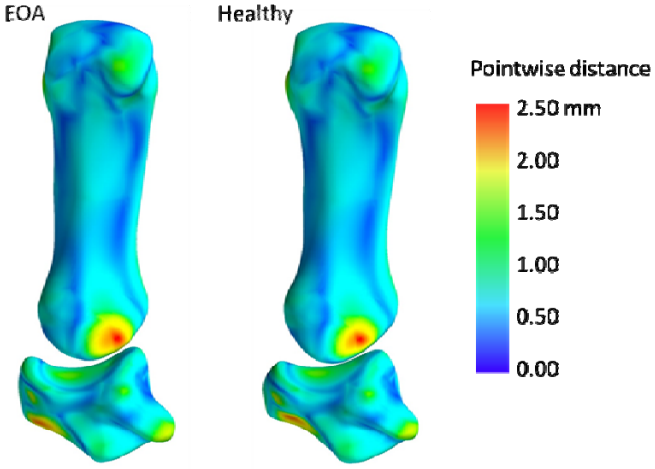

Figure 1: Absolute pointwise distance between LDA based reconstructions of early osteoarthritic (EOA) TMC bones and healthy, non-osteoarthritic TMC bones.

The LDA classifier achieved a leave-one-out sensitivity of 82.7 % and a specificity of 71.4 %.

CONCLUSIONS

Statistical shape modelling combined with LDA and pointwise distance mapping provided a quantified and visual presentation of the subtle differences between healthy and early osteoarthritic TMC joints. Our findings support the hypothesis that any radiographic changes indicate that osteoarthritic degeneration is well underway. Although the differences were subtle, the LDA classifier achieved a sensitivity of 82.7 % and specificity of 71.4 %.

INTRODUCTION

The human thumb is capable of a wide variety of functional tasks. This is mainly attributable to the unique anatomy of the saddle-shaped first carpometacarpal (CMC) joint, which allows a large movement arc in all 3 axes whilst also permitting a significant degree of joint surface translation.

Because of the degree of freedom possible in the CMC joint, degenerative changes often arise initially from ligament attenuation, leading to abnormal joint movement, and eventuating in debilitating arthritis [1].

Whilst *in vitro* cadaveric studies and static *in vivo* radiological studies have provided some insight into the complex and intricate movement of the thumb, these methods are limited by their ability to accurately assess dynamic CMC kinematics in human subjects during functional tasks. In the present study, we use 4-dimensional computed tomography (4D CT) to define the movement of the CMC joint during common physiological movements.

METHODS

The Aquilion®-One high speed CT scanner (Toshiba; Monash Medical Centre) is used to acquire rapid images during physiological movements of normal thumbs in four volunteers. The movements include abduction, opposition, and pinch. Images during these movements were then reconstructed into (Fig 1) and analyzed using specialized 3D manipulation software (Blender®). Anatomical landmarks were defined as per Cooney et al[2], and movement of the metacarpal was adjusted for a fixed trapezium in space. Tait-Bryan yaw-pitch-roll (abduction/adduction-flexion/extension-axial rotation) convention with extrinsic, right-handed, active Euler rotations were used to describe the position of bones in space. Dynamically changing joint ligament lengths were measured during movement by calculating distance between known landmarks of ligament insertion.

RESULTS AND DISCUSSION

A complex combination of movements occurs in the CMC joint during physiological actions. These include a large rotational arc along all 3 axes. Significant gliding and translation of the articular surfaces also occur and reach up to 6mm. The deep anterior oblique (beak) ligament and the dorsoradial ligament lengths vary during movement and in general, change inversely relative to each other. Instantaneous centers of rotation is not static and shifts widely from the center of the trapezium depending on the action performed.

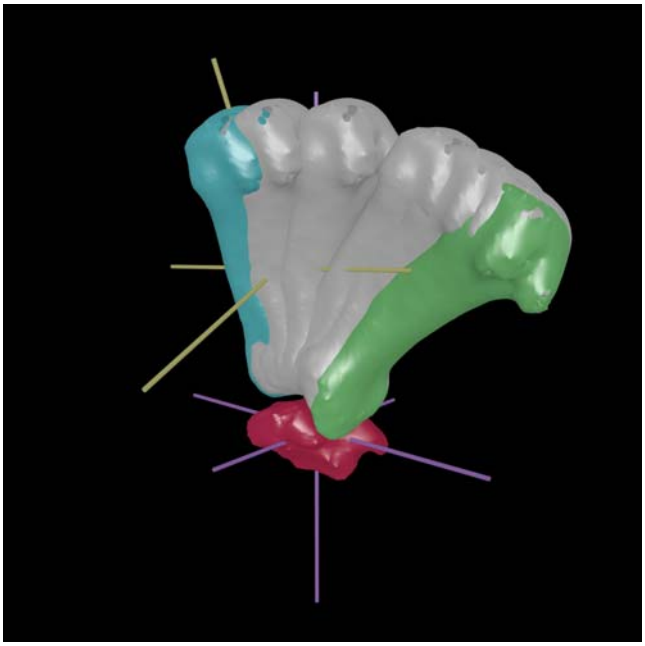

Figure 1: Reconstruction of 4D CT with metacarpal and trapezial axes during opposition movement of the thumb

CONCLUSIONS

We describe a method to accurate assess and quantitatively measure CMC joint movement using high resolution 4D CT. This allows a new way to visualize the complex movement of this joint *in vivo* and dynamically calculate ligament lengths and rotational pivot centers during physiological movements. Further investigation will shed light on how movements in arthritic and reconstructed CMC joints differ from normal subjects.

FOOT POSITION EFFECTS ON JOINT LOADING PATTERNS IN BACKWARD SOMERSAULT LANDINGS

[1,2] **Elizabeth J. Bradshaw**, [1]Karen Grech, [3]Corey W. Joseph, [4]Mark Calton, and [2]Patria A. Hume.

INTRODUCTION

Lower limb and low back pain and injury are prevalent in artistic gymnastics [2, 3]. The purpose of this study was to determine the effect of sport rules on the biomechanics of landings in artistic gymnastics. In this study the backward somersault dismount was examined for three foot positions; landing with the feet together (current competition landing technique), landing with the feet shoulder width apart, and landing with two feet together followed by a step backwards (formerly permitted on floor for women). This abstract reports the ankle, knee and hip joint reaction forces. It was hypothesized that the lower extremity joint reactions forces would be highest to lowest when performing the feet together condition (FT), the step backwards technique (SB), then the feet apart condition (FA).

METHODS

Seven female artistic gymnasts aged 10-15 years (Height = 145.3 ±11.6 cm; Mass = 37.5 ±8.9 kg; Competition Level = 7 ±2) were recruited for this study following institution ethics approval, as well as participant and parent assent/consent. Following a warm-up, the gymnast's bony landmarks on their trunk, legs and feet were identified and marked using 18 small retroflective ball markers (12.7 mm diameter, Innovision Systems, Columbiaville, MI, USA). The landing techniques were executed from a backward somersault off a 90 cm high foam vaulting box (A13-129, Acromat, Australia) to replicate the velocity conditions of apparatus dismounts. The gymnasts landed onto two 3 cm carpeted landing mats (Total Depth = 6.4 cm, AB-100, Acromat, Australia). The order of the techniques was randomised between the gymnasts.

A nine-camera three-dimensional motion capture system (Vicon, Oxford, United Kingdom, 250 Hz) and two portable, multicomponent force platforms (OR6-6-2000, AMTI, Watertown, MA, U.S.A., 1000 Hz) embedded in the landing surface captured the gymnasts landing movement. The Vicon dynamic full body plug-in-gait model was used to calculate kinematic and kinetic data. All Vicon data were smoothed using a Woltring filter with a mean square error of 20. The peak resultant ground reaction force and impulse were identified and normalised with reference to the gymnast's body weight for each landing technique. Cohen's effect size (ES) statistics were used to determine if there was a clinical difference between the landing techniques. Effect sizes above 0.19 were considered as showing a difference worthy of consideration (small = 0.2 to 0.59, moderate 0.6 to 1.19 and large $\geq$1.2 [1]).

RESULTS AND DISCUSSION

The peak ground reaction force, impulse, and peak joint reaction forces for the ankle, knee and hip are summarized in Table 1. The FA technique had the lowest external (ground) and internal (ankle, hip joint) forces. On average, however, the landing impulse was the same for the SB and FA techniques, which were lower than for the FT technique. Small differences (effects) were identified between the FA technique and both the FT (ES: Peak Force = -0.299, Hip Force = -0.213) and SB (ES: Peak Force = 0.292, Hip Force = 0.249) techniques for peak ground reaction force and the hip joint reaction force. Small differences were also identified between the FT and both the SB (ES = 0.335) and FA (ES = 0.389) techniques for impulse. A small difference was identified between the FA and SB techniques for the ankle joint reaction force (ES = -0.235).

Table 1: The ground (external) and joint (internal) reaction forces for gymnastics landings with three foot positions.

Measure	Feet Together		Step Back		Feet Apart	
	M	SD	M	SD	M	SD
Peak Force (BW) [2,3]	13.42	2.17	14.21	3.86	12.98	4.55
Impulse (BW.s) [1,3]	0.86	0.12	0.82	0.24	0.82	0.28
Ankle Joint Reaction Force (BW) [2]	7.22	7.77	7.83	6.01	6.78	7.14
Knee Joint Reaction Force (BW)	7.25	6.69	6.52	5.42	6.01	6.04
Hip Joint Reaction Force (BW) [2,3]	7.29	5.19	6.54	3.38	6.04	4.26

Notes: M and SD denotes mean and standard deviation respectively. Small effects are indicated as [1]between SB and FT, [2]between FA and SB, and [3]between FT and FA.

CONCLUSIONS

This study showed that the sports rules in artistic gymnastics that govern foot position during landings after an apparatus dismount, affect the external and internal loading patterns on the gymnast's body. In other sports such as basketball and volleyball, athletes typically land with their feet apart. It was revealed that landing with the feet positioned shoulder width apart generally resulted in lower external ground reaction forces and internal reaction forces, especially for the hip joint. Lower hip joint reactions may be desirable in gymnastics due to their potential relationship with hip and lower back injury.

STRATEGIES USED TO INCREASE ANGULAR IMPULSE GENERATION: DOUBLE TO TRIPLE TURNS

[1] **Antonia M Zaferiou**, [2]Jill L McNitt-Gray
[1]Rush University Medical Center, Chicago, IL, USA
[2]University of Southern California, Los Angeles, CA, USA
Corresponding author email: Antonia_Zaferiou@rush.edu

INTRODUCTION

Pirouettes are fundamental turns performed in ballet dance that can be performed as single or multiple body rotations [1,2]. Mechanically, there are many ways to accomplish a larger number of whole-body rotations about a vertical axis (e.g., via increasing the magnitude of the horizontal ground reaction force (|RFh|), position vector length (|rcm|), changing the direction of the RFh in order to increase sinθ, etc.) [1].

We expected that the strategies dancers used to increase angular impulse generated from double to triple rotations would be the same as the strategy used from single to double rotations (at a within-subject basis).

METHODS

Skilled dancers (n=9) volunteered to participate and provided informed consent. These dancers performed single, double, and triple pirouettes. The pirouettes were initiated in a stationary "fourth position" with each foot supported by a forceplate (Kistler, 1200Hz). The phase of interest in this study was the turn initiation phase, during which, dancers generate the linear and angular impulse required during the turn phase immediately following. Music with 81+/-1 bpm was used to standardize the initiation phase duration [1,2].

Segment kinematics were captured using a custom marker-set that enabled estimation of the initial total body center of mass (Optitrack, 100Hz) [3]. The impulse-momentum relationship was used to calculate the total body center of mass trajectory, which was used in order to calculate the angular impulse generated. To study the mechanisms used to increase the moment applied at each leg about a vertical axis through the total body center of mass, the variables contributing to the moment applied by the horizontal reaction force were quantified during a subphase of each leg's ground contact time before each leg's peak moment. This subphase was defined as the 25% turn initiation phase duration before the peak moment [2].

Within-subject non-parametric statistical methods were used in order to see if each dancer increased the angular impulse from double to triple turns in the way that she increased it from single to double turns. Cliff's analog of the Wilcoxon-Mann-Whitney test and a step-down Fisher-type analysis was performed using R software (R-project) [1,2].

RESULTS AND DISCUSSION

Five dancers increased the angular impulse and moment generated by at least one leg during initiation of a triple vs. double turn, however all dancers did so during initiation of a double vs. single turn (Figure 1). Only two dancers increased the magnitude of the horizontal reaction force and no one increased sinθ from double to triple turns (compared to eight and five, respectively, from single to double turns). Interestingly, one dancer (subject 9) switched from generating more angular impulse with her turn leg during singles and doubles to predominantly generating angular impulse with her push leg, via increases in the position vector length. Even though music with a constrained tempo was used to standardize the turn initiation phase duration, the turn phase duration tended to be greater with increased rotational demand, which could enable dancers to generate similar amounts of angular impulse between turn types.

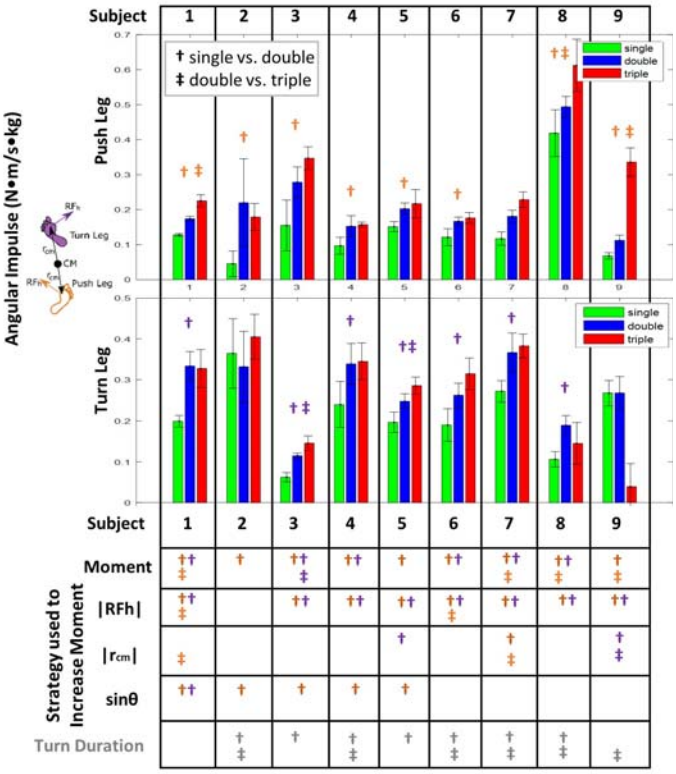

Figure 1: Bargraphs of the mean (SD) angular impulse generated by the push and turn leg per subject during the initiation of single (green), double (blue), and triple (red) pirouette turns. Statistically-significant differences in each variable between single and double turns are denoted with "†" and those found between double and triple turns are denoted with "‡" at the push leg (orange) and turn leg (purple). The bottom portion of the figure displays these symbols if there were statistically-significant increases in the following: moment, horizontal reaction force magnitude (RFh), position vector length (rcm), sinθ, or the turn phase duration.

CONCLUSIONS

These strategy-related findings can assist development of dance training technology and guidelines and advance our understanding of turning mechanics. Furthermore, this approach can be used to study how other types of turns are accomplished, such as gait redirection or cutting maneuvers.

INVOLVEMENT OF ELASTIC ENERGY OF PARALLEL BARS FOR ARTISTIC GYMNASTIC ELEMENTS

[1] **Chandana A.W.S**, [2]Wangang L, [3]Mingnong Y, and [4]Xubo W
[1]Sabaragamuwa University of Sri Lanka
[1,2,3,4]Wuhan Sport University

INTRODUCTION

The gymnast gains kinetic energy swing down from handstand position to hanging elements on the bars. Hence a considerable part of elastic energy is transmitted to the flexible bars as they bend in response to the gymnast's body shapes and positions. Dynamic simulations for High Bar movements and Parallel Bar movements with bar strain indicate that gymnast utilizes the dynamic strain of the bars to complete movements on bars [1,2,4]. Player can bend the flexible wooden bars to gain maximum amount of elastic energy when the player reaches the right bottom position of the movement. A part of this elastic energy causes to lift the player to complete long swing double tucked saltos on bars to upper arm support.

In this research, we observed the special vibration pattern of wooden parallel bars and metal posts after releasing the hands. This vibration patterns represent the correct force application and body positions to minimize the execution errors of the long swing double tucked saltos on bars to upper arm support.

METHODS

The mass 50kg player performed 4 repetitions of 'Long swing double tucked saltos on the bars to upper arm support'. The static stiffness constants of wooden bars were calculated using static force-displacement measurements of middle point of wooden bars and those consistent with International Gymnastic Federation's apparatus testing procedure [3]. Synchronized ten ViconT40(100Hz) camera set up and 14 mm reflective markers system were used to capture the dynamic movements of parallel bars and player. Hence observed coordinates of relevant markers throughout dynamic movements and calculated kinematic and kinetic values using Matlab R2014b software.

The Player started elements with four different phases such that changing the direction, place of the bars and initial shape of the body. Dynamic movements of middle points of the bars, tops of the metal posts and makers on the player's body were observed.

RESULTS AND DISCUSSION

Figure 1 represents 8 phases of the movement pattern of the long swing double tucked saltos to upper arm support. Phase AB indicates that player starts the element with stable steady handstand position on the middle point of the parallel bars. In this phase, player pulls and pushes the bars to swing down. Player reaches the horizontal position near to the point B and gains some elastic energy from the bars and reaches the bottom of the swing at the point C (34mm from neutral position of the bars) in the figure. At the point D, player starts to release his hands from the bars and completely releases the bars at point E. The phase EF:

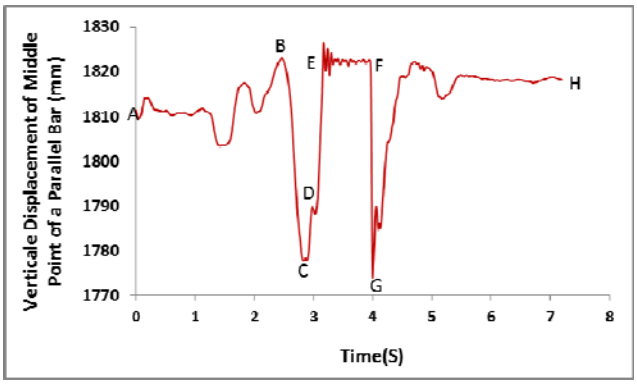

Figure 1: Vertical displacement of the middle point of the wooden bar corresponding to the movement pattern of the long swing double tucked saltos to upper arm support.

Player is completing his rotations independent of parallel bars. If player can apply specific force at the releasing phase, we show that the middle point of the bars vibrates according to the natural frequency (16.6Hz). In this situation, player performed this particular element without any execution errors. At the point F, player starts to land on the bars with upper arm support and completes the element at the point H with complete equilibrium passion of the handstand on the bars.

CONCLUSIONS

Complete released element such as long swing double tucked elements on the bars can be performed artistically without execution errors if player can apply the right force to generate natural frequency of the parallel bars.

ACKNOWLEDGEMENTS

This study was supported by the President and research team of the sports science Labotarary in Wuhan Sports University, China. I would like to thank to Gymnastic Olympic Champion (2008) Mr Yang Wei for his valuable comments on elastic energy of parallel bars.

INTRODUCTION

The barbell deadlift is a common resistance training exercise that has been utilized primarily by athletes to elicit muscular adaptations in strength, power and hypertrophy. Recently, this exercise is gaining popularity in clinical settings for its effectiveness in restoring motor function and increasing bone mineral density [1,2]. As understanding the stresses of this exercise is important in addressing its safety and efficacy, it is critical to understand the kinetic effects that different deadlift techniques impose on the joints. Two common deadlift techniques are the low-hip deadlift (LHDL) and the high-hip deadlift (HHDL). The techniques differ in the starting position of the bar relative to the foot (subsequently altering shank and torso angle) such that the bar is positioned over the metatarsal-phalangeal joints for the LHDL and over the navicular bone for the HHDL. Significant differences between these techniques has been shown for horizontal bar displacement [3]. This suggests that additional kinematic and kinetic differences may exist but this has yet to be examined.

The primary purpose of this research study was to compare differences in peak knee, hip and L5-S1 joint moments between LHDL and HHDL. It was hypothesized that, due to the difference between techniques in initial bar placement, torso and shank positions between the techniques, the HHDL would create a significantly lower moment at the knee but a larger moment at the hip and L5-S1 joints in comparison to the LHDL.

METHODS

Ten healthy adults participated in this research study (age: 24.3 ± 3.1 years; height: 176 ± 6.1 cm; weight: 97.2 ± 19.6 kg; sex: 8 males). Eight participants were competitive powerlifters and two were competitive weightlifters with 2 to 12 years of lifting experience. All participants had competed in their respective sports within the past year.

Prior to testing, each participant performed a warm-up of light aerobic exercise, dynamic stretching, and progressive deadlifts up to 65% of their self-reported one repetition maximum (1RM). Each participant then performed the LHDL and HHDL in a randomized order for three sets of a single repetitions at 85% of their deadlift 1RM. Rest periods were allowed between lifts. The technique was standardized based on a published protocol [3].

Kinematic data were collected for all trials using a 3D motion capture system (VICON, Centennial, CO, fs=100Hz) with 44 reflective markers. Hip centers were estimated using published regression equations [4]. The virtual location of the L5-S1 joint was estimated from standing at the vertical level of the posterior superior iliac spine (PSIS) and anteriorly half-way between the PSIS and hips and tracked using pelvis markers. Kinetic data were simultaneously collected using two in-ground force plates (OR6-7, AMTI, Watertown, MA, fs=2000Hz). The kinematic and kinetic data were then used to calculate joint moments at the knee, hip and L5-S1 joint using standard inverse dynamics techniques via custom routines written in Matlab (v2006b, Mathworks, Natick, MA). Knee and hip joint moments were averaged across both limbs and all moments were normalized to total weight (body + weights) x height. Peak sagittal extensor moments during the lift were selected. Statistical analysis was completed using SPSS software (version 24). All measures were compared between conditions using a dependent samples *t*-test (α = 0.05).

RESULTS AND DISCUSSION

The starting position of the body segments were significantly different between techniques with the torso angle greater (more horizontal) at the start of the HHDL condition (71.4° vs 63.8°, p=<0.001) and shank angle greater (more horizontal) at the start of the LHDL condition, (20.8° vs 11.4°, p=<0.001). No significant differences between lifting conditions were seen for hip extensor (p=0.177) and L5-S1 extensor moments (p=0.563). Knee extensor moments were significantly greater during the LHDL in comparison to the HHDL (p=<0.001) (Figure 1). Therefore, the hypothesis was only partially supported.

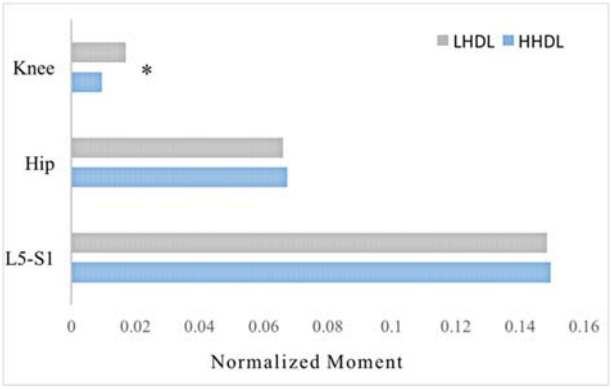

Figure 1: A comparison between peak knee, hip and L5-S1 moments during the LHDL and HHDL. * indicates significant difference between LHDL and HHDL

All moments peaked during the initial 12% of lift ascent, inferring this is the most demanding portion of the lift on all joints. Results from this study suggest that changing torso and shank angle during the initial deadlift pull alters the knee moment while moments at the hip and L5-S1 joint remain unchanged.

CONCLUSIONS

Findings from this study support the notion that the HHDL technique should be desired when attempting to minimize stress at the knee joint. More importantly, results suggest that altering shank and torso angle is not an effective approach to reducing moments generated at the low back.

SWIMMING PERFORMANCE ANALYSIS WITH INERTIAL MEASUREMENT UNITS

INTRODUCTION

Swimming is a sport in which motion analysis can have a significant impact on. The importance of precise training is highlighted by minute time gaps in international competitions.

The most sophisticated systems available for tracking and improving swimmer performances at present are implemented with multiple cameras and markers [1] or only a set of cameras [2]. Refraction under water can affect the accuracy of these systems. These sophisticated and often expensive camera systems are less affordable and inaccessible to the average swimmer and coach. Inertial Measurement Units (IMU) technology using wearable sensors has been an alternative solution due to portability and affordability.

More recently, Inertial Measurement Units have been used in obtaining swimmer parameters or more directly relatable measurements associated with performance [3]. The contribution of these to improving critical parameters is somewhat limited improvements can be made by proper examination of the 3D kinematics of a swimmer.

This paper focuses on the identification and application of Micro Electromechanical Systems with IMUs to obtain swimmer parameters for front crawl and for 3D motion reconstruction.

METHODS

The sensing system consists of 11 motion tracking devices placed as in **Figure 1**(a). Since the wireless communication is highly distorted under water, the network of the sensor modules was done as a "wired swimming suite". Also because of the maximum bus length of an Inter-integrated circuit (I^2C) link is less than 1 meter, an I^2C extender is used in each sensor module. As the sensor modules should be waterproofed, the fabricated PCBs which consist of IMU sensors and I^2C extenders were sealed using a silicon sealant. Then the waterproofed sensor modules were placed in a swimming suite. The sensing system is powered by a 2000mAh Lithium Ion Polymer battery which is capable of powering the sensing system for 2h.

The data processing algorithm of the system uses accelerometer, gyroscope and magnetometer readings as raw input data and stores them in a database after data fusion. These fused data are then converted into quaternions, which represent the orientation of each limb of the swimmer. The software backend of the application is capable of calculating any joint angle using quaternions, such as elbow flexion/extension, shoulder flexion/extension, shoulder abduct/adduct, shoulder internal rotation/external rotation. as well as the overall orientation of the body also can be analyzed using this application. Additionally, the 3D reconstruction of the swimmer's motion shown in **Figure 1**(b), was developed as a real-time standalone software application.

The 3D post-reconstruction of the swimmer's performance using the software enables coaches to offer better feedback. The tool can also provide and analyze the breathing pattern, kick pattern and stroke pattern which are important performance measurements. In addition, patterns of pitch and roll angle variations too can be observed.

Swimmers were clustered into elite, average or novice categories based on their performances. Data related to the full body motion of the swimmer, was collected and stored.

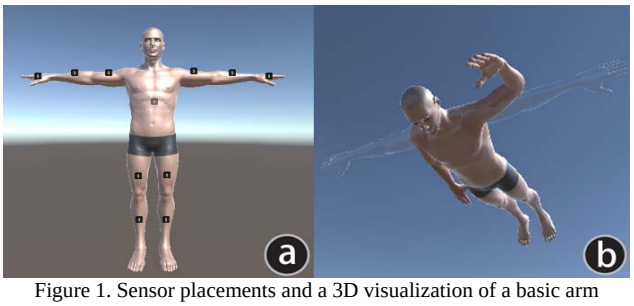

Figure 1. Sensor placements and a 3D visualization of a basic arm movement

RESULTS AND DISCUSSION

The sensing system for the arms, sense data at a rate of 33Hz, which is sufficient to sample the arm movements of a swimmer which takes a minimum time of 0.75s to complete one stroke. The tool which comprises of the sensor kit and a standalone application with a graphical user interface is capable of measuring any joint angle including elbow angle, which is ideally 110^0 - 120^0 in front crawl. In addition, it can measure the pitch angle representing body balancing and the roll angle representing body rotation.

Upon application to swimmers, elite and novice, distinguishable differences were observed. According to experimental results an elite swimmer has a body balancing angle of $7^0 \pm 7^0$. The roll angle of an elite swimmer varies consistently between $\pm 80^0$ while swimming. The roll angle of novice swimmers varies between $\pm 50^0$ and it's not consistent.

CONCLUSIONS

Experimental results show that the swimming performance could be improved based on the above factors. Therefore, this system which can evaluate above parameters can be used as a performance evaluating mechanism in swimming coaching.

BILATERAL COORDINATION, VARIABILITY AND ASYMMETRY OF GAIT: ARE DIFFERENT IN WOMEN AND MEN WITH FIBROMYALGIA?

Jose Heredia-Jimenez, Eva Orantes Gonzalez

[1]University of Granada, Spain.

Corresponding author email: herediaj@ugr.es

INTRODUCTION

In fibromyalgia (FM) patients, the gait analysis provided useful information about pain tolerance and physical status [1]. Gait asymmetry, variability of gait and bilateral coordination of gait had shown different values in a patient with a motor movement disease and healthy subjects.

A previous study concluded that women with FM showed higher gait variability and bilateral gait coordination than healthy women [2]. However, no previous studies had included men in the analyzed sample.

To clarify the effects of FM in gait disorders in men and women, the present study compares bilateral coordination, variability and asymmetry of gait in women and men with FM.

METHODS

We analyzed 15 women with FM (age 47.2±8.8 years; height, 1.62± 0.10 m; body weight, 70.3± 14.8 kg) and 10 men with FM (age, 46.8±9.6 years; height, 1.74±0.10 m; body weight, 83.1± 7.5 kg); who met the American College of Rheumatology´s criteria for fibromyalgia. All participants were volunteers and they provided informed consent to participate in the study.

Participants walked five trials at self-selected speeds along 18.6 m of walkway. A GAITRite mat (GAITRite system; CIRSystems Inc.,Clifton, USA) was positioned in the middle of the walkway to avoid acceleration and deceleration walking periods. Before that, participants completed a familiarization period.

Velocity in both groups was normalized. The variability of gait was computed using the equations proposed by Hausdorff et al. [3]: Coefficient of variation (CV) of swing time, CV of stance time, CV of step time and step width. The bilateral coordination of gait was measured through the relationship between the step timing of the left and right legs [4]. Besides, the gait asymmetry (GA) was analyzed through the ratios, indexes, and GA of swing time and stance time according to the equations of Patterson et al. [23].

Normality of data was conducted with Shapiro Wilk test. Unpaired t-test (parametric variables) or Mann–Whitney test (non-parametric variables) were used to compare gait parameters between groups.

RESULTS AND DISCUSSION

Normalized velocity was similar in both groups (FM women: 0.28 $\pm$ 0.05 dimensionless; FM men: 0.28 $\pm$ 0.04 dimensionless). Any of the parameters analyzed related with variability of gait, bilateral coordination and symmetry values of gait showed significant differences between women and men with FM (Table 1).

	WOMEN	MEN	p value
COEFFICCIENT OF VARIATION			
CV Swing time (%)	4.92 (0.24)	4.46 (0.32)	NS
CV Stance time (%)	3.77 (0.17)	3.51 (0.33)	NS
CV Step time (%)	3.99 (0.16)	3.52 (0.32)	NS
CV Step width (%)	3.38 (0.20)	2.74 (0.22)	NS
BILATERAL COORDINATION			
Phase (degrees)	180.2 (0.05)	180.5 (0.16)	NS
Phase_ABS (degrees)	2.15 (0.23)	2.10 (0.41)	NS
Phase_CV (%)	2.59 (0.09)	2.46 (0.19)	NS
PCI (%)	3.78 (0.19)	3.63 (0.36)	NS
SYMMETRY PARAMETERS			
Swing time ratio	3.31 (0.50)	2.83 (0.65)	NS
Swing time GA	3.31 (0.50)	2.83 (0.65)	NS
Swing time index	3.30 (0.50)	2.83 (0.65)	NS
Stance time ratio	1.02 (0.002)	1.02 (0.002)	NS
Stance time GA	1.73 (0.23)	1.84 (0.28)	NS
Stance time index	1.73 (0.25)	1.84 (0.28)	NS
Swing/Stance ratio	1.05 (0.01)	1.05 (0.01)	NS
Swing/Stance GA	4.90 (0.74)	4.67 (0.90)	NS
Swing/Stance index	4.89 (0.74)	4.67 (0.90)	NS

FM: fibromyalgia, CV: coefficient of variation, PCI: phase coordination index, GA: gait asymmetry.

Table 1. Variability of gait, bilateral coordination and symmetry values of gait between women and men with FM expressed as mean (standard deviation).

Although previous authors have shown contradictory results of the impact of FM in men and women in parameters such as pain level perception or fatigue, in bilateral coordination, variability and GA, both groups were affected in the same way walking at self-selected speeds.

A previous study compared women with FM and healthy women, obtained higher differences in the gait parameters analyzed in this study when women were walking at fast speeds [2]. So for future studies, a higher of velocity could be included in the study to determine if bilateral coordination of gait, variability and GA is different in men and women with FM.

CONCLUSIONS

Men and women with FM did not report different values of bilateral coordination of gait, variability and GA walking at self-selected velocity.

AGEING EFFECT ON SWING-LIMB CONTROL USING THE UNCONTROLLED MANIFOLD HYPOTHESIS

[1]Simon Taylor, [1]Daniel Lai and [1]Rezaul Begg
[1] ISEAL - Victoria University, Melbourne

Corresponding author email: simon.taylor@vu.edu.au

INTRODUCTION

Control of toe clearance and step placement is shared by kinematic organization between the stance and swing limb [1]. Evaluating control of the vertical and horizontal dimension of the swing limb is addressed through the concept of synergies and motor redundancy [2]. Natural perturbations during steady-state walking appear to be monitored by a hierarchical locomotor control system [3]. Understanding the way the control system organizes the structure of kinematic variability within the swing limb effector system can help gait retraining methods that are designed to facilitate adaptable gait patterns in clinical groups at risk of falls [4].

The Uncontrolled Manifold hypothesis (UCM) quantifies synergies using geometric relationship that maps element variables with a goal variable. A geometric manifold is defined in the space of segment angles, representing when covariation of elemental variables meets a task-relevant goal. Combinations of elemental variables that map points parallel to the manifold reflect redundancy in the task (i.e. goal-equivalent variance). Alternatively, the set of points orthogonal to the manifold plane reflect non-goal equivalent variance. The synergy strength of an effector is based on the structure of the variance about the manifold, defined by the ratio of goal-equivalent and non-goal equivalent variance (UCM_{ratio}). The UCM theory expects that a relatively higher UCM_{ratio} (>>1.0) reflects task stability, requiring relatively less control intervention [5]. We examine the effect of 1) age and 2) effect of response to change effector length on the UCM_{ratio}.

METHODS

28 healthy elderly and 28 healthy young participants completed 10 minutes of treadmill walking at preferred speed. 3D kinematic data of lower limb segments were collected from 9-camera OPTOTRAK CERTUS system (NDI, Waterloo, Canada). Kinematic data from the swing limb was exported and processed in Visual3D (C-Motion, USA). All kinematic signals were time-normalized to the swing phase: this included vertical and fore-aft dimensions of a swing-limb effector (vector from hip to distal toe); sagittal plane segment angles of the foot, shank and thigh; vertical trajectory of the toe. Segment lengths were obtained from model reconstruction in Visual3D. Two successive events derived from the sinusoidal trajectory of the vertical toe position, first maximum (MX1) and minimum (MTC), were used as reference states for defining four state-relevant time slices (from MX1+6% to MTC-6%, Figure 1). According to the change in vertical length of the swing-limb effector between MX1 and MTC, each swing phase cycle was classified into one of three sub-groups (strong, moderate, weak) that reflected the strength of the response to initial condition of effector length at MX1. The method of the Uncontrolled Manifold hypothesis was applied at the four state-relevant time slices, using input from segment angles and segment lengths [5]. A mixed ANOVA assessed main effects and interactions of age and response during the critical mid-swing period between MX1 and MTC.

RESULTS AND DISCUSSION

The synergy parameter UCM_{ratio} was significantly greater than 1 for both young and elderly groups ($p < .001$). There was a significant main effect for response ($p < .05$). There was a significant interaction of age and state on UCM_{ratio} ($p < .05$). There was a significant interaction of response (comparing between weak and moderate) and state on UCM_{ratio} ($p < .05$).

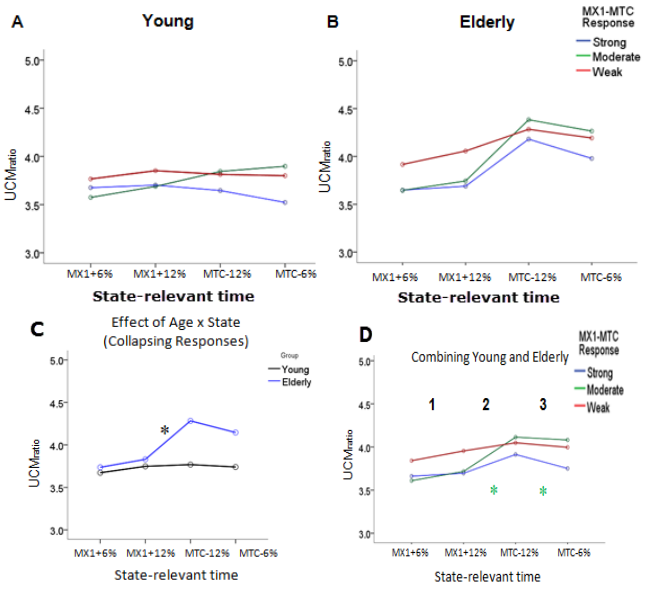

Figure 1: UCM_{ratio} of the vertical dimension of swing limb effector. A) & B) profiles for UCM_{ratio} for young and elderly across states and response types; C) interaction of age and time (collapsing response data); D) interaction of response and time (collapsing age data).

Ageing affects the synergy of the swing limb, which increases as mid-swing approaches. For the elderly, the length of the swing limb is invariant to perturbations in segment angles. Consistent with minimum intervention principle of UCM hypothesis, a 'strong' change to limb length is associated with weaker synergies [5].

CONCLUSIONS

Toe clearance control is important to reduce falls risk in elderly population. This study shows that ageing may be associated with less intervention to control the swing limb length as the MTC event approaches. Future work will need to assess if this is beneficial, or problematic, for reducing the risk of tripping.

THE IMPACT OF JOINT KINEMATICS RELIABILITY ON THE INTERSESSION AGREEMENT AND RELIABILITY OF GLOBAL GAIT SYMMETRY INDICES

[1] **Silvia Cabral**, [1,2] Rita Fernandes, [1] Vera Moniz-Pereira, [3] W Scott Selbie and [1]António P Veloso
[1] LBMF, CIPER, Faculdade Motricidade Humana, Universidade de Lisboa, Portugal

INTRODUCTION

Clinical implications of an asymmetric gait pattern led to our interest in restoring gait symmetry in clinical populations. Our initial goal was to develop a symmetry index that provides a comprehensive representation of the patient's symmetry based on the differences between bilateral lower limb and trunk kinematics. We developed, and tested experimentally, a global gait symmetry index (GGA) that was successful at distinguishing artificially induced asymmetry on a group level [1]. Unfortunately, in a follow up study the GGA demonstrated poor intersession repeatability and reliability [2]. In hopes of improving the repeatability and reliability, we removed potentially unreliable joint angle components from the GGA. For example, non-sagittal plane kinematics are accepted to be less reliable, and are thus excluded from popular gait indices such as the AsymGPS [3] (a global symmetry index which only includes sagittal plane kinematics of the knee and ankle), the GDI [4] and GPS [5]. The aim of this study was to verify whether intersession agreement and reliability of the GGA is affected by the inclusion of non-sagittal plane joint kinematics.

METHODS

Twenty three healthy adults (age, 34.8 ± 7.3 years; mass, 66.4 ± 9.2 Kg; height, 1.70 ± 0.07 m) provided informed consent and underwent two gait analyses, performed approximately one week apart. Kinematic data were collected at 200 Hz using markers and 13 cameras (Qualisys Oqus), and an eight-segment 6 DOF model was built (Visual3D, C-Motion). Symmetry was quantified using two indices: the GGA, which included 15 angular components (all three components of the hip, knee and ankle joints, as well as trunk-pelvis and pelvis-lab angles) and a variation of GGA (GGA_GPS), which included the nine angular components typically used in other indices (three components of the pelvis-lab and hip angles, the sagittal components of the knee and ankle and foot progression angle). Both indices were computed thus:

$$GGA = \sum_{i=1}^{N} \sqrt{\sum_{t=0}^{100} [l_{i,t} - r_{i,t}]^2}$$

, where i represents the angle components described above and $l_{i,t}$ and $r_{i,t}$ are the values of these angles obtained for the left and right sides, respectively, at each percent of the time normalised gait cycle (101 points).

More details on marker placement, modelling and data processing can be found elsewhere [2]. Intersession agreement and reliability were assessed based on the 95% Limits of Agreement (95% LOA), the standard error of the measurement (SEM), the minimal detectable change (MDC) and the intraclass correlation coefficient ($ICC_{c,k}$) (for the equations used see Cabral et al [2]). All data were processed and analysed in Visual 3D 5, SPSS 21 and MS Excel 2010.

RESULTS AND DISCUSSION

The intersession agreement and reliability of GGA and GGA_GPS were similar, being both very poor (Table 1). Surprisingly, the GGA_GPS was slightly less repeatable than the GGA, despite it not including non-sagittal plane kinematic variables. This suggests that inclusion of the non-sagittal plane components of joint angles did not have a detrimental effect on the index's function. The GGA, therefore, need not disregard what may be important kinematic asymmetries in the frontal and transverse planes [2], but the source of the poor intersession agreement is still unknown.

Table 1: Intersession agreement and reliability

Index	Mean	Diff (%)	SD_{diff} (%)	95% LOA (%)	SEM (%)	MDC (%)	ICC	95% IC_{ICC}
GGA	612	14 (2.3%)	194 (31.7%)	-366 to 394 (-59.8% to 64.4%)	137 (22.4%)	380 (62.1%)	0.30	-0.65 to 0.70
GGA_GPS	354	34 (9.6%)	141 (39.8%)	-243 to 310 (-68.6% to 87.6%)	100 (28.2%)	277 (78.1%)	-0.06	-1.49 to 0.55

CONCLUSIONS

The inclusion of potentially less reliable, non-sagittal plane joint angle components does not cause poor intersessional agreement of the GGA. Further refinements of the GGA, which are underway, have shown preliminary promise.

CORTICAL CONTROL OF OVERGROUND AND TREADMILL WALKING

[1] **Luisa Roeder**, [2]Tjeerd W Boonstra, [3]Simon S Smith, [1]Ian B Stewart, [1]Graham Kerr
[1] Queensland University of Technology
[2] University of New South Wales
[3] University of Queensland

INTRODUCTION

Synchronization of oscillatory activity amongst cortical neurons and along corticospinal pathways during locomotion indicates cortical control of human gait [1,2,3]. However, the temporal and frequency characteristics, their relationship and task-dependencies, and afferent/efferent components of corticospinal interactions are poorly understood.

METHODS

We investigated event-related cortical power, corticomuscular coherence (CMC), and the corresponding phase spectra during treadmill and overground walking in 22 healthy, young adults. Participants walked at their preferred speed (4.2, SD 0.4 km h^{-1}), which was matched across both gait conditions. Electroencepahlography (EEG) was recorded from 10 cortical sites according to the international 10-20 system, electromyography (EMG) from two leg muscles (tibialis anterior left/right) and temporal gait cycle events via foot switches. Time-dependent CMC relative to heel strike was assessed between EEG from bilateral sensorimotor cortices and EMG from the contralateral tibialis anterior (TA) muscle.

RESULTS AND DISCUSSION

Motor cortical power and CMC at beta frequencies (13-30 Hz) were increased during the double support phase of the gait cycle for both overground and treadmill walking. High beta (21-30 Hz) cortical power during double support was significantly increased during overground compared to treadmill walking. The phase spectra revealed a time lag of ~15 ms from EEG to EMG, indicating that corticospinal interactions at beta frequencies were governed by efferent activity.

Phasic modulation of beta-band synchronization indicates that cortical control of human gait is not continuous but confined to the double support phase of the gait cycle. We interpret these findings within a Bayesian framework of motor control suggesting that beta-band synchronization may provide a mechanism for coding prediction errors during walking.

CONCLUSIONS

Frequency-band-dependent differences in cortical synchronization between overground and treadmill walking suggest altered cortical control for the two gait modalities, emphasising the task-dependent sensitivity of cortical processes during walking in humans.

INTRODUCTION

The determination of gait variability is both a standard as well as sensitive approach for identifying and assessing individuals with mobility impairments, such as in patients with Parkinson's disease or multiple sclerosis. However, nonlinear approaches that are able to account for the dynamic nature of human locomotion might be more suitable in quantifying an individual's intrinsic ability to compensate natural external perturbations during walking and thus prevent falling [1, 2]. Here, use of the largest Lyapunov exponent (LyE) has increased in popularity as the approach assumes inter-stride dependence during continuous walking [3]. One important obstacle hindering exploration of the dynamic nature within walking however, is the requirement for large and continuous sets of consecutive gait cycles [4], which are difficult to capture in lab settings without discontinuities due to turning etc. While motorized treadmills are generally used to overcome this issue, they lead to non-physiological walking patterns due to their fixed walking speed. This paper therefore describes a novel approach to concatenate discontinuous sets of time-series collected using standard walking protocols, in order to yield a single large time-series with continuous sets of consecutive gait cycles, which is then appropriate for applying nonlinear methods for evaluating the dynamic nature of walking. Finally, in order to test the effectiveness of the concatenation approach, LyE was evaluated using concatenated time series obtained from multiple short series of walking under different bodyweight (perturbation) conditions.

METHODS

Twenty healthy subjects performed five walking trials (each 5 mins) on a treadmill under different weight conditions at self-selected walking speeds. Perturbation conditions were chosen to be *+40% bodyweight (W40), +20% bodyweight (W20), 0% bodyweight with harness (H00), -20% bodyweight (H20) and -40% bodyweight (H40), which were compared to baseline (N00).* The resulting time series were separated into **three different sets of shorter time series (STS)**. Those sets of STSs were then concatenated using an algorithm that is based on pose identification and matching. LyE were then calculated for the raw z-position (vertical) of the right heel marker in all time series (5-minute raw time series vs concatenated STSs). **Mixed factor ANOVA** was used to compare the effects of concatenation as well as weight-perturbation on the resulting LyEs.

RESULTS AND DISCUSSION

Mixed factor ANOVA showed significant differences between bodyweight conditions (p<0.001) as well as between different concatenated STS (p<0.001). The interaction of bodyweight conditions and the different concatenation trials, however, was not significant (p=0.138). A comparison of mean LyE (Figure 1) illustrated that conditions with the addition of external weight led to the largest divergence at the heel during walking. Furthermore, concatenation led to a magnification of divergence between cycles with shorter series leading to larger divergence.

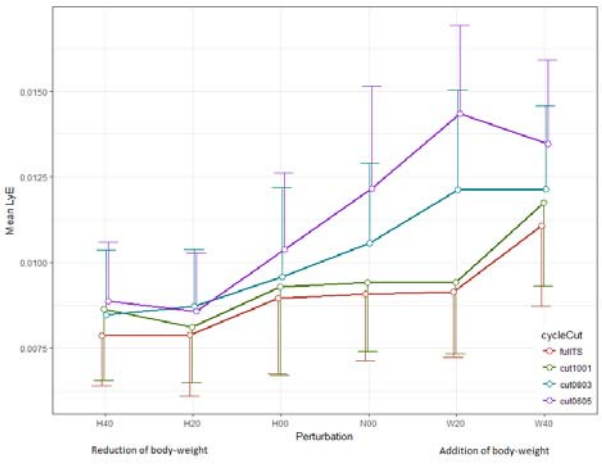

Figure 1: Mean value comparison of LyE for all perturbation conditions and different concatenated STS. The entire 5 min time series (fullTS in red) was compared with STSs including 10 intact consecutive cycles (cut1001 excluding 1 cycle every 10 cycles; in green), 8 consecutive cycles (cut0803 excluding 3 cycles every 8 cycles; in blue) and finally 6 consecutive cycles (cut0605 excluding 5 cycles every 6 cycles, in magenta).

CONCLUSIONS

Our results indicate that the proposed concatenation method can reliably be used for the calculation of LyE, however, caution must be exercised in interpreting LyE estimates when large number of consecutive cycles have been excluded (≥80% of the cycles excluded). This concatenation approach allows researchers to use overground walking protocols limited by the field of view, and still apply sophisticated nonlinear analysis approaches. Furthermore, the method not only allows already collected data to be re-analysed, but can also be extended to cross-platform datasets. In this manner overground walking protocols from large datasets (position, accelerometery, etc.) and real-world settings can easily be concatenated to exclude problematic cycles (e.g. data loss due to visibility or hardware-related issues) and used for further analysis and interpretation.

EFFECTS OF BULLET SPEED AND THE DISTANCE BETWEEN SHOT POSITION AND AN ARTERY ON ARTERY RUPTURE PROBABILITY OF A HUMAN THIGH BY GUNSHOT

[1] **Young Nam Jo**, [1]Moon Jeong Kang and [1]Hong Hee Yoo[†]
[1]Hanyang University
[†]Corresponding author email: crux704@korea.com

INTRODUCTION

Gunshot wounds are one of the major injuries of combatants on the battlefield. In Operation Iraq Freedom and Operation Enduring Freedom, about 20% of all injuries were caused by gunshot wounds and over 90% in the civil war [1]. In addition, about 54% of all combat wounds were in the extremities [1]. If someone is shot on their extremities, excessive bleeding due to artery rupture is usually the major cause of death. Therefore, the objective of this study is to conduct gunshot wounds simulation for a human thigh using a finite element method and to predict artery rupture probability depending on bullet speed and the distance between shot position and an artery.

METHODS

In this study, a finite element method was used to predict artery rupture by a gunshot wound. A human thigh including two major arteries was modeled based on human 3D scan data. The model was simplified to conical shape to minimize computational effort assuming that detailed shape of the thigh has little effect on artery rupture. Properties of thigh muscle were assumed to be equal to those of 10% gelatin. Kelvin solid model and Maxwell fluid model were used as linear viscoelastic model. Mie Gruneisen equation of state and Johnson Cook failure model were also used. Explicit solver (ANSYS AUTODYN) was used for finite element simulation. The simulation method was verified by comparing the gelatin penetration analysis results with experimental results [2].

We decided whether the arteries are ruptured or not by comparing analysis results of the artery maximum strain with experimental results of artery yield strain [3]. Artery rupture probability can be calculated from below equation.

$$P = \int_{-\infty}^{x} f_Y(x)\,dx$$

x : maximum strain

f_Y : propability density function of yield strain

Probability density function of artery yield strain is obtained from eighteen yield strain experimental results by the kernel density estimation method.

RESULTS AND DISCUSSION

Artery rupture probabilities depending on the distance between shot position and an artery were obtained (Figure 1). Bullet speed is 345m/s and angular speed is 8400rad/s. As shown in the figure, artery rupture probabilities decreased in the quadratic form as the distance increased. In addition, artery rupture probabilities depending on the bullet speed were obtained (Figure 2). Angular speed of bullet was assumed to be changed at the same rate as the bullet speed. Also in this case, artery rupture probabilities increased in the quadratic form as the bullet speed increased.

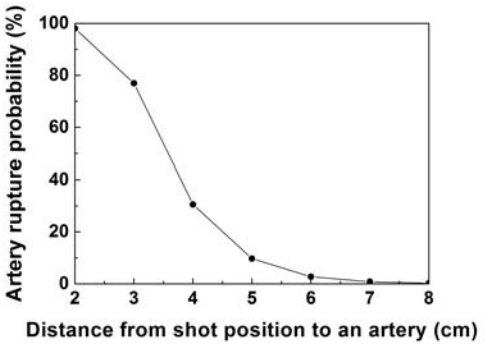

Figure 1: Artery rupture probability vs. distance from shot position to artery.

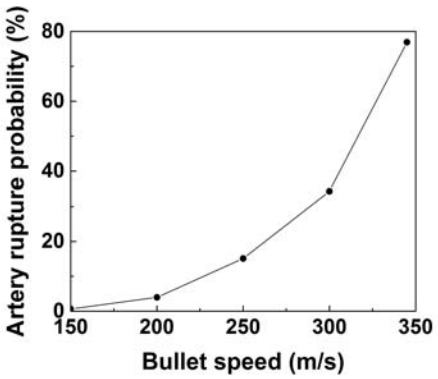

Figure 2: Artery rupture probability vs. bullet speed.

CONCLUSIONS

In this study, the artery rupture probabilities considering various shot location and bullet speed were predicted. However, validation of simulation results is limited because it is impossible to experiment on a human body. But we were able to find out the qualitative characteristics of artery rupture probability depending on gunshot conditions. This research can be used to predict survivability of combatants who perform combat mission though battlefield simulation.

INTRODUCTION

Blood marks analysis is a common technique used in forensics. However, current methods used have their limitations and deviations. The most commonly used trigonometric model is based on the linear movement of a blood drop, which disregards air resistance and gravitational force which affects all mass points in an area of space. Specific physical characteristics of a blood drop after its separation from a larger blood formation determine its spherical shape and typical patterns after impact.

The main goal of this paper is to map the flight trajectory of blood drops in an experimental model with the use of a firearm. These trajectories will be compared with mathematically definable functions and a mutual relation will be established.

METHODS

Blood samples with a volume of 100 ml were placed into a plastic bag and were shot at. The shot and subsequent blood dispersion were filmed by a high speed camera. For the purpose of the experiment was prepared wooden chamber (dimensions: 2 x 2 x 2 m). Blood samples were shot at from a distance of two meters by a Taurus .357 magnum handgun. Video to picture image converter software was used to convert the recorded video into individual images. These images were subsequently processed using GIMP 2.0 software.

According shaped patches may be incident angle backward subtracted. Spot is elongated in the direction from which it came. Line method is the basic method used in determining the origin of blood stains. Based precisely on the directionality of blood stains. Point of convergence is a point or area on a two-dimensional surface, where on the basis of directionality the blood traces directed all around. Determine the angle of incidence on the basis of the blood spots is possible if there is a suitable surface, which prevent it soak in and is not otherwise damaged. Balthazard formula described the incidence angle and the dimension of a blood droplet:

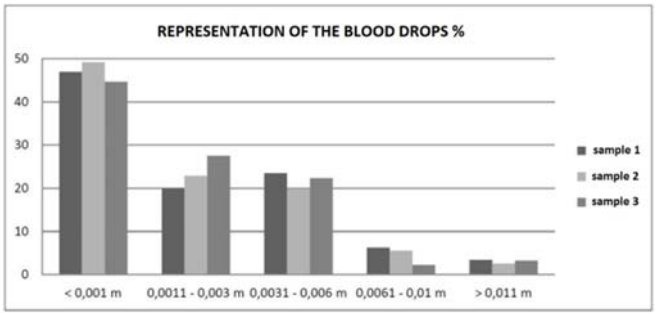
$$\sin \alpha = \frac{W}{L}$$

where **α** is the angle of incidence drops, **W** is the width and **L** is the length of the blood spots.

RESULTS AND DISCUSSION

Based on the physical and experimental models it was determined that the real flight trajectory of blood drops may be defined by a parabolic approximation while maintaining validity for 90 % blood drops. The parabolic approximation does not significantly differ from the ballistic curve and real flight trajectories in cases of lower flight velocities and blood drop sizes of less than 0,5 mm, meaning blood drops located in a distance of less than 0,5 m from the point of origin. From the progression of the curves capturing the flight of blood drops it was ascertained that for the purpose of using trigonometric models, it is best to use bloodstains located less than 1m from the convergence point, the reason being the fact that the deviation caused by the use of the parabolic approximation is minimal and doesn't cross 3 mm. The use of the parabolic approximation with distances of over 2 m leads to deviations of more than 3 mm when compared to reality.

Graph 1. Representation of blood drops by size, calculations were based on the analysis of the sample with the use of GIMP 2.0 software.



CONCLUSIONS

The outcome of these comparisons shows that the real world flight trajectory differs very little from the ballistic curve and parabolic approximation under the given experimental conditions. In crime reconstructions the angle of incidence of a blood drop impacting a horizontal surface plays an important role. In this area the outcomes of the ballistic curve and the parabolic approximation are nearly identical, especially for blood drops with low initial speeds, which constituted the majority under the specific experimental conditions.

DEFORMATION OF ELASTIN AND COLLAGEN FIBERS IN THE AORTIC MEDIA DUE TO CHANGES IN PRESSURE

[1] **Shukei Sugita**, [2]Takeo Matsumoto
[1]Nagoya Institute of Technology
[2]Nagoya University
Corresponding author email: sugita.shukei@nitech.ac.jp

INTRODUCTION

The aortic media comprises two alternating layers: smooth muscle-rich layers (SMLs), which mainly include smooth muscle cells, and elastic laminas (ELs), which are mainly composed of elastin and collagen. The elastic moduli of collagen (approximately 1 GPa [1]) and elastin (approximately 0.6 MPa [1]) are much higher than that of smooth muscle cells (10–100 kPa [2]), and collagen fibers have a wavy shape in low-pressure regions. Thus, elastin and collagen fibers have been considered as the main load-bearing elements at low and high blood pressures, respectively. However, the constituents of ELs and SMLs are different, suggesting that the deformation in ELs due to blood pressure is different from that in SMLs.

Herein, to investigate the deformations of ELs and SMLs and to compare them, we applied pressure to mouse aortas under a two-photon microscope and observed the movement of elastin and collagen fibers, particularly focusing on changes in their waviness.

METHODS

A pressure-imposed test was performed on mouse aorta under a two-photon microscope. After Slc:ddy mice were sacrificed by exposure to carbon dioxide, intercostal arteries were cauterized, and thoracic aortas were resected. The aortas were stretched in the longitudinal direction to their in vivo length, and an intraluminal pressure up to 160 mmHg was applied to the specimen using a syringe pump. Pressurization was stopped at every 20 mmHg, and microscopic images were captured. Microscopic images were captured with a two-photon excited laser scanning microscope (FV1200MPE, Olympus). A laser wavelength of 800 nm was introduced to the specimen, and autofluorescent light of elastin and second harmonic generation light of collagen were detected with a filter set (dichroic mirror, 485 nm; band-pass filter for fluorescence, 495–540 nm; band-pass filter for SHG, 400 ± 5 nm). Images were acquired at 0.5 μm intervals in the light axis.

Image analysis was performed with ImageJ 1.47v (National Institutes of Health). Areas of 30 × 30 μm^2 were selected, and the two-dimensional fast Fourier transform (2D-FFT) technique was applied to the selected images. Because high intensities were observed in the directions perpendicular to the directions of fibers [3], average intensities were calculated in every 10° area. As collagen and elastin fibers in the aortic media tend to align in the circumferential direction of the aorta, the probability distribution of fibers was similar to the normal distribution. Thus, we fitted the Gaussian function to the distribution with the following equation:

$$P = P_{base} + \left(P_{peak} - P_{base}\right)\exp\left\{\frac{-\left(\alpha - \alpha_{average}\right)}{2\sigma^2}\right\}$$

where, P_{base}, P_{peak}, $\alpha_{average}$, and σ are fitting constants. Because we found that lower waviness causes higher P_{peak} values in the probability distributions obtained in the 2D-FFT technique in the preliminary analysis, P_{peak} was used to evaluate changes in the waviness of the fibers.

RESULTS AND DISCUSSION

Typical images of collagen and elastin fibers under low and high pressures are shown in Figure 1. Collagen fibers had a wavy shape in the low-pressure region, and the waviness disappeared with a pressure increase. For collagen fibers, P_{peak} increased with a pressure increase ($p < 0.05$), and P_{peak} in SMLs was significantly higher than that in ELs by 60–120 mmHg, indicating that collagen fibers in SMLs become straight from a lower-pressure region. Images of elastin fibers did not show clear wavy shapes. However, P_{peak} increased only in SMLs with an increase in the pressure, indicating that fibers in SMLs have more circumferential aligned fibers than those in ELs. These results suggested that the aortic media in SMLs stretched more than those in ELs.

More alignment of collagen fibers in SMLs than in ELs may be caused by the difference in stiffness around collagen fibers. Fibers in ELs might be more difficult to become straight due to resistance from surrounding stiff tissues, and those in SMLs might be easier to become straight due to resistance from soft tissues. Furthermore, the aorta might be rotated around the longitudinal axis during changes in blood pressure, resulting in higher shear strain and more stretched fibers in SMLs than in ELs. Our previous study revealed shear strain between layers of the aorta during pressure-dimeter test [4].

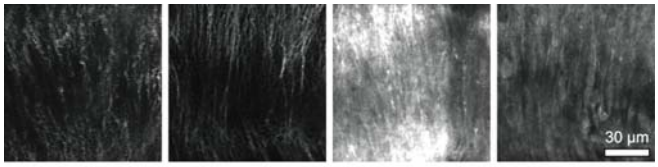

Figure 1: Typical images of elastin and collagen fibers in low and high pressures.

CONCLUSIONS

Deformation of elastin and collagen fibers was seen during pressurization. The alignment index of collagen and collagen fibers revealed that SMLs were more stretched.

BIOMECHANICS OF VASCULAR SMOOTH MUSCLE CELL IN ATHEROSCLEROSIS

[1]Josh Childs, [1]Hanna J. Sanyour, [1]**Zhongkui Hong**
[1]The Department of Biomedical Engineering, University of South Dakota
Corresponding author email: Zhongkui.hong@usd.edu

INTRODUCTION

Despite the therapeutic progress that has been made over the past decades, atherosclerosis still remains the major cause of the cardiovascular disease (CVD)[1]. It is well known that cholesterol accumulation in macrophage-derived foam cells is the principal component of atherosclerotic plaque. However, growing evidences suggests that cholesterol accumulation in vascular smooth muscle cells (VSMCs) is much larger than previously known, and about 40-50% of the total foam cells in the atherosclerotic plaque are VSMC-derived[2]. These macrophage mimicking cells have a reduced ability to remove lipid accumulation, as well as dying cells exacerbating inflammation in the atherosclerotic lesion.

It is also known that cholesterol is not only a major factor involved in fatty deposition in the atherosclerotic lesion, but it also plays an important role as a regulator of cell mechanics, spreading, and migration. A further complication is that the mechanical environment of the vascular wall undergoes progressive stiffening with aging and hypertension, and thereby accelerates the development of atherosclerosis. Therefore, in this study we investigated the combined effect of cholesterol and substrate stiffness on VSMC's functional characteristics such as cell stiffness and adhesion.

METHODS

Male Sprague-Dawley rats were used for this study and were maintained in accordance with the protocol of the Guide for the Care and *Use of Laboratory Animals* (NIH 83-23, revised 1996). All the experimental protocols and use of animals were approved by the Laboratory Animal Use Committee of the University of South Dakota protocol. Rats at 200-250 g were euthanized using regulated Carbon Dioxide delivery. Carbon Dioxide was delivered at a 30% of chamber/cage volume per minute flow rate at a 3 psi for 3 minutes. Death was confirmed by absence of both heart beat and blink reflex. Following euthanization and bilateral pneumothorax, the thoracic aorta was surgically removed and collected.

Two sets of primary VSMCs were established. One set underwent no treatment and were used as controls, while a the second was produced using both Fluvastatin (3R, 5S, 6E) and Methyl-β-cyclodextrin (Sigma-Aldrich, St. Louis MO) to deplete primary VSMCs cholesterol. Primary VSMCs were treated with 1μM fluvastatin supplemented with 10 % FBS medium for 72hrs and kept in a humidified incubator (Thermo Fisher Scientific, Waltham, MA) with 5% CO_2 at 37^0C. In parallel, primary VSMCs were treated with 5mM of Methyl-β-cyclodextrin and for 1 hour and then recovered with serum free medium DMEM/F-12 (Life Technologies, Carlsbad, CA) for another 1 hr.

Cell adhesion was measured for 50-70% confluent cells with atomic force microscope (AFM, Asylum research) system using fibronectin (FN) or N-cadherin coated stylus AFM probes on an at 100 nm/sec retraction speed. Cell stiffness was tested with spherical AFM probe (5μm diameter) at 1 μm/sec indentation speed.

RESULTS AND DISCUSSION

Our results showed that cholesterol depletion significantly increased N-cadherin mediated cell adhesion by ~20% and adhesion probability by ~35%, respectively. While α5β1/FN adhesion force significantly decreased upon membrane cholesterol depletion. Moreover, our results suggested that cholesterol depletion significantly reduced VSMCs stiffness by 47% compared to control cells.

CONCLUSIONS

Taken together, these results reveal that membrane cholesterol is a key regulator of cellular stiffness and integrin/cadherin-mediated cell adhesion. The knowledge that we obtained in this project may lead to a novel therapeutic strategy that could potentially control and block VSMC migration and prevent the formation of atherosclerotic plaque by regulating integrin and/or cadherin mediated cell adhesion.

VISCOELASTICITY OF FASCICLE OF SCIATIC NERVE OF DIABETIC RATS

[1]Cheng-Tao Chang, [2]Chou-Ching K. Lin and [1]**Ming-Shaung Ju**

[1]Dept. of Mechanical Engineering
[2]Dept. of Neurology, College of Medicine and University Hospital
Corresponding author email: msju@mail.ncku.edu.tw

INTRODUCTION

The biomechanical property of peripheral nerves is an important factor of diabetes mellitus induced neuropathy. *In situ* circular compression on rats reveals diabetic sciatic nerve has higher elastic modulus and longer relaxation time than those of the normal nerve [1]. Although hyper-viscoelastic properties of ultra-structures of peripheral nerve can be estimated by combining parallel compression and inversed finite element analyses [2]. However, multiple solutions are often obtained. Therefore, a direct mechanical test on fascicle is believed to solve the problem. The goal of this study was *in vitro* measurement of visco-elasticity of fascicle of sciatic nerves of diabetic rats using atomic force microscopy.

MATERIALS AND METHODS

Four diabetic and three (age matched) normal SD rats (300~350g) were used. Diabetes mellitus was induced by single intraperitoneal injection of streptozotocin when the rats were 8-week old. The rats were then maintained in a hyperglycemic state for 8 weeks. On the day of experiment the rat was anesthetized with an intraperitoneal injection of Zoletil 50 of 0.2 ml. A segment of sciatic nerve of 15 mm long was dissected from the lower limb and placed on a petri-dish coated with type IV collagen. Two micro-needles were employed to tease the nerve into isolated fascicles and the larger fascicle was left on the dish. The fascicle was dried in air over night and 3 ml phosphate-buffered saline (PBS) was redropped into the dish before the experiment.

An atomic force microscope (Agilent 5500 AFM system) was employed to scan the fascicle surface in liquid phase by contact mode with a contact force of 0.6~0.8 nN. Then a tip-less cantilever with a spring constant of 0.03N/m was utilized to compress on the top of fascicle. Each fascicle was first preconditioned by five cyclic compressions to displacement of 2500 nm from the contact position at a rate of 200 nm/s. After that, a compression-and-hold test was performed with the same maximal displacement and rate but the cantilever was held on the final position for 140 s.

The quasi-linear viscoelastic (QLV) model was employed to describe viscoelasticity of all fascicles. The reactive force F(t) in response to a displacement δ (t) is given by [3]:

$$F(t)=\int_{-\infty}^{t} G(t-\tau)\frac{\partial F^{(e)}(\delta)}{\partial \delta}\frac{\partial \delta}{\partial \tau}d\tau$$

$$G(t)=\left\{1+c\left[E_1\left(\frac{t}{\tau_2}\right)-E_1\left(\frac{t}{\tau_1}\right)\right]\right\}\left[1+c\ln\left(\frac{\tau_2}{\tau_1}\right)\right]^{-1}$$

where G the reduced relaxation function, $F^{(e)}(\delta)=A\delta^B$ the power law for instantaneous elastic response, E_1 the exponential integral function, c the viscous constant, and τ_1 and τ_2 the initial and terminal time constants of the relaxation function. All the parameters (A, B, c, τ_1 and τ_2) were obtained by using an efficient algorithm [1].

RESULTS AND DISCUSSION

In general, the diameter of a diabetic fascicle was smaller than that of a normal fascicle. Due to glycation, the diabetic fascicle had thicker collagen fibril than the normal fascicle. The results are consistent with [4], showing up regulation of collagen in rats wtih diabetes mellitus. Typical force-displacement curves of a normal (N3) and a diabetic fascicles (D3) fitted quite well by the corresponding QLV models (Fig. 1). The peak force of fascicle D3 was higher than that of fascicle N3 when subject to same displacement. The mean parameters of the power law of the normal vs. the diabetic fascicle are: *A* (0.404 vs. 0.594) and *B* (1.225 vs. 1.127) and for the QLV model, *c* (0.040 vs. 0.018), τ_1 (0.015 vs. 0.005) and τ_2 (1706.1 vs. 2838.2). The results reveal that the diabetic fascicle is stiffer and less viscous than the normal fascicle. The results are in good agreement with previous studies on the whole nerve [1].

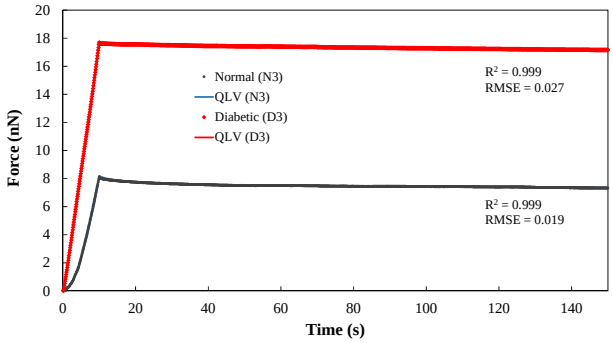

Figure 1. Force histories of normal (N3) and diabetic (D3) fascicles (dot lines) compared with the results of QLV model simulations (solid lines).

CONCLUSIONS

A new method based on atomic force microscopy was developed for *in vitro* parallel compression of nerve fascicles. The diabetic fascicle is stiffer and more viscous than healthy fascicle. The fascicles of both the healthy and diabetic rats are less viscous than the whole nerve. Further study will be inverse finite element analyses of the parallel compression to obtain constitutive equations of the fascicles.

STOCHASTIC SIMULATION OF KNEE MECHANICS ENABLED VIA NOVEL SOLUTION TECHNIQUES AND HIGH THROUGHPUT COMPUTING

[1] **Colin R Smith**, [1]Darryl G Thelen
[1]University of Wisconsin-Madison
Corresponding author email: crsmith25@wisc.edu

INTRODUCTION

Internal knee mechanics result from complex interactions between passive ligamentous structures, articular contact, limb dynamics, and neuromuscular coordination. Understanding the contributions of each of these factors to knee behavior can enable improvements in surgical treatments for knee pathologies. Dynamic musculoskeletal simulation is a potentially powerful approach to gain insight into these interactions. However, conventional musculoskeletal models rely on a simplified representation of the knee [1], which doesn't include ligaments or contact. Further, musculoskeletal models often presume mean parameter estimates, thereby ignoring the inherent uncertainties in model predictions. In this abstract, we describe a multibody knee model and simulation framework which leverage recent advancements in musculoskeletal simulation, statistical shape modeling, and high throughput computing (HTC). The framework is used to stochastically simulate muscle, ligament and cartilage loading during complex movements such as gait.

METHODS

The three-body knee model has six degree-of-freedom tibiofemoral and patellofemoral joints (Figure 1). Fourteen ligaments are represented by bundles of nonlinear springs. An elastic foundation model is used to compute contact pressure between articular cartilage surfaces [2]. The ligament attachment and articular geometries are constructed from subject-specific MR images [3] or generated from a statistical shape model to investigate population variability [4]. A novel simulation routine, Concurrent Optimization of Muscle Activations and Kinematics (COMAK), simultaneously predicts muscle forces, ligament loads and cartilage contact pressures that are consistent with overall movement dynamics [3]. We leverage HTC to perform thousands of independent simulations in parallel, allowing us to perform extensive sensitivity studies. By parameterizing the constitutive properties, neuromuscular coordination patterns, and knee geometries as population distributions, we are also able to use HTC to perform Monte Carlo simulations to assess the influence of parametric uncertainty on simulated knee mechanics.

RESULTS AND DISCUSSION

COMAK is able to simulate internal knee mechanics over a gait cycle in less than 30 minutes on a standard desktop computer. When deployed in parallel on a HTC grid, several thousand stochastic gait simulations can completed in a few hours [3]. The framework has been used to investigate the influence of ligament properties on cartilage contact pressures during walking [3]. We have also simulated the effects of patella height on the behavior of the knee extensor mechanism in normal and crouch gait [5].

The COMAK solution technique and HTC enable increasingly complex simulations of internal joint mechanics to be performed. In our own lab, we are using the framework to simulate the influence of surgical factors on knee behavior following anterior cruciate ligament (ACL) reconstruction and patellar tendon advancement (PTA) procedures. The knee model and COMAK simulation routine were initially implemented in custom code, but are now being ported into OpenSim 4.0. Model predictions, e.g. cartilage contact pressures, can be visualized in FEBio (Figure 1). A webinar demonstrating the use of OpenSim with the freely available HTC resources of the Open Science Grid is available online [6].

CONCLUSIONS

Advances in imaging, shape modeling, solution algorithms and computing resources enable the simulation of detailed joint mechanics during movement. These advances provide a powerful platform to simulate complex orthopedic procedures and predict the effect of surgical factors on joint behavior during functional movement.

CAN MUSCULOSKELETAL MODELS AND OPTIMAL CONTROL REPRODUCE RESULTS FROM AN EXPERIMENTAL EXOSKELETON STUDY?

Stanford University
Corresponding author email: dembia@stanford.edu

INTRODUCTION

Recent advances in the design of assistive exoskeletons have proven that reducing the metabolic cost of walking is a feasible endeavor [1]. Musculoskeletal modeling and simulation can be used to enhance our understanding and the design of these devices: simulated devices can be tested without limitation, for specific objectives, and over many subjects and scenarios. Recent studies have sought to understand how an exoskeleton device, similar to that in [1], affect plantarflexor muscle mechanics and energetics [2, 3]. Modern optimal control techniques show promise in overcoming the challenges of earlier computational tools (e.g., sensitivity to parameters [4] and long computation times), and allow one to readily optimize device parameters with global objectives (e.g., integrated over a motion). In this study, we utilized an existing optimal control framework [4] to find spring stiffness values for an assistive ankle device such that muscle effort of walking was minimized. To assess the promise of our approach for simulation-based design of exoskeletons, we compared our metabolic cost reductions and optimal spring stiffness to those from a recent experimental study [1].

METHODS

We collected motion capture data of 6 male individuals walking overground. We simulated the stance phase of the data, as this was the portion of the gait cycle during which the clutched spring in Collins et al. [1] was engaged. We used these data with the OpenSim software package (version 3.3) [5] to compute trajectories of joint angles, joint moments, muscle-tendon lengths, and moment arms. These quantities are inputs to the optimal control framework [4].

We first used the optimal control framework to solve for muscle excitations that achieved the observed motion while minimizing the sum of squared muscle excitations and activations (unassisted condition). The musculoskeletal model included 5 degrees of freedom (ankle, knee, and hip flexion; hip abduction, hip rotation) from one leg, and 40 muscle-tendon actuators. We then added a spring to the ankle of the model to produce an assistive torque, and solved a new optimal control problem to obtain the stiffness (and resting length) of the spring that minimized the same measure of effort (assisted condition). We estimated the change in metabolic cost from the spring using the energetics model of Umberger and colleagues [6]. To compare our results to those from a recent experiment [1], we also solved a series of optimal control problems wherein we fixed the stiffness of the spring.

RESULTS AND DISCUSSION

The optimal spring stiffness for minimizing muscle effort, averaged over all subjects, was 133 N-m/rad, with values ranging from 98 to 180 N-m/rad for individual subjects (Figure 1, red dots). The spring resulted in an average reduction in metabolic cost of 2.8%, with values ranging from -0.2% to 7.8% for individual subjects. Similar to the experimental results reported by Collins et al. [1], we observed a bowl-shaped relationship between the change in metabolic cost and the spring's stiffness. The optimal stiffness found by Collins et al. was 180 N-m/rad, with which they achieved an average reduction in metabolic cost of 7.2%. One potential reason why our optimal stiffness is lower is that unassisted soleus activation was lower than we expected, based on our EMG measurements. The spring reduced activity of the soleus and tibialis anterior, but medial gastrocnemius activity remained similar to that from the unassisted condition (Figure 1).

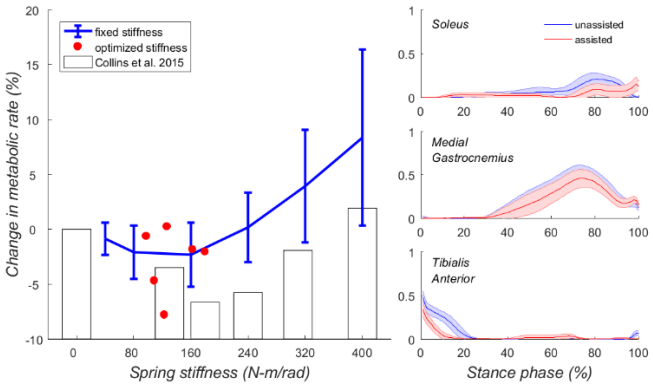

Figure 1: Left panel: Change in metabolic rate versus spring stiffness, compared to the experimental results of Collins et al. [1]. Right panels: Simulated muscle activation with no spring and with the optimal spring, averaged over 6 subjects.

CONCLUSIONS

We used an optimal control framework to optimize the stiffness of a passive ankle exoskeleton, and achieved results that bore similarity to experimental findings. This suggests that this method may be a valuable approach for studying the interaction between muscles and exoskeletons**.** The framework was able to solve for optimal spring stiffness efficiently, with each optimal control problem converging in under an hour. An interesting area of future work is to understand the factors leading to varying optimal stiffness and metabolic savings across subjects.

SIMULATION OF RESIDUUM-SOCKET DYNAMICS IN WALKING FOLLOWING LIMB LOSS

Brian R. Umberger, Andrew K. LaPrè, Russell T. Johnson, Ryan D. Wedge and Frank C. Sup
University of Massachusetts
Corresponding author email: umberger@umass.edu

INTRODUCTION

Predictive simulation is a potentially powerful approach for designing assistive devices to restore mobility and for improving the efficacy of rehabilitation protocols. Most musculoskeletal models used to simulate gait following unilateral transtibial amputation assume the prosthesis is rigidly affixed to the residual limb. Also, many such models represent the prosthesis by simply removing the ankle muscles and replacing them with a rotational spring at the ankle joint. These modeling choices may limit the predictive utility of the model-based design approach, as there is considerable motion at the residuum-socket interface [1] and the dynamics of the prosthesis are different than a spring-actuated biological ankle. Directly modeling the socket-residuum interface is of considerable clinical relevance, as skin lesions due to loads on the residual limb within the socket are a major concern for people who use a prosthesis.

It is unknown if including socket dynamics in a musculoskeletal model will affect the basic gait patterns predicted for walking, or if realistic socket motions and loads can be predicted. Therefore, the purpose of this study was to compare simulations of walking in people with unilateral transtibial limb loss using models of the prosthesis and socket interface of different levels of complexity.

METHODS

The models of limb loss were based upon a reference model with 9 segments, 11 degrees of freedom and 18 Hill-type muscle actuators, with motion restricted to the sagittal plane. The four limb loss models were: a simple model with the right ankle muscles replaced by a rotational spring (Simple); a model with an amputated right shank segment and a passive prosthesis rigidly affixed to the residual limb (Rigid); a prosthesis model that permitted socket pistoning (Pist), and a prosthesis model that permitted socket flexion and pistoning (FlexPist) (Fig 1A). The socket flexion, socket pistoning, and prosthesis flexion motions were treated as viscoelastic. Due to the presence or absence of specific articulations, the limb loss models varied from 10-12 degrees of freedom. The five models were identical except for the presence and representation of the prosthesis.

Simulations of walking at 1.2 m/s for a full gait cycle were generated via the OpenSim API using direct collocation [2]. Model controls and states were optimized to minimize the sum of cubed muscle activations and the deviations from experimental able-bodied joint kinematics (Exp; Fig 1B).

RESULTS AND DISCUSSION

Kinematic deviations from the able-bodied gait data were greater in the limb loss models than for the reference model (Fig. 1B), and mirrored kinematic adaptations seen experimentally in people with unilateral transtibial limb loss [3]. Simulations generated using the various limb loss models generally resulted in similar joint kinematics (Fig. 1B), ground reaction forces and muscle activations, with the

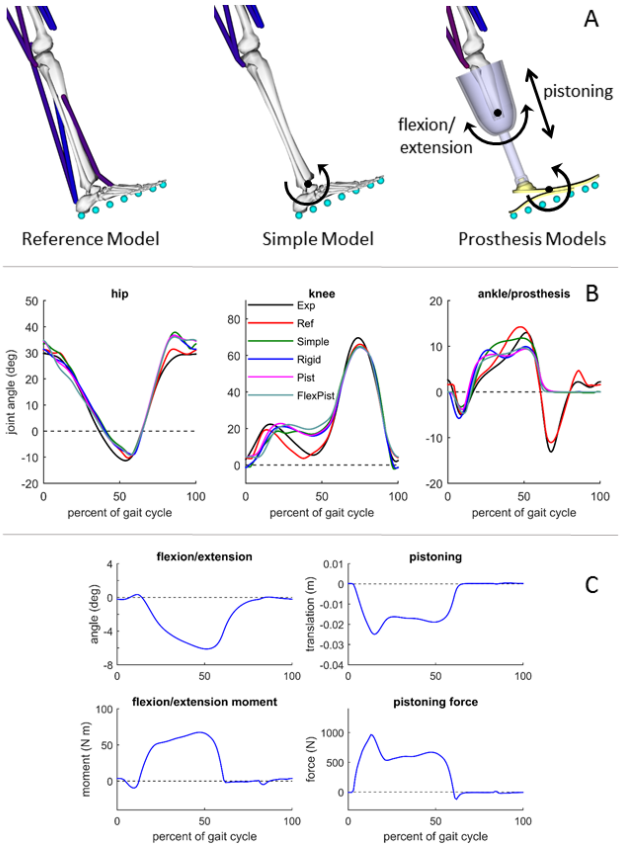

Figure 1: A) Model configurations; B) right/affected side joint kinematics; and C) socket kinematics and kinetics.

Simple model predicting different ankle kinematics in stance than the other three limb loss models. The two models with dynamic socket-residuum interfaces predicted realistic kinematics [1] (Fig. 1C), with approximately 6º of peak socket extension and 2.5 cm of peak axial compression during stance (Fig. 1C). The loads predicted at the socket interface were considerable (Fig. 1C) and represent targets that can potentially be altered or reduced using predictive simulations of new prosthesis designs or other clinical interventions.

CONCLUSIONS

Musculoskeletal models with a simple representation of the prosthesis may be useful when only the gross kinematics and kinetics of the body are of concern. However, models that include the dynamics of the socket interface provide a distinct advantage in that the effects of novel prosthesis designs or rehabilitation protocols on loading of the residual limb may be evaluated.

DOES A TWO-ELEMENT MUSCLE MODEL OFFER ADVANTAGES WHEN ESTIMATING ANKLE PLANTAR-FLEXOR FORCES DURING HUMAN CYCLING?

INTRODUCTION

Hill-type muscle models drive computational simulations that seek to reproduce the dynamics of measured movement. However, current models, parameterized using the best available data, are often "too weak" to reproduce the net joint torques generated by healthy adults. Two possible explanations are that, (i) the models' maximum isometric strength is based, in part, on muscle masses measured from elderly cadavers, and (ii) broad muscles, with heterogeneous fibre lengths, may be assigned force-generating properties that are not well characterized by scaling the behaviour of a single sarcomere to whole muscle [1].

This study tests a new explanation for why Hill-type models may appear weak: they neglect the contractile properties and recruitment patterns of slow and fast fibres. Most models used in simulations assume a single contractile element (CE). However, skeletal muscles have a mix of slower and faster fibres with distinct contractile properties, and the fibres' recruitment patterns may vary depending on the demands of the task [2]. We hypothesized that a Hill-type model with two CEs, representing independently recruited slower and faster fibres, can generate time-varying muscle forces comparable to those predicted by a 1-element model – while requiring substantially less total excitation.

METHODS

We tested our hypothesis by analysing a series of forward dynamic simulations that reproduced measured ankle mechanics during cycling. First, we generated a set of "nominal" simulations in OpenSim™ [3] using an ankle model actuated by two muscle-tendon units (MTUs): a plantarflexor and a dorsiflexor, each represented by a 1-element Hill-type model. The simulations reproduced the joint angles and crank forces of an elite female cyclist who pedalled on an instrumented ergometer at five different cadences: 60, 80, 100, 120 and 140 RPM, all at a 13N m^{-1} load [4]. We obtained nominal predictions of muscle forces and excitations using computed muscle control [5]. Next, we generated 500 "test" simulations in which the plantarflexor was replaced by a 2-element Hill-type model. Our 2-element plantarflexor comprised a near-massless block and three MTUs (two proximal to the block and one distal). The two proximal MTUs functioned as the CEs and were assigned properties of slow and fast fibres; the distal MTU had properties of tendon. We prescribed the ankle mechanics from the nominal simulation while predicting the block's motion and systematically altering the excitations applied to the CEs. In particular, we varied the total excitation of the 2-element plantarflexor between 60-105% of the excitation predicted from the nominal simulation, and we varied the distribution of the total excitation applied to the fast and slow CEs between 0-100%. Finally, we quantified the RMS errors between muscle forces derived from the nominal and test simulations, identifying simulations in which the 1- and 2-element plantarflexor models generated similar force.

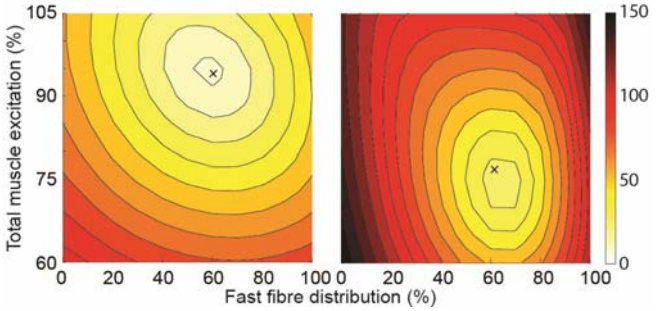

Figure 1: RMS errors for forces derived from the nominal and test simulations for 60 RPM (left) and 140 RPM (right). The crosses mark the test simulations that yielded forces most comparable to the nominal simulations – yet required less total excitation.

RESULTS AND DISCUSSION

As hypothesized, the 2-element plantarflexor required less total excitation than the nominal plantarflexor to generate comparable forces (Fig. 1). This result was true at all cadences, but was especially evident at higher cadences. At 60 RPM, the test simulations with the smallest RMS errors required just 94% of the excitation predicted by the nominal simulation. At 140 RPM, the 2-element plantarflexor required just 77% of the excitation predicted by the nominal simulation.

RMS errors were smallest when about 65% of the total excitation was applied to the fast CE. Surprisingly, this distribution did not vary with cadence. However, at the higher cadences, the forces predicted by the 2-element plantarflexor were sensitive to the distribution assumed. For example, at 140 RPM, the RMS errors deteriorated rapidly when the fast CE was assigned less than about 40% or more than about 80% of the total excitation applied (Fig.1, right).

CONCLUSIONS

Considering the contractile properties and recruitment patterns of slower and faster muscle fibres may help improve the fidelity of muscle-driven simulations and increase the apparent strength of models. These strategies may be particularly applicable to studies of muscle coordination during rapid movements, in which shorter contraction-relaxation cycles are required. In future studies, refined "nominal" simulations are needed that consider the metabolic cost when solving for muscle excitations, and additional "test" simulations are needed that distribute the total excitation to the CEs in a time-varying manner.

VARIABILITY OF NEUROMUSCULAR AND BIOMECHANICAL ADAPTATIONS ACCOMPANYING SPINAL PAIN

Professor Deborah Falla
Centre of Precision Rehabilitation for Spinal Pain (CPR Spine), School of Sport, Exercise and Rehabilitation Sciences, College of Life and Environmental Sciences, University of Birmingham, United Kingdom

Spinal pain is a leading cause of years lived with disability, with massive associated socioeconomic costs. More than half of those affected by an acute episode of pain still report pain and disability one year later. Assessment and management of chronic spinal pain disorders is an international challenge and comes at great individual and societal cost. Most conservative treatments for spinal pain often rely on a "one size fits all" approach and show only small to moderate treatment effects, with one treatment showing little superiority over another. Importantly, these minimal gains rarely last in the long term and it is this lack of long term effectiveness which impacts on return to work or optimal function. Effective and early management of pain and neuromuscular function via exercise is promoted as a critical element of management for spinal pain, recommended by clinical practice guidelines internationally. Yet, like other conservative treatments for non-specific pain, the effects of exercise are typically only small to moderate with little evidence of superiority of one exercise program over another.

A number of studies have revealed the complexity and individual variability of neuromuscular and biomechanical adaptations accompanying pain, and the heterogeneity between patients with respect to the contribution of physical features to their chronic pain disorder. Recent evidence of biomechanical and neurophysiological adaptations in people with spinal pain will be presented in this lecture which collectively supports the assumption that the outcome of exercise interventions can be optimized when better targeted towards each individual. By the end of the lecture participants will be able to recognize the variability of movement and neuromuscular changes associated with spinal pain and appreciate the scope and limitations of exercise for the relief of pain and for restoration of optimal physical function.

VERSATILE MODEL FOR COMPUTATIONAL SIMULATION OF THREE-DIMENSIONAL MULTICELLULAR DYNAMICS

INTRODUCTION

Multicellular dynamics have a key role in determining the macroscopic behaviors of living tissues during development, homeostasis, and disease. Especially, based on chemical regulatory pathways, autonomous tissue dynamics emerge from the integration of various cell mechanical behaviors in three-dimensional (3D) space, such as cell deformation, movement, division, and apoptosis. Typical examples of 3D multicellular dynamics are the epithelial deformation in morphogenesis, the collective cell migration in cancer metastasis, and the regeneration of high-order tissue structures. However, while such 3D multicellular dynamics is fundamental to general soft tissue dynamics, little is about how individual cell behaviors are spatiotemporally coordinated across the macroscopic tissue dynamics. To investigate general multicellular dynamics, we developed a versatile mathematical model for simulating 3D multicellular dynamics based on the 3D vertex model framework[1-7].

METHODS

In the 3D vertex model, an individual cell shape is represented by a polyhedron comprising the arbitrary number of polygons. Each polygon expresses the boundary face between neighboring cells, and comprises the arbitrary numbers of vertices and edges. Since all polygons are shared by neighboring polyhedrons, all vertices and edges compose a single network that expresses the entire structure of a 3D cell aggregate (Fig. 1).

In the network, as a topological constraint, each vertex is connected to exactly four edges, by which each vertex coordinate corresponds to a meeting point of exactly six boundary faces. Moreover, the topology of the network and the numbers of vertices and edges are dynamically rearranged to express the changes in the configuration and number of cells.

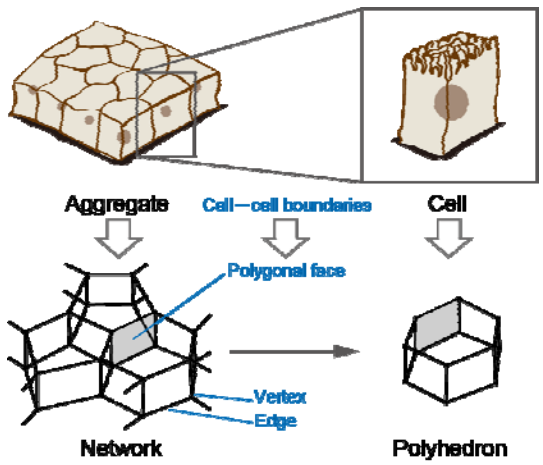

Fig. 1: 3D Vertex Model for Simulating 3D Multicellular Dynamics

RESULTS AND DISCUSSION

The model enables to express the entire degree of freedom of multicellular kinetics at the single cell level, i.e., cell deformation, rearrangement[7], division[6], and death[1] in 3D space. Moreover, the model expresses active and passive mechanical behaviors of individual cells such as cell viscoelasticity and active force generation[4]. Furthermore, by coupling intercellular molecular signaling with cell mechanical behaviors, the model successfully expresses the coupling phenomena of mechanical deformation and chemical patterning[3]. Computational simulations using the model provided quantitative predictions of 3D multicellular dynamics at the single cell level. Several studies have demonstrated the applicability and usefulness of this model for analyzing general multicellular tissue mechanics, such as epithelial deformation and collective cell migration.

CONCLUSIONS

This study focuses on understanding the self-organizing mechanisms of living tissues in the processes of development, homeostasis, and disease. To investigate well-organized dynamics of multicellular tissues in the living body, we developed a powerful mathematical tool to analyze dynamics of general multicellular tissues, and revealed the regulation mechanisms of the autonomous processes of organogenesis. This work will contribute to the multiscale biomechanics of tissue dynamics by bridging the mechanical hierarchy of structures and functions ranging from the microscopic cellular level to the macroscopic organ level.

INTRODUCTION

Cells in the epithelial tissue are physically organized by the formation of cell-matrix and cell-cell adhesions. The later are mediated by the calcium-dependent cell adhesion receptor called E-cadherin (E-cad), and are required for development[1-4], while a loss of these adhesions is associated with cancer development and metastasis.[5] E-cad is a multidomain protein wherein the extracellular domain (ECD) forms the adhesive homotypic interaction while the intracellular domain (ICD) interacts with the cytosolic β- and α-catenin as well as the actin cytoskeleton.[2-4,6-9] A force-dependent conformational change in α-catenin allows sensing of mechanical tension in the tissue.[10-16] Here we study the mechanism of cell-cell adhesion formation and mechanical signaling using hybrid live cell-supported lipid bilayer assays, which has been successfully utilized in dissecting adhesion and signaling by a number of other receptors including the T-cell receptor[17-19], the EphA2 tyrosine kinase[20,21] and integrin receptor[22-24].

METHODS

Adhesion formed by MKN28 epithelial cells on supported lipid bilayers functionalized with fluorescently labeled E-cad-ECD was monitored by epi-fluorescence microscopy while cell-bilayer contact was imaged by Reflection Interference Contrast Microscopy (RICM). Activation of α-catenin was determined by the staining of cells with a conformationally sensitive antibody, α18, which binds specifically to the active conformation.[12] E-cad clusters were physically manipulated by creating nanoscale features on the substrate using nanolithography.[17-21,25]

RESULTS AND DISCUSSION

Interaction of cells with the E-cad-ECD functionalized bilayer resulted in an enrichment of the protein on the bilayer. However, very few cells formed adhesion on fluid supported lipid bilayers while they did so readily on viscous bilayers suggesting a step of kinetic nucleation in the process of E-cad clustering. Cells formed micron-scale clusters of E-cad by extending and retracting filopodia on the bilayer surface.[26] Staining of cells adhering to bilayers with the α18, either in control or in low acto-myosin tension condition, showed the presence of activated α-catenin in both conditions. On the other hand, a restriction of E-cad clustering by creating physical barriers on the substrate revealed that α-catenin is activated during the micron-scale clustering of E-cad. These suggest that micron-scale clustering induced activation of α-catenin is sustained in the absence acto-myosin tension.[27]

CONCLUSIONS

Filopodia retraction-mediated clustering of E-cad involves a step of kinetic nucleation, and is associated with a sustained activation of α-catenin.[1,26,27]

INTRODUCTION

We have been developing a computational biomechanics especially on cellular scale physiological flow problems [1-4]. In cellular scale, fluid motions are typically dominant by the viscous effect, not by the inertia, and the flows can be assumed as the Stokes flow. To solve Stokes flow problems, we used a boundary element method (BEM) because BEM can explicitly treat viscous stress jump across cell membrane and it shows high accuracy with reasonable mesh size and time step. In this paper, we briefly review our recent work of cellular scale physiological flow problems solved by a BEM.

METHODS

Assume that fluid flow is governed by the Stokes flow. Flow field around cells can be expressed by the following boundary integral equation:

$$\boldsymbol{v} = -\frac{1}{8\pi\mu}\int \boldsymbol{J}\cdot\boldsymbol{q}\,dS + \frac{\lambda}{8\pi}\int \boldsymbol{v}\cdot\boldsymbol{T}\cdot\boldsymbol{n}\,dS, \qquad (1)$$

where μ is the viscosity of extracellular fluid, λ is the viscosity ratio of inner cytoplasm and outer fluid, S is the surface of cell membrane, $\boldsymbol{n}$ is the outward unit normal vector on the surface, and $\boldsymbol{J}$ and $\boldsymbol{T}$ are single- and double-layer potentials of the Green's function, respectively. The surface load $\boldsymbol{q}$ is given by the membrane mechanics. The membrane is modeled by a hyper-elastic material and the equilibrium equation is solved by a finite element method. Once the surface load $\boldsymbol{q}$ is given, equation (1) is solved by a BEM.

RESULTS AND DISCUSSION

We first investigated single red blood cell (RBC) motions flowing through a thin micro-pore (Fig.1a). The resulting RBC deformation towards the flow direction is suppressed by increased cytoplasm viscosity, while the gap between the membrane and solid wall becomes smaller with the cytoplasm viscosity. We analyzed transit time and found that the nondimensional transit time increases nonlinearly with respect to the viscosity ratio, whereas it is invariant to the membrane elasticity. These results will be useful for designing a microfluidic device to measure cytoplasmic viscosity.

We next investigated hydrodynamic interactions of RBCs (Fig.1b). The hydrodynamic interaction induces self-diffusion of RBCs even without Brownian motions. We analyzed flow-induced RBC diffusion by calculating the pairwise interactions between RBCs in simple shear flow. The shear-induced RBC diffusion is significantly anisotropic and the diffusivity monotonically decreases with the viscosity ratio of inner and outer liquids. The scaling argument also suggests that the diffusivity is proportional to the shear rate and haematocrit in a semi-dilute environment.

We also investigated sperm cell swimming in a fluid flow (Fig.1c). When a sperm cell swims in a shear flow, it can hydrodynamically change its swimming direction, allowing it to swim upwards against the flow. Which suggests that the upward swimming of sperm cells can be explained using fluid mechanics. Mammalian sperm cells must swim against the flow in the oviduct to find the egg cell. Thus such upward swimming is important for the fertilization process.

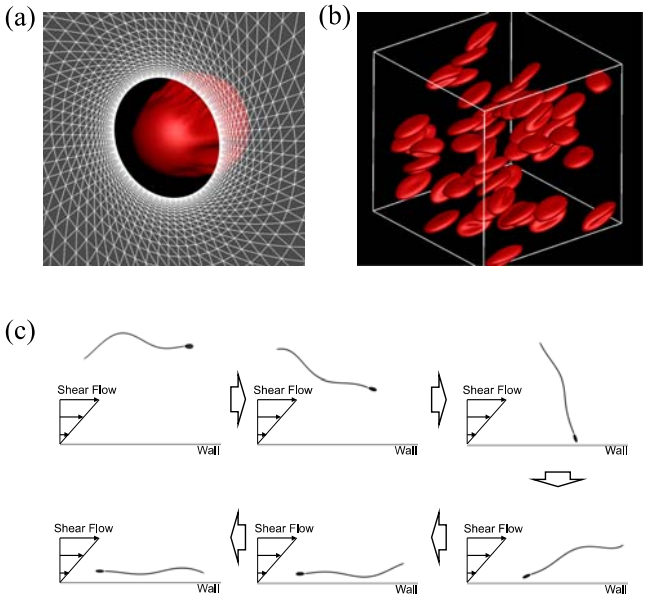

Fig.1 Computational results of cellular flows (a) single RBC flowing through a thin micro-pore (b) hydrodynamic interactions of RBCs in a semi-dilute suspension (c) upstream swimming of a sperm cell in shear flow near a boundary wall.

CONCLUSIONS

In this study, we have developed a computational biomechanics on red cell suspensions and swimming of a sperm cell. Our findings would be helpful for better understanding of cellular mechanics and utilizing micro fluidic devices. We expect to develop a model that can express biological functions based on mechanics by integrating cellular and macroscopic biomechanics in the near future.

ELASTIC MODULUS AND NANOSTRUCTURE OF A SINGLE TRABECULA IN BOVINE CANCELLOUS BONE

[1] **Satoshi Yamada**
[1] Division of Human Mechanical Systems and Design, Faculty of Engineering, Hokkaido University
Corresponding author email: syamada@eng.hokudai.ac.jp

INTRODUCTION

The cancellous bone is organized into a three-dimensional network of single trabeculae, and its strength depends on the network. The elastic modulus, strength, and nanostructure of single trabeculae are important factors in determining the strength of the cancellous bone. Accordingly, a single trabecula must be investigated to further understand the impact of aging, osteoporosis, and medicines on the risk of fracture of the cancellous bone. However, few studies have executed measurements of the elastic modulus on a single trabecula because of the technically challenges such studies present. Furthermore, the nanostructural effects on the mechanical properties of a single trabecula have not been elucidated, although various studies have been conducted on multiscale mechanical characterization in the cortical bone [1]. Thus, this study aimed to elucidate the elastic modulus of a single trabecula and the nanostructural effects on its mechanical properties.

METHODS

First, we investigated the elastic modulus of relatively large trabeculae by tensile tests and assessed the nanostructural effects at the hydroxyapatite (HAp) crystal scale on the elastic modulus by X-ray diffraction (XRD) techniques [2]. In this study, 18 trabeculae (at least 3 mm in length) were dissected from the edges of the cancellous bone in the proximal epiphysis of 3 adult bovine femurs. The specimens were fixed to thin metal jigs using superglue, and the tensile tests were conducted using a small tensile testing device under optical microscopic observation. Second, the specimens were perpendicularly irradiated with collimated characteristic X-rays of Mo-Kα and an XRD pattern was detected using an X-ray imaging plate to investigate the *c*-axis orientation of the crystals within a single trabecula and the degree of crystal orientation, evaluated as $\langle\cos^2\beta\rangle$ [1]. To investigate the deformation behavior of the crystals under the loadings, tensile tests were also conducted during XRD measurements. The HAp crystal strain ε^H in the longitudinal direction was calculated at each loading condition. Furthermore, energy-dispersive X-ray spectroscopy was performed on the cross-section of the specimens to evaluate the mineral content.

Although such tensile tests are suitable for the observation of the crystal deformation behavior, it is rather difficult to completely isolate, fix, and examine small bone specimens. While three-point bending tests do not require fixation of the specimen to a jig with a resin or glue, the tests generally require complete isolation of the specimen, deflection measurements at high resolution, and very precise loading. Therefore demonstrate a novel experimental method to investigate the elastic properties of a single trabecula on the basis of cantilever bending [3]. The micro-cantilever bending (MCB) test does not require a specimen to be isolated completely from the cancellous bone, and the specimen can be fixed easily during the test. A total of 10 rod-like trabeculae (1.12 ± 0.17 mm in length) inside the cancellous bone were dissected from the proximal epiphysis of an adult bovine femur. A specific single trabecula was isolated while keeping one extremity connected to the cancellous bone. The specimen was fixed into a holder almost vertically by embedding the cancellous bone portion in the epoxy resin. The load was perpendicularly applied to the free end. The elastic modulus in the longitudinal direction was calculated from the force–deflection relationships. The specimen was assumed to be a vertical circular cylinder of orthotropic material, and the shear stress was considered to be negligible. Then, we evaluated the degree of *c*-axis orientation of the crystals using XRD.

RESULTS AND DISCUSSION

The elastic modulus of single trabeculae was 11.5 ± 5.0 GPa by tensile tests [2] and 9.1 ± 5.4 GPa by MCB [3]. There was no significant difference between them and the values were observed to be at 42% of the cortical bone specimens taken from a bovine femoral diaphysis [1]. The mineral content was significantly smaller than in the cortical bone [2]. The *c*-axis of the HAp crystals aligned in the longitudinal direction within a single trabecula and were independent of the bone axis [2]; moreover, $\langle\cos^2\beta\rangle$ was smaller than the cortical bone [1]. The crystals were linearly deformed under tensile loading and the ratio of ε^H to tissue strain (strain ratio) had significant correlation with the elastic modulus [2]. However, the mineral content and $\langle\cos^2\beta\rangle$ did not vary broadly and did not correlate with the elastic modulus, although there were statistical correlations in both single trabeculae and cortical bone specimens, suggesting that a single trabecula may have a particular elastic modulus and nanostructure locally, and the difference in the elastic modulus between trabecular and cortical bone tissue may depend on the crystal orientation and mineral contents. Furthermore, the strain ratio may represent the nanostructure of a single trabecula and would determine the elastic modulus as well as mineral content and orientation. This study demonstrated the differences of the elastic modulus and nanostructure between a single trabecula and the cortical bone and the relationship between the elastic modulus and crystal orientation and deformation. The investigation of the effects of the elastic modulus, strength, and structure at the trabeculae scale on the strength of the cancellous bone is an essential topic to consider in future studies.

RESPIRATORY RESPONSES DURING CLINICAL WALKING AND DAILY-LIFE ACTIVITIES ARE DIFFERENT IN PEOPLE WITH CHRONIC OBSTRUCTIVE PULMONARY DISEASE

[1] Sidney Baroi, [2] Renae McNamara, [3] Simon Gandevia, [2] David McKenzie, [1,3] **Matthew Brodie**

INTRODUCTION

Chronic obstructive pulmonary disease (COPD) is a progressive lung disease that is life threatening. Worldwide over 65 million people live with COPD [1] resulting in 3 million instances of early mortality each year. People with COPD have impaired ability to transport oxygen across the air-blood barrier between the alveoli and capillaries. During walking and activities of daily living (ADLs) muscle work is increased. People with COPD may have difficulty meeting the oxygen demand required to produce cellular ATP energy, find walking tiring and are therefore at increased risk of sedentarism, cardiovascular disease and depression.

In the clinic, lung function is often assessed **at rest** using a spirometer to measure forced expiratory volume in the first second (FEV_1). The GOLD threshold for moderate versus severe COPD is 50% of the predicted FEV_1 value based on patient demographics [2]. However, **in daily-life** it is not known how **activity** may influence respiratory responses for people with moderate to severe COPD. In this paper we used a wearable device to measure the effect of walking on respiratory frequency (breaths per minute) both in the clinic and during daily-life. Contrasting responses between people with different severity of COPD are discussed.

METHODS

Ten people with moderate to severe COPD (age 72.3 ± 10.8 years, BMI 28.2 ± 6.9 and FEV_1 41 ± 10 % predicted) gave informed consent before being assessed at Prince of Wales Hospital (ethical approval HREC 15/325). Physical assessments included the six-minute walk test (6MWT), the 30 second sit-to-stand test (STS) and the upper limb endurance exercise test (ULEET), 6 minutes lying and 6 minutes sitting. During the clinical assessments and for the subsequent 35 hours participants wore a Zephyr Bioharness (www.zephyranywhere.com). The wearable device included a flexible strap located at sternum height that measured chest expansions and contractions associated with breathing and a triaxial accelerometer that measured activity levels.

RESULTS AND DISCUSSION

In the clinic, the type of activity performed had a significant effect ($p<0.001$) on respiratory frequency and intensity level. Walking (6MWT) increased the breathing rate most.

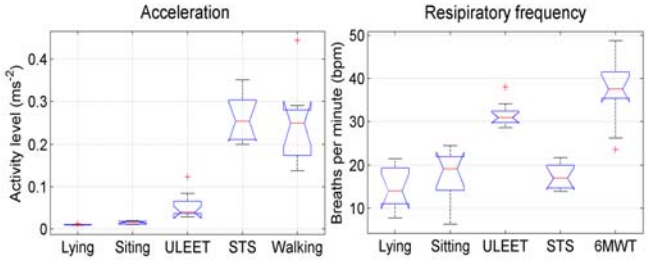

Figure 1: *Clinical assessment of intensity level and respiratory frequency during different activities.*

As 8 of the 10 participants were below the GOLD 50% threshold, a median split (37% FEV_1 predicted) was used to group people as having ***'Severe'*** versus ***'Moderate'*** COPD.

During the 6MWT the *Moderate* group had significantly ($p=0.04$) greater capacity to increase respiratory frequency (↑ 29 ± 10 bpm) than the *Severe* group (↑ 16 ± 7 bpm).

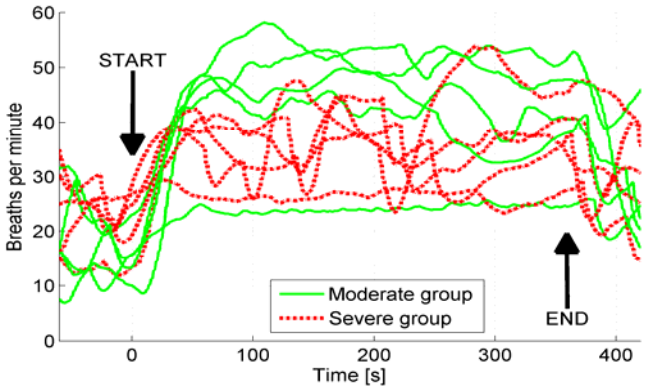

Figure 2: *Increased breathing rate during the 6MWT.*

In daily-life, no difference was observed in the time the device was worn between the *Moderate* (32.3 ± 2.4 hours) and *Severe* (33.1 ± 1.6 hours) groups. The *Moderate* group spent a significantly ($p=0.04$) greater proportion of time being active (23 ± 5 %) than the *Severe* group (17 ± 3 %). This indicates that the *Moderate* group may have been relatively less affected by COPD during ADLs.

Both groups spent a similar proportion of time (3 ± 2 %) engaging in high intensity (HI) ADLs (≥ 0.02 ms^{-2}). However, respiratory frequency in the *Severe* group (26.2 ± 3.9 bpm) was significantly higher ($p=0.008$) than the *Moderate* group (17.4 ± 3.8 bpm). This indicates that for the *Severe* group the respiratory systems may have had to work harder to meet oxygen demand during ADLs.

Clinical vs daily-life respiratory response. A significant interaction between HI ADLs, the 6MWT and COPD severity was observed (2-way ANOVA $p=0.01$). For the *Moderate* group, breathing rate was significantly higher ($p=0.008$) during the 6MWT (42.4 ± 11.0 bpm) compared to HI ADLs (17.4 ± 3.8 bpm). However, for the *Severe* group, the smaller difference in breathing rate between the 6MWT (35.0 ± 4.9 bpm) and HI ADLs (26.2 ± 4.0 bpm) did not reach significance. This indicates that the *Severe* group may have been at greater risk of exceeding respiratory capacity during ADLs than the *Moderate* group.

CONCLUSIONS

The remote assessments revealed differences in respiratory responses during exercise for people with *Moderate* versus *Severe* COPD. The clinical and daily assessments provided complementary information that may be useful to prevent future hospitalizations. Lager studies are now required.

BIOMECHANICAL ANALYSIS OF THE METATARSAL OSTEOTMY FOR THE TREATMENT OF THE METATARSALGIA

INTRODUCTION

Metatarsal osteotomy is a decompressive surgical procedure for the treatment of metatarsalgia and it involves elevating or shortening of the metatarsal. It is known to be effective in pain relief by reducing localized plantar load which causes compression nerve pain on the forefoot plantar soft tissues However, transfer metatarsalgia after surgery may occur due to inadequate elevation or shortening distance which causes changes in the load transfer mechanism at the metatarsals or reduces mechanical stability of the implant [1, 2]. This study is aimed to analysis metatarsal sliding osteotomy (MSO), one of the several metatarsal osteotomies to treat metatarsalgia. Using a plating system to fix the metatarsal fragments on wide osteotomy plane, MSO can be very effective in providing in mechanical stability. In this study, biomechanical effectiveness of MSO was investigated in terms of the load transfer mechanism and biomechanical stability of the implant by using finite element analysis (FEA).

METHODS

A previously-validated 3D FE model of the foot was used in this study [3]. The MSO surgical models were constructed by cutting 2nd metatarsal bone 45° obliquely to the shaft axis 1.5cm apart from the proximal end, followed by sliding of the distal fragment to the dorsal direction. The sliding was incrementally repeated for 5 times (model Types 1~5), each time by 5% of vertical length of the osteotomy plane. Following osteotomy, a Leibinger plating system (titanium, 4-holes, 1×24mm, Stryker, USA) with four screws (titanium, Ø2) was dorsally implanted for bone fixation. The loading and boundary conditions for the terminal stance (50% of the gait cycle) which generate the maximum load to the forefoot was considered. The models were subjected to the 660N (110% of the total body weight) ground reaction force while the tibia axis angle was kept constant at 60° to the ground. And the forces of plantar flexor tendons for the terminal stance were applied to the foot bones [4]. To analyze load transfer mechanism of the metatarsals, relative changes of the peak plantar pressure (PPP) under the metatarsal heads and peak principle tensile stress (PPTS) were predicted with respect to the pre-operative condition (i.e., intact) as it may be related to load transfer at the metatarsals [1]. Tensile stress at the metatarsal shaft due to bending of the metatarsal may increase as much as load magnitude to metatarsal head because of the arch structure of the foot bones. Also, to analyze mechanical stability of the implant, peak von Mises stress (PVMS) was predicted and likelihood of the yield was derived by dividing PVMS by yield stress of titanium.

RESULTS AND DISCUSSION

As the sliding distance of the MSO increases (Type 1 → Type 5), the more even stress distribution was noted at the adjacent metatarsals. The PPP increased by up to 124% and 117% and 142% as compared to the pre-op for 1st(1MT), 3rd(3MT), 4th(4MT) metatarsal regions, respectively. Similarly, PPTS increased by 114% (1MT), 122% (3MT), 122% (4MT) respectively. At the same time, PPP of the surgically treated region (2MT) gradually decreased to 82%~41% and PPTS was reduced to 69%~47% of the intact. But beyond the 15% sliding (Type 3), the decreasing trend of PPTS remained relatively unchanged. Meanwhile, mechanical stability increased with the sliding distance. The likelihood of yield of implant was gradually decreased as sliding distance increases (41% in Type 5) [Fig. 1]. It should be noted that increase in load transfer to the 1MT and 4MT away from the operated 2MT may suggest effective load redistribution after MSO that may be able to further prevent metatarsalgia by reducing load at the central forefoot region [1]. And the MSO is effective in the aspect that the mechanical stability is increased even if the large sliding distance is used for the high decompression effect.

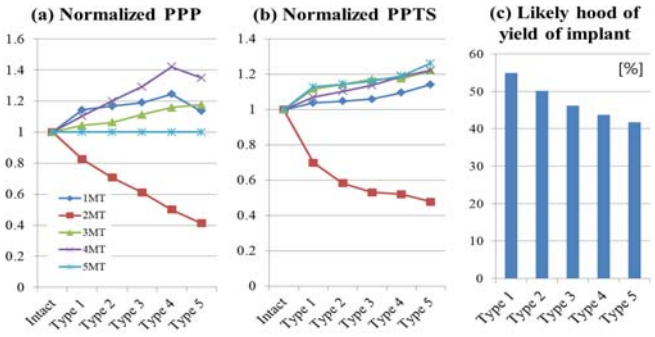

Figure 1: FEA results, (a) Normalized PPP and (b) PPTS, (c) Likely hood of yield of implant.

CONCLUSIONS

The MSO may decompress gradually at the surgically treated region and increase mechanical stability as sliding distance increase. But, the sliding distance greater than 15% of the vertical length of the osteotomy plane (Type 3) appear to be the maximum allowable limit for MSO as the effectiveness of the surgery remained relatively as seen with PPTS results. Simultaneously, beyond this point, the load transfer to other adjacent joints showed too much increase which may further induce metatarsalgia to other metatarsal joints.

A NOVEL SURGICAL TECHNIQUE OF CAPSULORRHAPHY FOR THE TREATMENT OF HALLUX VALGUS: CADAVERIC STUDY

Sergio Luis Orozco-Villaseñor, Israel Miguel-Andrés & Jose De Jesus Mayagoitia Vazquez
Department of Biomechanics at CIATEC A. C. Mexico
Corresponding author email: imiguel@ciatec.mx

INTRODUCTION

Hallux valgus is a complex malformation of the first metatarsophalangeal joint, where the big toe of the foot is deviated laterally. This permanent deviation produces a painful swelling of the joint. There is no clear evidence of the etiology leading to the development of hallux valgus and it could be produced for several factors, such as ill-fitting shoes or flatfoot deformity [1-2]. This malformation is more frequently found in elderly people and women. Although there are several surgical techniques for the treatment of the hallux valgus deformity, none of them are completely satisfactory [2-3]. The objective of this investigation was to develop a new surgical technique for the treatment of the hallux valgus malformation.

METHODS

Six cadaveric feet with the hallux valgus malformation were treated in this study, average age 63.33 years (range 78-49 years), Figure 1a. The new surgical technique is described through the following procedure: surgical approach was done from the medial part of the metatarsophalangeal joint. The joint capsule was incised longitudinally as shown in Figure 1b. The capsule was opened in order to expose the bony malformation of the metatarsal head. Then, exostectomy of the first metatarsal head was performed. The medial side of the metatarsal head was smoothed and the abductor hallucis muscle was released. In this stage, the big toe is relocated according to its natural position. Once the undesirable bone was removed, the surplus tissue of the joint was removed and the metatarsophalangeal joint capsule was sutured through the capsulorrhaphy technique, Figure 1a-c. Finally, the abductor hallucis tendon was attached to the bone close to the joint capsule and the soft tissue was sutured, as shown in Figure 1d. The new surgical technique finishes with the use of a bandage to cover the wound and hold the metatarsophalangeal joint stable.

RESULTS AND DISCUSSIONS

Six cadaveric feet were treated with the hallux valgus deformity, five feet with mild deformity (more than 23 degrees of lateral deviation) and one foot with moderate deformity (more than 30° of lateral deviation). All feet were successfully treated and the hallux valgus malformation corrected. The metatarsophalangeal joint angle was less than 19° after the surgical technique in all cases. Although there are several techniques for the treatment of hallux valgus deformity, none of them are completely satisfactory. This could be explained as the hallux valgus is a complex malformation which involves several factors [2-3]. As the etiology of hallux valgus is not well understood, the complete surgical success of this malformation is quite difficult.

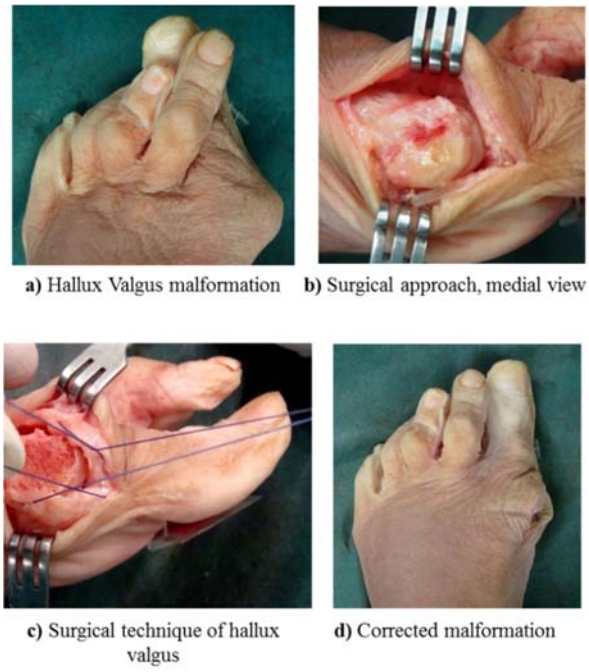

Figure 1 Surgical technique of capsulorrhaphy; a) Hallux valgus malformation, b) Surgical approach from the medial part, c) Surgical technique of hallux valgus and d) Corrected malformation.

CONCLUSIONS

The clinical outcome of the treatment of the hallux valgus deformity applying this new capsular repair was successful. It is clear to observe the reduction of the metatarsophalangeal angle and the relocation of the big toe to its natural position. The joint capsule was closed with suitable tension and the metatarsophalangeal joint mobility conserved.

ACKNOWLEDGEMENTS

WHAT KINEMATICS AND CONTACT MECHANICS DIFFERENCES BEWTEEN STANDARD AND MEDIAL PIVOT PROSTHESIS: AN EXPLICIT FINITE ELEMENT ANALYSIS BASED ON GAIT CYCLE

[1] **Shu Liming**, [1]Yamamoto Ko, [1]Sugita Naohiko and [1]Mitsuishi Mamoru

INTRODUCTION

The kinematics and contact mechanics have strong influences on the performance after total knee replacement (TKR). In order to mimic the biomechanics of normal knee joint, a wide range of prostheses have been designed and evaluated since 1950s. Standard prosthesis (SP) and medial pivot prosthesis (MPP) are basically representative designs based on anatomical approach [1]. As to SP, symmetrical elliptic-shaped grooves were designed on the tibial insert component to achieve the stability on coronal and sagittal planes. However, there is an anterior sliding of femur on the tibia termed “a paradoxical motion” due to contradicting with physiologic rollback, which has been found on the clinical trials [2]. MPP has been designed with a ball-in-socket joint on medial side and a joint on lateral side which moves front to back and rotates around the center of medial side, based on the analysis of tibial articular surface. For understanding the kinematics and contact mechanics differences between the above two kinds of prostheses, experiments and the dynamic explicit finite element analysis have been used in this paper.

METHODS

The experimental kinematics data were obtained by wear testing machine based on ISO 14243-1 from EndoLab [3]. The anterior-posterior resistance was 9.3N/mm to simulate the capsule and other secondary soft tissue restraint. Besides, the restraint was zero when the TKR prosthesis was in, or within 2.5 mm in either direction of the reference point. The tibia rotation resistance was 0.36Nm/°. The rotation resistance was also zero when the TKR prosthesis was in, or within ±6° either sense away from the reference position.

The TKR model was developed in ABAQUS™/Explicit (HKS, Pawtucket, RI) in order to analyze the kinematics and contact mechanics during gait cycle based on the above experimental conditions. Three prostheses were analyzed: SP1 (Adler Ortho S.R.L, Italy), SP2 (DePuy International, UK) and MPP (Adler Ortho S.R.L, Italy). Considering that a rigid body has little influence on calculation accuracy [4], all the components were set as a rigid body meshed by R3D4 element with 1.5 mm approximate global element length for reducing the computer expense. The coefficients of friction on the contact surfaces among femoral component, tibial insert component and tibial tray, were set as 0.04 and 0.15, respectively. The surface-to-surface penalty contact property has been assigned to the two contact surfaces. Boundary condition was applied to the femoral and tibial tray components to simulate gait cycle. The axial load axis was shifted using an offset of 7% of the tibial width in medial direction. In order to simulate the resistance on experiments, a set of nonlinear spring with same mechanical property was added into the TKR model. The degrees of freedom on flexion-extension and inferior-superior directions were set free for femoral component. The remaining four degree of freedoms were set free for tibial tray component. The tibial insert component was fixed by hinge connection and surface contact with tibial tray.

RESULTS AND DISCUSSION

A good agreement between model-prediction and experimental results can be achieved. Results of Anterior-Posterior (A-P) translation of three prostheses have been shown in Figure 1, as an example.

For SP1, small A-P translation and Internal-External (I-E) rotation have been found during gait cycle, where a hinge-joint property is exhibited. A-P translation and I-E rotation of SP2 are much larger than that of SP1, where I-E rotation kinematics of normal gait is reproduced. However, large A-P translation may lead to a paradoxical motion, making patients feel like “walking on ice”. Small A-P translation and large I-E rotation have been found on MPP due to the medial pivot.

Based on contact mechanics simulation, a similar trend of contact area on gait cycle has been found on lateral side. However, for the medial side, the contact between MPP components has a much better performance than that of SP.

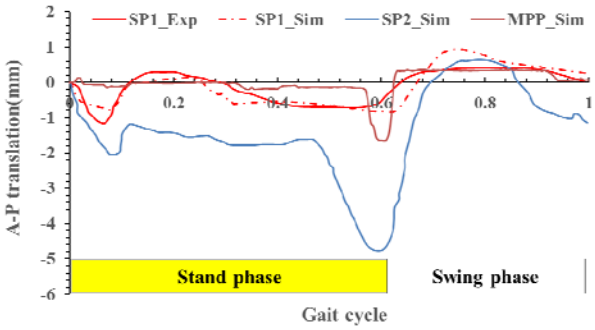

Figure 1: The experimental and FEM A-P translation results as a function of gait cycle

CONCLUSIONS

An explicit finite element method has been developed to simultaneously predict the kinematics and contact mechanics differences between SP and MPP with experimental verification. The results present MPP has a much stable and normal knee like kinematic performance.

QUANTITATIVE EVALUATION OF 3D WEIGHT-BEARING LOWER EXTREMITY ALIGNMENT AND IMPLANT POSITION USING BIPLANAR SLOT RADIOGRAPHY AND 3D SURFACE MODELS

[1] **Koichi Kobayashi**, [1]Daisuke Okaniwa, [1]Daisuke Nakahara, [1]Makoto Sakamoto and [1]Yuji Tanabe
[1]Niigata University
Corresponding author email: kobayasi@clg.niigata-u.ac.jp

INTRODUCTION

Weight-bearing alignment of the lower extremity is crucial for understanding biomechanics of the normal and pathological functions at the hip, knee, and ankle joints as these joints are subjected to high levels of load and moment throughout life. In addition, implant position with reference to bone is a critical factor affecting the long-term survival of artificial joints since implants could alter the mechanical load applying to the host bone tissues.

The purpose of this study was to develop a biplanar system using a slot radiography (SR) and 3D surface models for evaluating 3D weight-bearing alignment of the lower extremity and component positioning of total knee arthroplasty (TKA) and total hip arthroplasty (THA) with respect to bone. Validation of the system was performed using model bones and artificial knee and hip joints.

METHODS

We used a SR system (Sonial Vision Safire 17, Shimadzu, Kyoto, Japan) with a custom-made rotation table to capture x-ray images at 0 deg and 60 deg relative to the optical axis of an x-ray source. The SR system produces collimated fan beam x-rays synchronized with the movement of a flat-panel detector, allowing to obtain a full length x-ray image of the body with reduced dose and small image distortion compared with conventional x-ray systems.

Camera calibration was performed beforehand using an acrylic reference frame with 72 radiopaque markers to determine the 3D positions of the x-ray source and the image plane in the coordinate system embedded in the reference frame. Polymeric pelvis, femur, tibia and TKA and THA components were used to validate accuracy of the system. Computed tomography scans of the pelvis, femur and tibia were performed to allow the reconstruction of the 3D surface models. For the TKA and THA components, the Computer-Aided-Design (CAD) models were obtained from the manufacturer. Local coordinate system of each surface model was defined based on 3 reference markers attached to each model.

The femur and tibia were immobilized at three different knee alignment positions; extension, axial rotation, and varus deformity. For each alignment the femur and tibia were imaged using the biplanar SR system at front (0 deg), left (60 deg), and right (-60 deg) table positions. A virtual biplanar imaging system was built on a custom made software using the aforementioned camera calibration data. The 3D positions of the femur and tibia were recovered by manually matching the projection of the 3D surface model to the corresponding biplanar images. The TKA femoral and tibial components as well as THA acetabular cup and femoral stem were installed to the host bones by experienced arthroplasty surgeons. The 3D position of each implant with respect to the host bone were recovered using the above-mentioned matching method. Manual image matching was done by 4 to 5 raters and accuracy and precision were presented by average and standard deviation (SD) values of differences between the estimated position parameters and the ground truth which was obtained from the position of the reference markers attached to each model.

RESULTS AND DISCUSSION

Overall, the largest average and SD values were -0.3 mm and 0.7 mm in translation and -0.3 deg and 0.7 deg in rotation for assessing the knee alignment, and -0.3 mm and 1.2 mm in translation and 0.3 deg and 0.7 deg in rotation for assessing the implant position (Table 1). These results were similar to our previous technique using a biplanar imaging system with conventional x-ray [1,2], and another biplanar technique using a EOS imaging system [3], demonstrating that the present method has an adequate accuracy for the clinical usage. In addition, the conventional x-ray system requires about 2 times longer SID (Source Image receptor Distance) than that in the present system, and needs to merge multiple radiographs obtained from imaging plates instead of using a single image produced by a built-in process in the SR system. Thus, the present system could save space and time. Further, we will develop an automatic image matching technique to eliminate the intra- and inter-rater variabilities.

Table 1: Overall average ± SD of the estimated position parameters.

Knee alignment	Translation, mm	Rotation, deg
Extension	-0.1 ± 0.7	-0.3 ± 0.7
Axial rotation	0.1 ± 0.7	0.2 ± 0.5
Varus deformity	0.2 ± 0.5	-0.1 ± 0.5
Implant position	**Translation, mm**	**Rotation, deg**
TKA femur	-0.3 ± 0.6	-0.0 ± 0.5
TKA tibia	-0.0 ± 0.8	-0.2 ± 0.6
THA cup	0.1 ± 1.2	0.3 ± 0.7
THA stem	-0.3 ± 0.6	-0.0 ± 0.5

CONCLUSIONS

We have developed a biplanar system using a slot radiography for assessing quantitative 3D weight-bearing alignment of the lower extremity and component position in reference to bone. Validation of the system suggested that this technique has a potential for clinical usage.

INTRODUCTION

In joint replacement patient dissatisfaction is still reported. This is being addressed via various techniques in the area of computer-assisted surgery (CAS). Much attention is given to most practiced surgeries. Small joint implantations, like total ankle replacement (TAR), are limitedly investigated. For these, the appropriate implant-to-implant and implant-to-bone adaptation are big issues that can be addressed by design personalization [1]. This is nowadays feasible, thanks to the progresses in bio-imaging, subject-specific joint modeling, and advanced additive manufacturing [2]. Current TAR designs are non-full patient-specific and anatomy-based, resulting frequently in dissatisfactions. Generally, these have articular surfaces either cylindrical (CYL) or based on truncated-cone with medial apex (TC) [3]. Recently it was demonstrated that these surfaces can be best approximated by a saddle-shaped truncated skewed-cone with lateral apex (STC) [3]. Modern CAS technologies are expected to enhance personalization in TAR [1]. Surgical navigation systems (SNS), three-dimensional (3D) computer-aided-design (CAD) by scanning/reconstruction tools, and 3D-printing (3DP) via selective-laser-melting (SLM), represent cutting-edge technology. In particular, metal sintering via SLM may allow rapid prototyping and fabrication of complex personalized medical devices [2].

The aim of this study was to report on the development of a full process for personalized TAR design, starting from ankle imaging and CAD modeling, through manufacturing process via 3DP in plastic or metal powders, up to implantation and biomechanical testing via SNS. A novel STC TAR was produced accordingly, tested kinematically in-vitro via SNS, and relevant results compared with other designs based on standard articulating surfaces.

METHODS

10 cadaver lower limb specimens with normal ankles were analyzed. For each ankle, high resolution MRI (GE, Little Chalfont-UK) and CT (Philips, Best-NL) scans were performed for 3D CAD modeling (AnalyzeDirect™, Overland Park, KS-USA) of the original articulating bone surfaces [3]. These were then imported in softwares (Creo™, Needham, MA-USA; Geomagic™, Morrisville, NC-USA) to produce 3 sets of custom-fit virtual articular prosthetic surfaces: CYL, TC and the novel STC. Dynamic simulations were performed in ADAMS™ (Newport Beach, CA-USA). In the manufacturing phase, prototypes of these surfaces were obtained in acrylonitrile butadiene styrene (ABS), and also using cobalt-chromium powders (ASTM F1537-15; 45µm) via SLM (SISMA, Piovene R.-IT).

During in-vitro tests (Figure 1), each specimen was positioned in a special testing rig and frontal and axial moments were applied to the calcaneus in the three anatomical planes in a number of joint positions. In each experiment, the natural ankle was tested first by imposing manually-driven dorsi/plantar-flexion cycles. An adapted SNS (Stryker®, Kalamazoo, MI-USA) was used to track talus, calcaneus and tibia motion, via active trackers [4]. Each of the 3 implant sets was then implanted one at a time and the motion and loading test was repeated. Ankle dorsi/plantar-flexion (Dor/Pla), inversion/eversion (Inv/Env) and internal/external (Int/Ext) were calculated [4]

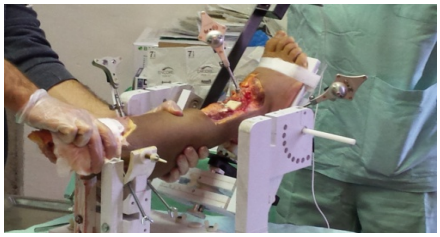

Figure 1: Experimental set-up using SNS

RESULTS AND DISCUSSION

Dynamic simulations revealed more natural behavior using the STC surfaces. In in-vitro tests, intra-specimen repeatable motion patterns were observed at the natural and implanted ankle (standard deviation less than 1.0°). After TAR, in dorsi/plantar-flexion cycles a good restoration of physiological motion occurred, with ranges being about 34° for Dor/Pla and 3° for both Inv/Env and Int/Ext, regardless of the prosthesis components design. Kinematics resulting from torque application showed that STC surfaces in ABS have values closer to the natural ankle than the CYL and TC. Similar values were obtained using the corresponding metal prototypes. For the latter, mechanical tests confirmed also the appropriateness of manufacturing in terms of microstructure, density, wear resistance and strength [2].

CONCLUSIONS

The novel personalized STC-based TAR, suitably manufactured, implanted and tested via a combination of CAS techniques, resulted in more physiological kinematic performances than current TAR surfaces. The present process also support the feasibility and efficacy of personalization in TAR, now available also for final implant manufacturing via SLM and for implantation via SNS. When compared to existing TAR, the present novel TAR is expected to be more respectful of the soft tissues, this likely reducing complication and failure rates.

INTRODUCTION

Accurate subject-specific representation of bone geometry is important for biomechanical analysis of femoroacetabular impingement (FAI), patellofemoral pathology (PFP), cerebral palsy (CP) and osteoarthritis (OA) [1]. From the Musculoskeletal Atlas Project (MAP) a free open-source software developed, known as MAP Client, which enables rapid creation of subject-specific bone geometries from sparse multi-modal imaging. MAP Client morphs a mean model, derived from healthy adult cadavers (27 lower-limbs and 214 femurs), to an individual's bone geometries using statistical shape modelling [2]. The use of sparse imaging is both cost- and time-effective, however, it is not known whether MAP Client can accurately generate bone geometries for clinical populations. Further, optimal morphing techniques and minimum imaging requirements remain unexplored. The aim of this study was to examine the fit accuracy of femur and pelvis geometries generated by different morphing techniques using MAP Client in both adults and children with and without a clinical condition.

METHODS

Magnetic resonance images were obtained from 4 adult symptomatic FAI patients (38.5±7.9 yrs), 4 FAI control subjects (24.3±3.4 yrs), 4 children with PFP (13.5±1.9 yrs), 5 PFP controls (11.0±2.1 yrs), 2 children with CP (11.5±2.1 yrs), and 1 CP control (13 yrs). A standing 3-dimensional motion capture trial of each patient was also used. The affected femur and pelvis were semi-automatically segmented and reconstructed with Mimics v17 (Materialise, Leuven, Belgium). A sparse version was created by removing bone geometries, although key bone features defined on the mean model were preserved.

Two modelling workflows were used for all patients. These workflows included an initial coarse fitting step and a final localized mesh-fitting step. In coarse fitting, either host mesh (HM) [3] or principle component (PC) [4] fitting was performed. The HM fitting morphed the mean bone over the subject's sparse geometry, but was constrained by a bounding host mesh. The PC fitting morphed the mean bone according to a statistical shape model to fit the subject's sparse geometry. The number of PCs was identified as the optimal point between shape fit accuracy, i.e. root mean square error (RMSE), and shape fit variance. All fitting was manually optimized by tuning discretization and smoothing-weights with the aim of an RMSE two-fold the image pixel size. Fit accuracy (RMSE) was assessed between sparse and MAP Client generated geometries and surface-to-surface similarity was assessed between full and generated geometries using the Jaccard index.

RESULTS AND DISCUSSION

Preliminary results were from FAI and CP patients. Optimal number of PCs was 4-5. Both workflows had similar final RMSE for CP (PC: 1.56±0.08 mm; HM: 1.41±0.03 mm) and FAI femurs (PC: 1.74±0.33 mm; HM: 1.91±0.27 mm). Although FAI pixel size was smaller (0.67 mm) compared to CP (0.88 mm), larger RMSE in FAI femurs may be because FAI images did not contain mid-shaft femur (Figure 1). Registering mean bones to sparse geometries may have caused creases or other bone shape artefacts in the final model. Preliminary HM results from full femur and pelvis geometries of CP showed higher similarity in femurs (0.93±0.01) than pelvises (0.63±0.01). Lower Jaccard index for pelvises may be due to poor registration of an adult pelvis (i.e. mean model) to a child pelvis (i.e. patient).

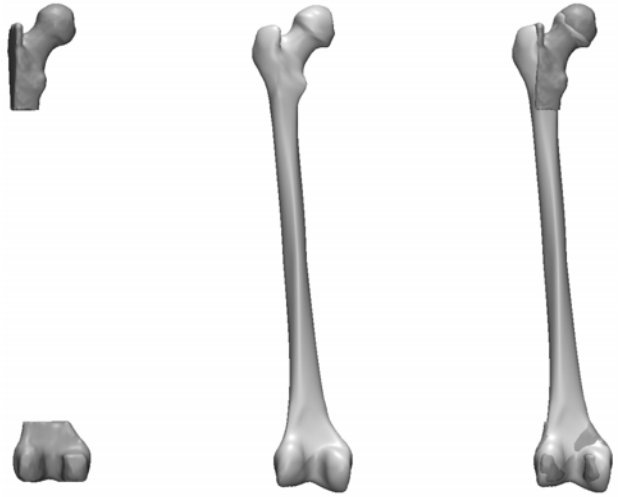

Figure 1: FAI femur (middle) generated from sparse geometry (left) and overlay result (right).

CONCLUSION

MAP Client generated femur geometries for FAI and CP patients with fit accuracies close to image sensitivity, although they displayed bone shape artefacts. Poor surface-to-surface similarity with CP pelvis geometries generated from full segmentation indicated a mean pelvis model for healthy children may be required. With sparse imaging, adjustments to optimize fit may not be sufficient to rectify initial registration errors. Optimized solutions are currently being explored to fit subject's bone geometries, including a hybrid workflow containing both HM and PC fitting. We are still identifying key bone features that produce accurate fitting results. We are now using full bone geometries of matched healthy controls (children and adults) to further compare critical bone features and morphing methods.

COMPARING STATISTICAL SHAPE MODEL BASED MESH FITTING METHODS USING OPEN SOURCE SCALISMO TOOLBOX: TOWARDS PATIENT-SPECIFIC BIOMECHANICS MODELING

INTRODUCTION

Use of Statistical Shape Models (SSMs) in the medical field (diagnosis, morphometric analysis, surgical interventions, etc.) has been promising [1]. It can play an even greater role in building accurate patient-specific biomechanics models that are fast, reliable, and have clinical utility rather than just providing insights. However, its role in shoulder biomechanics modeling is not fully explored. SSM based shoulder biomechanics modeling can benefit from their abilities to automatically identify muscle or tendon insertion regions, to provide inter-individual anatomical variations for quick biomechanical comparisons, to predict missing or deformed bone shapes etc. But first, we need to prove SSMs capability to fit to randomly selected bone shapes from the population and to select best registration methods for this purpose. To conduct such analysis, an SSM must establish a correspondence between the target shape and the SSM. Thus, this study has two aims, first, to explore the utility of an open source toolbox (SCALISMO) [2] to create scapula SSM, and second to compare two mesh-based fitting methods to find the best registration result that solve the problem of point-to-point correspondence between shapes

METHODS

CT scans of 27 dry scapulae were first used to build the SSM of scapula bone using an Iterative Median Closest Point – Gaussian Mixture Model (IMCP-GMM) pipeline that was proposed earlier [3]. The scapula SSM quality was tested using generality, specificity and compactness criteria. The fitting method was conducted using the open-source toolbox SCALISMO. The fitting process was initiated with a landmark-based alignment step, followed by a rigid alignment using Iterative Closest Point (ICP) algorithm between a target mesh and the SSM and then using two different model fitting methods: (A) a Gaussian process regression to build posterior model involved in an ICP non-rigid registration, and (B) Parametric registration using the deformation field issued from the SSM and a *Limited-memory* BFGS (L-BFGS) optimizer. The fitting quality from the two methods was tested on two sets of targets (internal: from the SSM learning base and external: not from learning base and manually segmented from CT scans, four targets each). The similarity of fitted surface with target was evaluated by Dice Coefficient. Correspondence quality was evaluated using the root mean square distance, mean distance, and Hausdorff distance between the same indices.

RESULTS AND DISCUSSION

The entire SSM building pipeline and fitting algorithm was successfully implemented in SCALISMO toolbox. SCALISMO can be effectively used for shape modeling pipelines as it facilitates the use of outside libraries (for e.g., ITK) and provides a graphical user interface for quick visual analysis. The internal targets had superior fitting quality than the external targets (Table 1 and 2). When the correspondence quality of the methods was compared,

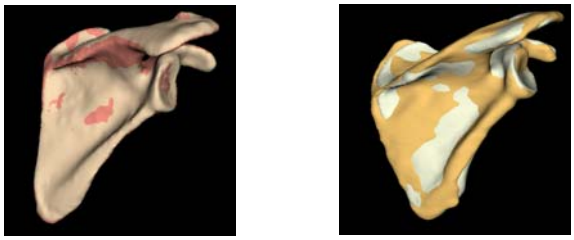

Figure 1: Example ICP non-rigid registration result on internal instances (fitted – pink, target – beige) and external instances (fitted – grey, target – golden)

method A (Corr RMS:(1.46 ±0.34) mm) performed slightly better than method B (Corr RMS:(1.56 ±0.31) mm). Both the methods resulted in below average similarity index as evident from dice coefficient (Table 2). However, the mean distance and root mean square errors for correspondence were below 1.4mm and could be clinically acceptable.

Higher Hausdorff distances observed in external instances were probably due to the lower generality of the SSM to represent the population and more learning base instances would be needed to increase this generality.

Table 1: Mean values of similarity and correspondence quality on internal targets. DC = Dice Coefficient, HD = Hausdorff Distance, MD = Mean Distance, RMS = Root Mean Square

Fit Type	DC	HD (mm)	MD (mm)	RMS (mm)
A	0.88±0.04	3.02±0.25	0.42±0.03	0.57±0.02
B	0.86±0.05	3.49±0.25	0.44±0.03	0.58±0.01

Table 2: Mean values of similarity and correspondence quality on external targets.

Fit Type	DC	HD (mm)	MD (mm)	RMS (mm)
A	0.38±0.43	16.08±5.52	1.16±0.21	1.29±0.25
B	0.37±0.42	13.35±4.12	1.17±0.21	1.32±0.31

CONCLUSIONS

SCALISMO is an efficient toolbox for SSM building as well as for benchmarking. Although both the methods were effective, more evaluations would be necessary by changing the various parameters in the fitting process, by improving the generality of the SSM or by increasing the compactness of the SSM. Once validated, SSMs could be used for developing advanced patient-specific biomechanics models.

INTRODUCTION

Musculoskeletal modelling has tremendous potential to influence clinical decision-making. However, the ability of models to diagnose or predict clinical outcome is currently limited by the difficulty in capturing the subject-specific anatomy and physiology of the individual. Accurate representation of bone geometry, for example, is critical for predicting muscle and joint contact forces, as it influences the muscles' length, moment arm, and line of action.

Customising musculoskeletal models from medical imaging data is time-consuming and not feasible for routine clinical use. It is more common to use simple length scaling of a template model to match a set of anatomical landmarks (i.e. retroreflective markers placed on body segments) and thus, generate a 'patient-specific' model. However, linear, isotropic scaling does not capture variation in bone shape and the scaling process can result in bone dimensions that are non-physiological.

This paper illustrates the use of an articulated statistical shape model to customise the lower limb bones, muscles, and joints of an OpenSim musculoskeletal model. The method is developed within the Musculoskeletal Atlas Project (MAP), a Python-based open-source framework.

METHODS

A combined statistical shape model of the pelvis, femur, patella, tibia, and fibula was created from a training set of 26 left lower limb bones manually segmented from CT images. Muscle and ligament attachments were identified from a SOMSO model (www.somso.de, Sonneberg, Germany) and embedded onto the parametric bone meshes (Figure 1a). Anatomical landmarks were also embedded in each bone's reference mesh to generate consistent anatomical coordinate frames (Figure 1b).

Customisation was performed via an optimisation procedure that adjusted the principal components of the shape model (n=5), along with translation of the pelvis (3DOF) and rotational degrees of freedom of the hip (3DOF) and knee (2DOF) [1]. The hip joint centre was constrained to fit within the acetabulum of the pelvis and the knee joint axis was altered to ensure contact between the femur and tibia throughout knee flexion. Muscle volumes were scaled by subject height*mass using the regression provided by Handsfield et al. [2]. Tendon slack lengths were then optimised to ensure that muscle fibres were within physiological limits of the force-length relationship [3].

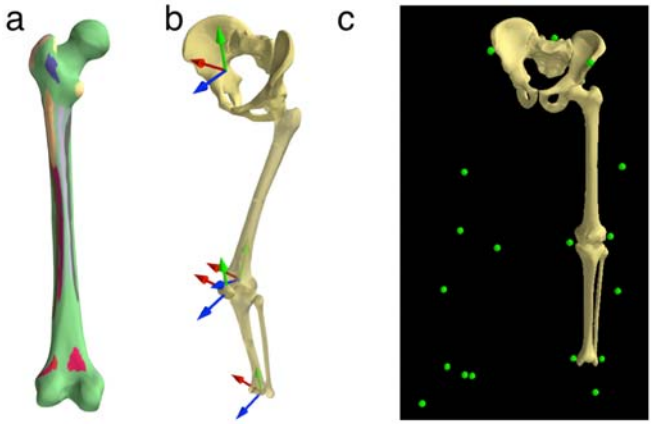

Figure 1. Parametric mesh of femur (a) illustrating regions of muscle attachment sites and (b) articulated lower limb model. MAP Client interface showing scaling of model to match motion capture marker.

We tested the ability of the model-based shape estimation to predict lower limb geometry using only 7 motion capture markers. A leave-one-out analysis was used to determine the accuracy of the predicted bone geometry compared to segmented models.

RESULTS AND DISCUSSION

Shape model scaling of lower limb geometry using 7 markers was accurate to <5mm RMS error. Compared to linear isotropic scaling, our method reduced surface error estimation ($p<0.001$) and provided a feasible set of muscle-tendon parameters that were consistent with the scaled bone geometry.

CONCLUSIONS

We have presented an articulated shape model to customise a lower limb OpenSim musculoskeletal model. The method has been implemented in an open-source software framework, The Musculoskeletal Atlas Project, which can be easily shared and provides users with access to OpenSim's Python API.

DEVELOPMENT OF A PERSONALIZED LINEAR ELASTIC MODEL OF THE KNEE JOINT FROM EX VIVO SIX DEGREES OF FREEDOM STIFFNESS MEASURMENTS

INTRODUCTION

Personalised knee joint models usually rely on the subject's anatomy [1], typically derived from medical images, assigning material properties from public atlas and sometimes adapting these properties to match some global knee stiffness measurements. An alternative approach with no need of detailed anatomy could be based on personalising a model using a few easily detectable anatomical characteristics and integrating this with a-priori information on the mechanical relationship between forces and kinematics. It has been shown before that this relationship can be expressed using a discrete set of compliance matrices [2]. Aiming at model personalisation, these matrices, created using data from ex vivo tests, could be updated using ad hoc simple experiments performed on the specific subject (e.g. instrumenting clinical tests performed in Orthopaedics). This study aims to propose and validate this approach by defining a numerical procedure for estimating the knee compliance in different specimen conditions.

METHODS

Ethical clearance was obtained from the local Human Research Ethics Committee. Two knee specimens from two male donors (SP1: age 60 years, mass 91 Kg, Stature 1.83 m; SP2: age 88 years, mass 91 Kg, Stature: 1.78 m) were obtained fresh frozen from a body donation program. After 24 hours thawing at room temperature, the tibia, fibula and femur of each specimen were cut at mid shaft. Specimens were tested using an accurate hexapod robot system, including a six degrees-of-freedom (DoFs) Gough-Stewart platform-based manipulator coupled with a six DoFs load cell, and developed for biomechanical joint testing [3]. The femur was fixed to the ground and the tibio-fibular complex was secured to the moving robot plate. Experiments were conducted at 0°, 15°, 30°, 60° and 90° of knee flexion. At each angle, five position control tests were performed, including single DoF experiments in both positive and negative directions (±10 mm, or ± 10° with a 20% non-linearity permitted). Tests were performed on the intact specimens and sequentially after the resection of the anterior cruciate, posterior cruciate and lateral collateral ligament. Assuming linear dependence between forces and displacements, a compliance matrix (C) was calculated for each of the twenty experiments solving an optimization problem (fmincon, MATLAB©, The Mathworks Inc., USA) by minimising the cost function J(C)

$$\mathrm{J(C)} = \|[C][F] - [X]\|_{mm} + w \cdot \|[C][F] - [X]\|_{rad}$$
$$Subject\ to: \mathrm{[C]\ symmetric\ and\ positive\ defined}$$

where F and X are matrices built by concatenating the matrices of the force/moments and linear/angular displacements, w is a weight factor, which, to account for the subject specific anatomy, was set equal to the femoral inter-epicondylar distance.

A leave-k-out cross-validation was used to evaluate the accuracy of each compliance matrix to predict the linear/angular displacements (k=5, four subgroups: model training, fifth subgroup: validation). Translation and rotation errors were quantified for each matrix in terms of root mean square difference between predicted and measured displacements, normalized by the range of the measured data in each axial coordinate (NRMSE). Mean and standard deviation of the NMRSE were calculated for each specimen. Agreement between measured and predicted values was also assessed using the slope (a_1), intercept (a_0), and regression coefficient (r) obtained from a linear regression analysis.

RESULTS AND DISCUSSION

Cross-validation results were very encouraging, with average NRMSE lower than 10% for both specimens and for both translations (SP1: 9.6% ± 1.9%; SP2: 8.4% ± 1.6%) and rotations (SP1: 6.1% ± 0.7%; SP2: 6.7% ± 1.1%).

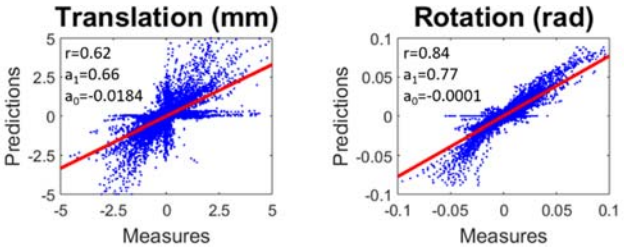

Figure 1: Results of the linear regression analysis.

Strong linear correlation was found for the rotations (r=0.84) but lower for the translations (r=0.62). The disagreement between predictions and measures was mainly introduced by values observed at low ligament strains, which could be due to local non-linearities of the force-displacement function. Further analysis is ongoing to investigate this hypothesis.

CONCLUSIONS

The approach proposed in this study is promising toward a simple personalization of knee models. Further improvements are expected from the ongoing inclusion of data coming from force control tests, which were collected by simulating the Lachman [4] and the Pivot-Shift tests [5].

MECHANOSTATISTICAL MODELLING: A LINK BETWEEN FINITE ELEMENT MUSCLE MODELS AND RIGID BODY MUSCULOSKELETAL SIMULATIONS

[1]**Geoff Handsfield**, [1]Ju Zhang, [1,2]Thor Besier, [3]David Lloyd, [1,2]Justin Fernandez

INTRODUCTION

Finite element models of muscle capture spatially varying material behaviour, complex fibre architecture, and interactions between muscles that combine to provide detailed muscle responses during active contraction. The primary drawback of these models is computational cost, which prohibits their use in large scale multibody simulations. In contrast, rigid body models typically employ simplified 1D approximation of Hill type muscles with limited description of muscle fibre architecture. High fidelity 3D muscle models may be approximated by multiple 1D muscles in parallel and series but still under-approximates the rich continuum information. Alternatively, 3D finite element models may be precomputed across a solution space for rapid lookup and interpolation. A recent method gaining traction is surrogate modelling based on a population of simulation data. In this study we explore regression-derived surrogate models of muscle that can then be integrated into rigid body musculoskeletal packages such as OpenSim.

METHODS

A 3D finite element (FE) model of the triceps surae (medial and lateral gastrocnemius and soleus muscles) was developed using T1-weighted MRI and diffusion tensor imaging (DTI). Scanning was conducted on a 3T Siemens Skyra scanner using an echo planar imaging DTI sequence (slice thickness: 3mm, resolution: 1 × 1mm, TE: 74ms, TR: 4400ms, 20+1 directions, B0: 400mm/s^2) and a 3D T1 VIBE Dixon sequence acquired in the sagittal plane (resolution: 0.8×0.8×0.8mm^3, TE: 5.22 ms, TR: 10.4ms). We segmented the triceps surae in T1-weighted images using ITK-Snap [1]. A pole-zero material law was used for passive muscle tissue with a Hill-type model in the fibre direction. We defined muscle fibre direction according to the first eigenvector of the DTI signal, processed using DSIStudio. FE simulation was conducted in custom developed CMISS software. The model was solved for 36 combinations of musculotendon length and activation levels across a range of physiological positions during gait to create a population space. A multivariate regression method, called partial least squares regression (PLSR)[2] was used to relate simulated muscle mechanics with activation and musculotendon length. PLSR implementation was performed using Scikit-learn [3] and provided an arbitrarily dense solution space interpolating the 36 input sample points from the FE simulations. Additional software resources were implemented from the GIAS2 library (https://bitbucket.org/jangle/gias2). Based on the 36 inputs of muscle length and activation level, a set of 36 responses were associated from the FE model. Response sets included contracted muscle geometry, stress and strain fields, and forces imparted to the bone. To test the accuracy of the derived mechanostatistical model we compared PLSR predictions with FE simulations in a leave-one-out experiment.

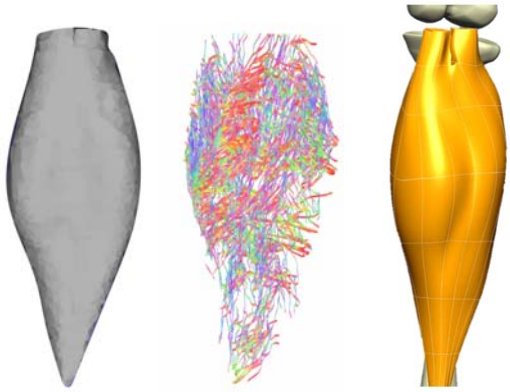

Figure 1: A model of the triceps surae was developed from T1-weighted MR images (left) and DTI-informed fibre tracts (center). FE simulations were used to model the contracting muscle group.

RESULTS AND DISCUSSION

The RMS error of muscle shape prediction was 0.042 mm for a simulation of 50% elongation and no contraction (passive). For a simulation of 80% elongation and maximum contraction, the RMS error was 0.063mm. The maximum error for muscle strain was 3% between the mechanical simulation and the mechanostatistical prediction for a 50% elongation and no contraction. The maximum error was 8% for an 80% elongation and maximum contraction. Further, principal components analysis of strain revealed a quadratic relationship between the zeroth and first mode of variation of strain, suggesting that a higher order relationship may exist for muscle strain when viewed in the context of a statistical solution space.

CONCLUSIONS

In this study, partial least squares regression was used to interpolate the solution space of 36 FE simulations of a contracting triceps surae muscle group. The shape and strain patterns were similar between mechanical simulations and statistical predictions based on the interpolation method. Future work will include using higher order, such as quadratic, regression to better capture the relationships between simulation inputs and outputs. This technique may prove useful for efficiently relating the solutions from complex FE modeling with rigid body simulations of gait from frameworks such as OpenSim.

EXPOSURE TO A UNIQUE VISUAL STIMULUS WITH KINESTHETIC SENSATION RESULTS IN SYNCHRONIZED RECIPROCALLY INDUCED SPONTANEOUS MUSCULAR RECRUITYMENT

INTRODUCTION

In previous studies, after participants acquired a sense of body ownership to a specific body part displayed on a digital monitor over their actual body part, they observed repetitive movements of the digital image from a first-person point-of-view. When this occurred, participants experienced an illusory sensation that their real body part was moving synchronously with the observed movements on the monitor. We call this sensation KiNvis (kinesthetic illusion induced by visual stimulus) [1,2]. We previously reported that in the early stages of training, the subject's hand started to move when KiNvis began [3]. We hypothesized that this biomechanical behavior, observed in the subject during KiNvis, may be a result of sensory-motor integration. Specifically, the neurological mechanisms following the visual stimulus may begin to work parallel with KiNvis and provoke the mechanical effect in the body segment. The present study aims to examine the idea that while the participants have a sense of body ownership, the visual stimulus of a moving-hand image induces spontaneous muscle activity synchronized with the visually presented movements.

METHODS

Eighteen students participated in the experiment. In the experiment, sitting in a comfortable chair with a head resting and wearing a head-mounted display, participants watched a real-time image of a static hand or a recorded image of a moving hand. The recorded movie consisted of repetitive wrist flexion-extension movements, which took 6 seconds for one cycle. The visual stimulus sessions consisted of five sessions in total (one static-hand observation and four moving-hand observations).

To detect spontaneous muscular recruitments, electromyography (EMG) was recorded during hand observation from the flexor carpi radialis and the extensor carpi radialis. We calculated two measures to quantify involuntarily generated muscle activity: RMS amplitude and synchrony index. RMS amplitude was the sum of moving averages of RMS with 1-second time-windows for the two muscles. Synchrony index, the main interest of the present study, is the sum of averaged correlation values between RMS and reference model of a pseudo RMS pattern of muscle activity, which reflects the degree of reciprocal activity in antagonist muscles. The pseudo RMS was created from a sine wave to be synchronized with the movement pattern of the displayed hand movements.

Further, to discuss brain-level changes we measured motor evoked potential (MEP) during watching a static-hand image and a moving-hand image before and after the observation sessions. We calculated the standardized amplitude of peak-to-peak MEP divided by the amplitude of the maximum M-wave for the radial nerve.

RESULTS AND DISCUSSION

The results showed that both synchrony index and RMS amplitude increased as sessions proceeded. Observation of hand movements did not statistically influence the MEP amplitude of the muscle related to the movements, but it changed kinesthetic sensation of their own hand.

These results demonstrated that observing hand movements for an extended period of time resulted in the activation of muscles synchronous with the visual image without any conscious effort. The kinesthetic sensation and spontaneous muscle activation were positively related. The correlation coefficient between the kinesthetic sensation and synchrony index was weak but still positive after excluding the outlier from the analysis. Both kinesthetic sensation and spontaneous muscle activation increased parallel as the session proceeded, suggesting that they were modulated by the common mechanism between movement execution and its sensation. For example, the kinesthetic sensation in the present study can be explained by assuming that unconscious and very low level motor recruitments (not necessarily kinesiological motion or measurable through EMG) elicited the "illusory" kinesthetic sensation in their real hand. This possibility cannot be proven in the present study, and thus further investigations are required to clarify the mechanism intermediating visually observed movements and spontaneous motor recruitment.

CONCLUSIONS

The present study has for the first time demonstrated that a long lasting visual stimulus of a moving-hand with kinesthetic sensation could elicit a spontaneous and unconscious hand movement that is synchronized with the observed reciprocal movement.

NEW INSIGHTS INTO USING THE EMG POWER SPECTRUM TO ASSESS FIRING PATTERNS DURING MUSCLE FATIGUE

Michael J. Asmussen, Vinzenz von Tscharner, and Benno M. Nigg
University of Calgary
Corresponding author email: Michael.Asmussen@ucalgary.ca

INTRODUCTION

It has frequently been reported that the mean power frequency from a surface electromyography signal is reduced when performing a voluntary contraction during a fatiguing task [1]. Typically, the reduction in mean power frequency observed during these fatiguing tasks is attributed to changes in the shape of the motor unit action potential due to a slowing of conduction velocity. What is also known is that when individuals perform isometric contractions until volitional exhaustion, bursts of muscle activity appear in the surface electromyography signal [2]. Hypothetically, this rhythmic activation of the muscle is likely attributed to synchronous or "clustered" firing of motor units. We suspect that the distinct bursts in muscle activity observed during these fatiguing tasks are due to synchronous or "clustered" activation of motor units and that this type of firing pattern can substantially influence the EMG power spectrum. Therefore, the purpose of this study was to examine how clustered activation of motor units changes the power spectrum of an EMG signal and determine how these changes relate to power spectra changes observed during fatiguing tasks.

METHODS

Three different EMG signals were modelled by convolving a signal motor unit action potential with a pulse train representing the firing patterns of motor units –an **EMG random** signal comprised of a random distribution of potentials, **EMG clustered** signal comprised of "clustered" firing of action potentials, and an **EMG combined** signal comprised of both clustered and random potentials. For the EMG clustered signal, the potentials fired in discrete time windows ranging from 0 to 100 ms in length (i.e., cluster window). For the EMG combined signal, a number of signals were created with different ratios of clustered to random motor units (i.e., cluster ratios). These ratios were 1:1, 1:2, 1:4, 1:10 clustered to random motor units. For each modelled EMG signal, the mean power frequency was calculated and the shape of the power spectrum was described. A one way ANOVA determined differences in these metrics of the EMG signals created from a random or clustered distribution of impulses with different cluster window sizes. A separate ANOVA was performed for each EMG signal created from a different cluster ratio and a Bonferroni correction was applied to the alpha value for the additional ANOVAs.

RESULTS AND DISCUSSION

The results indicated that having an EMG signal created from clustered motor units resulted in a reduction in the mean power frequency. When the EMG signal contained all clustered motor units, the mean power frequency was reduced in relation to the EMG random signal ($F_{(20,1980)}$ = 32333.6, p <0.001) and this was true for all cluster window sizes between 5 and 100 ms (p < 0.05). Similar results emerged for the different cluster ratios, but the effects were not as large (Figure 1).

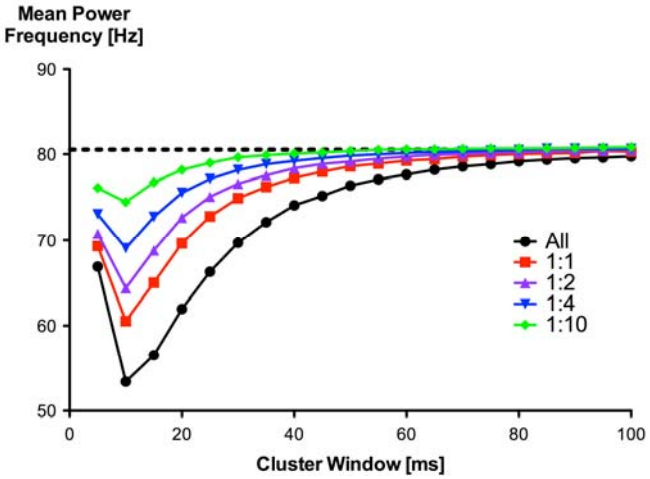

Figure 1: Mean power frequency as a function of cluster window size for each cluster ratio. Dashed line denotes the mean power frequency of the EMG random signal.

In addition to the metrics of the power spectrum, the shape of the power spectrum was analyzed descriptively. The EMG signal created from the random distribution resulted in a normally distributed power spectrum. The power spectrum of the EMG signal containing clustered motor units, however, resulted in a multi-modal power spectrum.

The results show the "clustering" of motor units changes the shape of the power spectrum and typical measures used to evaluate power spectrum changes, namely the mean power frequency. These model findings match what is observed experimentally. Specifically during fatiguing tasks, the mean power frequency is reduced and the power spectrum has been reported to be multi-modal [3]. Therefore, the "clustered" activation of the motor units may be an additional factor contributing to EMG changes observed during fatiguing tasks.

CONCLUSIONS

Motor unit action potential clustering creates substantial changes to the EMG power spectrum shapes and its metrics. In addition to slowing of conduction velocity, clustered impulses of motor units may also drive EMG changes observed in a muscle fatiguing task. Based on these findings, researchers should examine the whole power spectrum, rather than a single metric, to assess the genesis of changes in an EMG signal during fatiguing tasks.

CONFOUNDING FACTORS IN THE ANALYSIS OF FATIGUE-INDUCED MOTOR UNIT FIRING ADAPTATIONS

[1] **Paola Contessa** and [1]Joshua C. Kline

Corresponding author email: pcontessa@delsys.com

INTRODUCTION

Previous studies of muscle fatigue have reported various adaptations in motor unit (MU) firing behavior, including decreases [1,2] and increases [3] in MU firing rate during fatigue. We previously suggested that inconsistencies among the observations may be due in part to the practices used to analyze the MU data. For instance, the practice of analyzing MU firing rate as a function of recruitment threshold may confound the observations of firing adaptations because recruitment threshold itself decreases as muscle fatigue develops [1,3]. In a similar manner, grouping MU data across different subjects may obscure subject-specific firing adaptations and produce confounding observations of MU behavior with fatigue [2,3]. In this study, we investigated the influence of these practices when analyzing MU firing adaptations from the Vastus Lateralis (VL) muscle during a fatigue protocol to verify whether they may obscure the underlying MU behavior and prevent a clear understanding of MU firing adaptations with muscle fatigue.

METHODS

Five healthy subjects (3 males and 2 females, 24-33 yrs.) performed a series of isometric knee-extension contractions sustained at 30% maximal voluntary contraction (MVC) force and repeated until the endurance limit. Torque during knee extension and surface electromyographic (EMG) signals from the VL were recorded during each contraction (dEMG System, Delsys Inc.). Surface EMG signals were decomposed into the constituent action potentials (MUAPs) [4]. Changes in the firing rate of MUs in subsequent contractions of the fatigue protocol were analyzed:

1) As a function of MU recruitment threshold vs. MUAP amplitude (to avoid the possible confounding effect of decreasing recruitment threshold with fatigue).
2) For MU data grouped across subjects vs. MU data from individual subjects (to avoid the possible confounding effect of grouping subject-specific firing adaptations).

RESULTS AND DISCUSSION

When we assessed the firing pattern of MUs as a function of recruitment threshold, we observed a consistent decrease in MU firing rates during the fatigue protocol (Figure 1A). But when the same MU data were analyzed as a function of MUAP amplitude, we found a clear indication that MU firing rates progressively increase throughout the series of fatiguing contractions (Figure 1B). When we assessed the firing pattern of MUs by grouping MU data as a function of MUAP amplitude from all subjects, there was no clear trend in MU firing rate (Figure 1C). But when the same MU data were analyzed for individual subjects, a clear trend for firing rates to progressively increase with fatigue was observed consistently in all subjects (Figure 1D).

CONCLUSIONS

The practice of analyzing MU firing adaptations as a function of recruitment threshold provides false indication

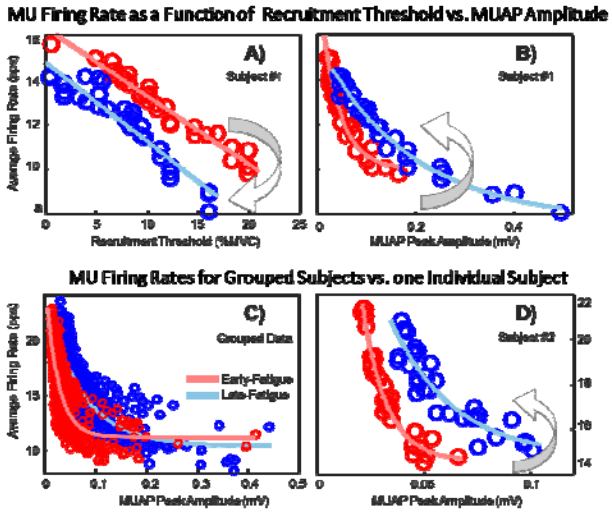

Figure 1: Fatigue-induced firing adaptations as a function of MUAP amplitude (A) vs. recruitment threshold (B); and for grouped data (C) vs. a representative subject (D).

of a fatigue-induced decrease in MU firing rate because recruitment threshold decreases with fatigue to compensate for the decrease in force generation capacity [1,2], i.e. higher-threshold MUs are recruited at lower forces. Because higher-threshold MUs fire at lower firing rates [3], MU firing rates appear to decrease when analyzed as a function of recruitment threshold. MUAP amplitude has also been reported to decrease with fatigue [5]. But, in contrast to recruitment threshold, a decrease in MUAP amplitude would not compromise the analysis of the MU data but rather accentuate the observed increase in firing rates. The practice of grouping MU data across subjects obscures subject-specific firing adaptations with fatigue, which are consistent in trend but differ in magnitude among subjects likely due to individual differences in muscle mechanical and biochemical characteristics. Our study shows that both analysis practices may obscure the actual behavior of MUs when analyzing MU data during fatiguing contractions.

THE EFFECTS OF PAIN ON MOTOR LEARNING OUTLASTS THE DURATION OF THE PAINFUL STIMULUS

INTRODUCTION

Pain affects movement planning and execution, and may interfere with plastic mechanisms associated with motor learning [1]. Understanding how pain affects the ability to learn new motor skills is of fundamental importance when training sports in the presence of pain or developing movement strategies to overcome pain in rehabilitation. In particular, subsequent motor retention, as an indicator of persistent changes in strategy, cannot be inferred from performance during a single training session. Although animal studies suggest that pain reduces motor performance during both acquisition and retention of the training task, results in humans are often conflicting, in part because of differences in methodology [2]. Force field environments are ideal to investigate motor adaptations during learning, as changes in strategy persist after removal of force field and motor retention is often observed after a single training session. This study aimed to assess the effects of pain on the acquisition and retention of a novel arm-reaching task.

METHODS

Twenty-two participants performed sets of 100 forward arm-reaching movements using a robotic manipulandum under each of 4 conditions: Baseline 1, Baseline 2, Force Field 1, and Force Field 2 (Fig. 1). The robot generated a null field during Baseline sets and a viscous, velocity-dependent field during Force Field sets. During all sets, 1 out of 5 movements (i.e. 20 per set) was randomly set to a "channel" trial in which are arm was forced to follow a straight path. Before Baseline 2 and Force Field 1 conditions, participants received an injection of either hypertonic (Pain group, N = 11) or non-painful isotonic (Control group) saline into the anterior deltoid (ADEL) muscle. The Force Field 2 condition was initiated after pain had recovered. Surface electromyography (EMG) was recorded from the ADEL, posterior deltoid (PDEL), biceps brachii (BB), and triceps brachii (TRB) muscles. Motor performance during each movement was assessed by peak speed of movement, peak orthogonal distance from a straight path, and force adaptation index (regression between the ideal and actual force profiles). EMG envelopes were time-normalized, and the average across the last 50 baseline trials was subtracted. The EMG envelopes from the first 20 (early) and last 20 (late) trials of each condition (i.e. Epochs) were transformed to the wavelet domain and compared between groups using wavelet-functional ANOVA [3]. Significant contrasts were transformed back to the time domain for visualization. Performance parameters were assessed by a 3-way ANOVA with Group, Condition, and Epoch as factors.

RESULTS AND DISCUSSION

Pain did not affect the performance of the arm-reaching task, i.e. no main effect or interactions with Group factor (all $p > 0.23$). During early Force Field conditions, both groups showed increased deviation of hand trajectory ($p < 0.001$) and reduced force adaptation index ($p < 0.001$) than baseline, but peak speed did not change ($p > 0.1$). Participants showed retention of the trained task, demonstrated by smaller hand deviations during Force Field 2 than Force Field 1 ($p < 0.03$). Following the first saline injection, the Pain group reduced ADEL and PDEL EMG in the absence of the force field (Figure 1, Baseline 2). The Control group responded to the force field with increased EMG activity of all muscles. In contrast, the Pain group showed smaller increase in EMG activity, resulting in large between-group contrasts in EMG envelopes – particularly ADEL, which remained mostly less than baseline levels despite resistance to the force field. Strikingly, similar patterns of ADEL, PDEL, and TRB EMG were observed upon re-exposure to the force field in the absence of pain, suggesting retention of the previously learned motor strategy after complete resolution of pain.

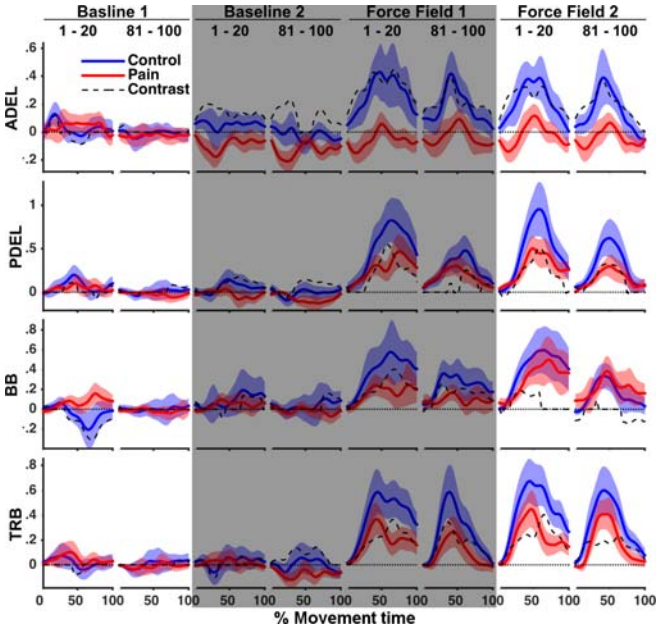

Figure 1: Changes in EMG envelopes relative to late baseline. Dotted lines show significant group differences. Shaded trials performed after saline injection in ADEL.

CONCLUSIONS

Pain can interfere with the motor strategy used to learn a new motor task even when motor performance is unaffected. Motor strategies learned during pain are sustained after cessation of painful stimulus.

INTRODUCTION

Rodents are model organisms integral to the exploration of craniofacial and dental evolution. Even though the developmental pathways to their skull morphogenesis have been extensively studied in the past, most investigations focus on the effect of traits related to their DNA sequence, e.g. genes and growth factors. Renaud et al. [1] however, recently argued that the phenotypic plasticity of epigenetic processes, such as dietary aspects and muscle driven remodeling, could favor the selection of pre-existing variances that are far more direct than genotypic influences recruited in macro-evolutionary trends.

We hypothesize that this may be attributed to the unique characteristics and/or anatomic locations of rodent mandibles, such as the cervical loop region of the incisor, hosting large populations of epithelial and mesenchymal stem cells. As these cells are highly mechanosensitive, it stand to reason that extracellular loads associated to their feeding ecology, could affect their fate, behavior and differentiation and thus drive postnatal incisor and mandibular growth rates.

METHODS

A rodent's skull (mouse with a mixed C57Bl/6-Sv129 genetic background) was scanned by μCT in order to reconstruct a 3D model, required for the intended Finite Element Analysis. Upon segmenting the main components of the mandible (e.g. incisor, molars, alveolar bone, mesenchyme, cervical loop), boundary conditions were assigned to the temporomandibular joint while considering the muscle architecture involved in the initiation and stabilization of the jaw movement during biting [2].

Two masticatory scenarios were identified, incisal biting (gnawing) and chewing at the molars and both of them examined for two load intensities, corresponding to a food type each (soft and hard pellets). The mastication loads were equally distributed over the molars and incisors (both sides) as literature advocates bilateral biting to be more realistic than unilateral.

To determine cell plasticity for each feeding ecology, dissected cervical loop and preameloblasts were subjected to the calculated stress values and their gene expressions analyzed.

RESULTS AND DISCUSSION

Chewing and gnawing resulted in varying loading patterns, with biting type exerting a dominant effect on the stress variations experienced by the mandible and loading intensity correlating almost linearly to the stress increase. During gnawing, the cervical loop of the incisor exhibited twice the stress intensity of chewing, while increasing the strain of the tissue up to 16%. Recent literature on the cellular response of stem cells to mechanical stimulus advocates that this range of strain is sufficient to regulate their differentiation process [3], a response validated by the in vitro experiments reported within this study.

The results indicate that in the absence of masticatory forces cells actively proliferate, whereas biting gives rise to load specific gene expressions e.g. gnawing inhibited the proliferation of preameloblasts, inducing their differentiation into enamel-secreting ameloblasts. This allows rodents to compensate for the enamel that is progressively ground off their incisors, as masticatory loads drive epithelial stem cells and progenitors to differentiate into new enamel-producing ameloblasts.

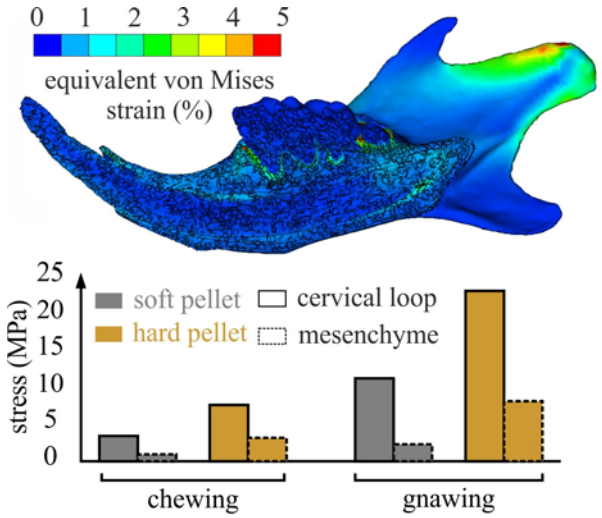

Figure 1: Indicative strain alterations in mandible cross-section during gnawing of hard pellets and recorded stress values for varying scenarios.

CONCLUSIONS

The simulation provided refined insight on the mechanobiology of the cervical loop of mouse incisors, indicating that food consistency could exert a prevailing role on stem cell behavior by affecting their quiescent, mitotic or differentiation status. The results suggest that the effects of masticatory forces on stem cell niches can influence micro evolutionary divergence patterns in both teeth and mandibles of rodents.

INTRODUCTION

In this study, we observe intracellular calcium signaling response to stretch in a single osteoblastic cell with video rate temporal resolution. Our originally developed cell stretching microdevice enables in situ observation of stretched cell without excessive motion artifact such as focus drift. Residual minor effect of motion artifact was corrected by fluorescent ratiometry method with calcium indicators Fluo 8H and Calcein red-orange. We succeed to detect intracellular calcium signaling response to stretch with video rate temporal resolution.

METHODS

The mouse osteoblast-like cell line MC3T3-E1 cells were seeded onto fibronectin coated 35mm glass bottom dish with built-in cell stretching microdevices developed by the authors at cell density 5.0×10^4 cells / dish. Fluorescent Ca^{2+} indicator dye Fluo 8H and cell labelling reagent Calcein Red-Orange were loaded into the cells.

The cell stretching MEMS device developed by authors was used to apply stretching stimuli. The microdevice consists of one pair of arms fabricated from photoresist SU-8 and a cell stretching sheet fabricated from silicone elastomer. Two metal needles were set onto the arm. One needle was held by the micro manipulator to fix one end of stretching sheet. Another needle connected to the piezo electric actuator (MC-140L, Mess-Tek) was set onto the other end of the sheet to apply uniaxial stretch. In the present study, uniaxial stretch with 10% magnitude was applied to the cell with constant strain rate 5% / sec.

Fluorescent images were obtained by using an inverted confocal laser scanning microscope (A1R, Nikon). Recorded image size was 512×128 pixels. Image acquisition rate was approximately 30 frames / sec. Obtained images were analyzed using ImageJ software (NIH). To reduce motion artifact due to out of focus during stretch, the change in concentration of intercellular calcium was evaluated by ratiometric microscopy method. The fluorescent ratio value was defined by (Fluo8H / Calcein Red-Orange).

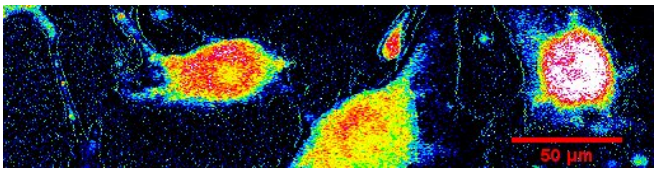

Figure 1: Pseudo color image of fluorescent ratio value in osteoblast like cells on the cell stretching MEMS device.

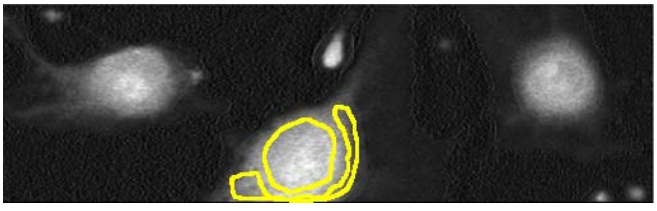

Figure 2: Definition of ROIs on cell nucleus region and peripheral region.

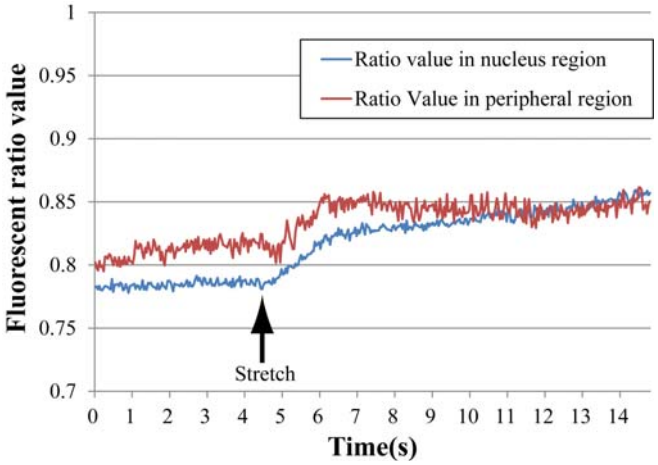

Figure 3: Time course change in fluorescent ratio values in cell nucleus region and peripheral region.

RESULTS AND DISCUSSION

Figure1 shows representative image of osteoblast like cells on the cell stretching microdevice. This image is pseudo color mapping of fluorescent ratio value ((Fluo8H / Calcein Red-Orange). Figure 2 shows definition of ROIs which were used to calculate and measure the fluorescent ratio value. One ROI was set onto the cell nucleus region and another was on the peripheral region. Figure 3 shows time course changes in fluorescent ratio values under stretch application. In the figure, the time point of stretch application is indicated by the black arrow. There were different time lags between stretch application and the rising time point of fluorescent ratio value in two ROIs. This result suggests that osteoblastic calcium signaling response to stretch stimuli is initiated around cell nucleus region and propagates to peripheral region.

CONCLUSIONS

In this study, we have succeeded to conduct the in situ observation of osteoblastic intracellular calcium signaling response to stretch stimuli with video rate temporal resolution.

CHARACTERIZATION OF THE FRUSTRATED DIFFERENTIATION OF MESENCHYMAL STEM CELLS INDUCED BY NORMADIC MIGRATION BETWEEN STIFF AND SOFT REGION OF GEL MATRIX

INTRODUCTION

Mesenchymal stem cells (MSCs) have been known to exhibit substrate stiffness-dependent differentiation, and history of the mechanical dose from culture environment to MSCs sensitively is found to alter its phenotype. A certain level of substrate stiffness and duration period on that determine the fate of MSCs [1]. In relation to this, we have found before that microelastically-patterned hydrogel with heterogeneous distribution of matrix stiffness allow MSCs to suppress fate determination into specific differentiation lineages, and contribute to keep the undifferentiated state [2]. We call such mode of MSCs as "frustrated differentiation", which serves to construct culture substrate for MSCs to maintain their stemness in high-qualified state. The basis of this phenomenon is in the enforced oscillation of mechanical dose from environment to MSCs during the nomadic migration between stiff and soft region of gel matrix, which would eliminate the history of experience on a certain level of stiffness. In this study, to fully characterize the frustrated differentiation of MSCs, we investigated oscillation of the mechanical dose and mechanical signal input to MSCs employing the long-term traction force microscopy for MSCs culture on the microelastically-striped patterned gels. In addition, we performed cDNA microarray analysis for the MSCs culture in such mode of frustrated differentiation.

METHODS

To design such heterogeneous microelastically-patterned gels, we have applied the photolithographic microelasticity patterning of photoculable gelatins using a custom-built, mask-free, reduction-projection-type photolithographic system. 20 μl of the styrenated gelatin (StG) sol solution was spread between vinyl-glass and a usual cover glass. Only for implementation of traction force microscopy, 5 μl of 30% StG sol solution with fluorescent beads was spread over the latter cover glass. Human bone marrow MSCs were seeded onto the gel, and the emergence of frustrated mode of differentiation was characterized with immunofluorescence and RT-PCR analysis for the expression markers. Transcriptome analysis was performed using Affymetrix GeneChip Human Genome U133 Plus 2.0 Array.

RESULTS AND DISCUSSION

To verify the oscillation of mechanosignal input to MSCs, traction stress dynamics was analyzed with the traction force microscopy. From the displacement of the fluorescent beads, we calculated the traction force of the cells by using finite element method. We found that the traction force of the cells strongly fluctuated depending on the elasticity where the cell adhered (Fig.1). We also found that the standard deviation of the traction force on the elastically-patterned gels was larger than that on the homogeneous gels. These results clearly indicate that on micro-elastically patterned hydrogels, mechano-signal oscillates because the cell intersects the micro-pattern every few hours.

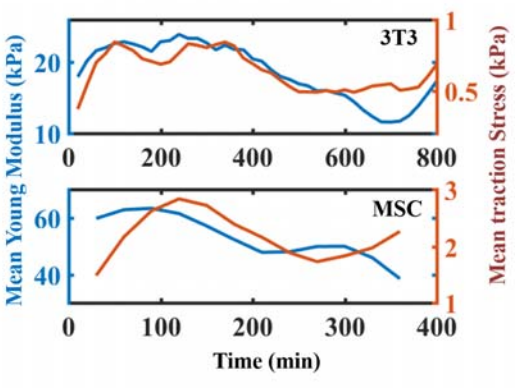

Figure 1. Time series of mean young modulus (blue) and mean traction stress (orange). Up: NIH-3T3 cell. Down: MSC.

From the exhaustive analysis for mRNA expression, MSCs which experienced normadic movement between stiff and soft region of microelastically-striped patterned gels were found to exhibit the characteristic transcriptomes compared with those on the plain control gels with homogenious elasticity. Expression of genes relating to cell motility was markedly up-regulated. Whole responses in the mRNA expression are presented and discussed in details.

CONCLUSIONS

By applying traction force microscopy, it was verified that oscillatory input of mechanosignals into MSCs cultured on microelastically-patterned gel, which induces frustrated differentiation. Transcriptome of the MSCs in frustrated differentiation was characterized.

MECHANOTRANSDUCTION AND REDOX REGULATION OF STEM CELLS

INTRODUCTION

Reactive oxygen species (ROS) such as superoxide, hydroxyl radicals and hydrogen peroxide that mainly generated from NADPH oxidase (NOX) from mitochondria could function as a second messenger in redox signaling. Emerging evidences suggest that the balance between ROS and antioxidant enzymes could regulate stem cell fate, function and survival. It has been reported that matrix elasticity (stiffness of underlying substrate) mimic that of native tissues can direct stem cell lineage specification. The mechanotransduction and redox signaling pathways shared the similar effects on the physiological response of stem cell but their direct correlation has not yet been explored. In our previous studies, we observed the changes in expression of lineage specification markers and antioxidant genes in stem cells cultured on various surface elasticity gelatinous substrates [1, 2], indicating the possible connection between these 2 distinct signaling pathways.

This study focuses on an investigation of the interplay between mechanotransduction and redox signaling of the stem cells. We examined the ROS production, mRNA expression of differentiation markers and redox related genes in stem cells on substrates with different stiffness, in order to gain a better understanding of the relationship between mechanotransduction and redox balance in stem cell physiology.

METHODS

The surface elasticity tunable hydrogel was fabricated using photocurable styrenated gelatin [3]. The elasticity of the gelatinous gel was measured using atomic force microscope The soft (3 kPa) and stiff (80 kPa) hydrogels were used for mesenchymal stem cells (MSCs) cultured for one week. The expression of osteogenic markers and redox genes such as thioredoxin (TRX), superoxide dismutase (SOD), peroxiredoxin (PRX), and glutaredoxin (GRX) were monitored using real-time PCR. The mitochondrial superoxide production in MSCs on various stiffness substrates was investigated using MitoSoxred staining.

RESULTS AND DISCUSSION

The mRNA expression analysis showed the up-regulation of TRXs, SODs PRXs and GRX on the hydrogels in comparison to the rigid tissue culture dish control (TC) (**Fig.1**). The MSCs on the 3 and 80 kPa gels showed some similarities and differences in expression patterns of the redox/ antioxidant genes. These antioxidant enzymes play a critical role in ROS scavenging system and also considered to be important, particularly for the cell that undergone lineage specification. The osteogenic lineage specification markers of the cells on the hydrogels exhibited the stiffness dependent expression patterns, since the expression of the genes such as alkaline phosphatase, collagen I or bone morphogenic protein 6 increased on the stiff 80 kPa gels but suppressed on the soft 3 kPa gels.

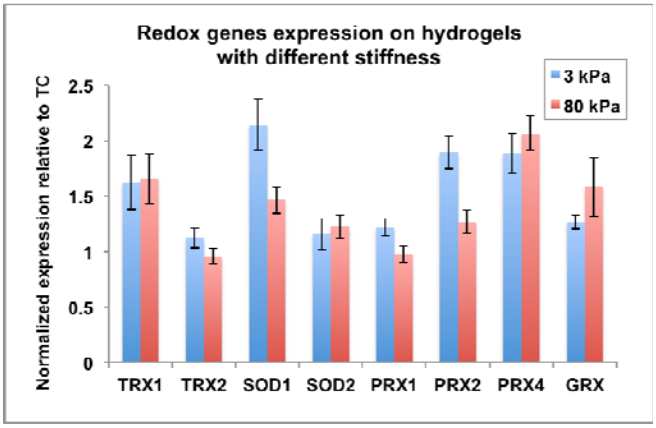

Figure 1: The redox genes expression of the MSCs on different surface elasticity hydrogels.

The analysis of mitochondrial superoxide production was in a good agreement with the up-regulation of the redox genes. In comparison to the control TC that exhibited the red fluorescent signal of mitochondrial superoxide, the MSCs on the hydrogels showed the weak fluorescent, suggesting the decreased in the ROS production. Live cell imaging of the cellular redox state and antioxidant activity of the cells on various elasticity conditions are now being investigated to further clarify the affect of substrate elastic on the redox state of the stem cells.

CONCLUSIONS

The mechanical stimuli from the underlying substrates could modulate the cellular redox balance, ROS production and expression of the lineage specific markers of the stem cells. Understanding of the integrative mechanism between mechanotransduction and redox homeostasis of the stem cells would provide significant implication in stem cell physiology.

MECHANICAL AND BIOCHEMICAL ADAPTATIONS OF CARDIAC MUSCLE TO AEROBIC EXERISE TRAINING

[1] **Kevin R Boldt**, [1]Jaqueline L Rios, [1]Venus Joumaa and [1]Walter Herzog
[1]University of Calgary
Corresponding author email: krboldt@ucalgary.ca

INTRODUCTION

Adaptation of the heart in response to aerobic exercise training has important implications for sport performance, fitness, and health [1]. These adaptations manifest predominantly as structural changes to the heart: proportional increases in heart volume and ventricular wall thickness [2]. However, less is understood about how the heart muscle adapts mechanically and biochemically.

Shortening velocity and power output are dictated by the biochemical makeup (proportions of myosin heavy chain (MHC) isoforms α–MHC and β-MHC) of the actin-myosin crossbridges [3], with larger proportions of α–MHC leading to faster contraction rates and higher power outputs for a given resistance.

The purpose of this study was to evaluate the differences in power output of isolated cardiac muscle cells and MHC composition between hearts from sedentary and exercised rats.

METHODS

Twenty-four 3-month-old Sprague-Dawley rats were randomized into four groups: moderate duration exercise (MD) (n=6), high duration exercise (HD) (n=6), extra high duration exercise (EHD) (n=6), or no exercise (CON) (n=5). Animals were trained on a treadmill for 11 weeks at 25m/min. MD animals completed 30 minutes of exercise 5 days/week, HD animals completed 60 minutes 5 days/week, and EHD animals completed 60 minutes 7 days/week. In weeks 9, 10, and 11, EHD animals also completed 2, 3, and 4 sessions/day (up to 4 hours/day, 7 days/week). One week following the end of the exercise training, hearts were excised and strips of trabecular muscle were skinned in a 1% Triton solution. Half of each sample was frozen in liquid nitrogen for biochemical testing and the other half was dissected further for mechanical testing.

Mechanical testing consisted of isolating and attaching myocyte bundles on one end to a force transducer and at the other end to a length controller. Average sarcomere length was set to 2.4 µm using laser diffraction. Myocytes were maximally activated before the force was dropped to 90% of the maximum force, allowing the sample to shorten. The corresponding shortening velocity was measured. This protocol was repeated for 10% force decrements ranging from 10-100% of isometric force. Force-velocity data were fit to Hill's equation and peak power was calculated.

For biochemical testing, muscles were ground into a powder, dissolved in a sodium dodecyl sulphate buffer, and loaded into 0.75mm thick 7.5% acrylamide separating gels. Electrophoresis was run at 72V for 44 hours at 4°C. Gels were then stained with Coomassie Blue and scanned with a Biorad Calibrated Densitometer to determine relative concentrations of α–MHC and β-MHC isoforms.

Data were analyzed using one-way ANOVAs and Tukey's post hoc testing when indicated. Pearson correlations were conducted between peak power and %α–MHC. The level of significance was set a priori to α=0.05.

RESULTS AND DISCUSSION

There was a dose-dependent decrease in peak power output from the CON to MD and HD animals (p=0.038). However, this trend was reversed for the EHD animals (Figure 1; solid bars). Similarly, the same trend was present for the relative proportion of α–MHC to β-MHC, with a decreasing proportion of α–MHC from CON to HD, with a reversal for EHD (p=0.024) (Figure 1; lined bars).

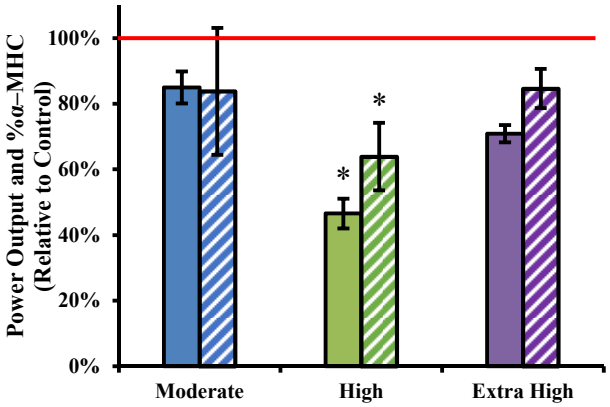

Figure 1: Peak power output (solid bars) and %α–MHC (lined bars) for animals following exercise training. Bars represent mean±SEM. Red line indicates mean control value. *indicates significantly different from controls.

A significant correlation between power output and MHC composition was observed (r=0.668, p=0.003). Therefore, adaptations to the MHC isoform expression are likely a significant mechanism for alterations observed in power output.

CONCLUSIONS

Our data suggest that adaptations of the heart to endurance exercise occur not only at the structural level [2], but also mechanically and biochemically within the muscle cell. Further, this adaptation appears to be dose-dependent, until exercise becomes excessive and adaptation is inhibited.

CENTRE OF MASS ACCELERATION: AN ON-FIELD EFFICIENCY PARAMETER FOR RUGBY TACKLE.

[1] Pavan Davide, [1] Colangelo Alessandra, [1] Cibin Federica, [1] Guiotto Annamaria, [1] Voltolina Gilberto, [2] Casagrande Tiziano, [2] Sgorlon Andrea, [2] Sbrocco Giorgio, and [1] **Sawacha Zimi**

INTRODUCTION

Because of the contact nature characterizing rugby, the tackle is one of the most performed on field tasks.
Acceleration at contact, along with high impact speed and correct body posture are recognized, as well as great force delivery on the opponent, to be fundamental to perform an effective and safe tackle. To quickly regain the standing posture after grounding is finally essential to aim for the ball. Despite recent studies investigate speed and acceleration of the player performing a tackle [1], there is not an objective parameter to assess the tackle efficacy.
The aim of the present study was to assess the efficiency of the tackle, directly on-field. With this purpose the center of mass (CM) acceleration was used as a guide variable, to develop a screening tool for tackle effectiveness.

METHODS

Subjects belonging to the U18 team of the Italian Rugby Federation (FIR) Academy took part in the study and were randomly divided into two groups: 13 athletes performed the front-on tackle (mean ± standard deviation (SD) BMI: 29.26±4.41, age: 24.20±4.49 years), while 9 athletes performed the side-on tackle (mean ± SD BMI: 28.32±2.96, age: 17.13±0.64 years). All the athletes regularly take part in international fixtures. Subjects, after signing informed consent, performed 6 repeating side-on tackles in the rugby field at 2 different heights: between the knee and the hip (KH) and between the hip and the pelvis (HP). Video sequences and plantar pressure (PP) distribution were acquired by means of a Novel Pedar system and 4 synchronized cameras (GoPro Hero3+); hence peak PP (PPP), peak vertical ground reaction force (PV), hip, knee and ankle joints kinematics were determined [5,6] and their position with respect to the tackle task evaluated with purposely developed Matlab code. Specific features were tracked bilaterally directly on the motion sequences [5]: acromion, C7, L5, anterior iliac spine, posterior iliac spine, greater trochanter, lateral femoral epicondyle and calcaneus, two points on the shoes corresponding to the 1st and the 5th metatarsal head, lateral humerus epicondyle. Key instants were recognized as: left foot PV, right foot PV, contact instant. After proper calibration, tackler's center of mass (CM) acceleration have been calculated basing on 2D trajectory reconstruction; positive and negative CM acceleration peaks have been recognized in three phases of the task: start-contact (PC), contact-grounding (CT), and grounding-ball retrieve (TR). Student's t-test has been performed to detect differences in data from different tackling techniques and different impact heights.

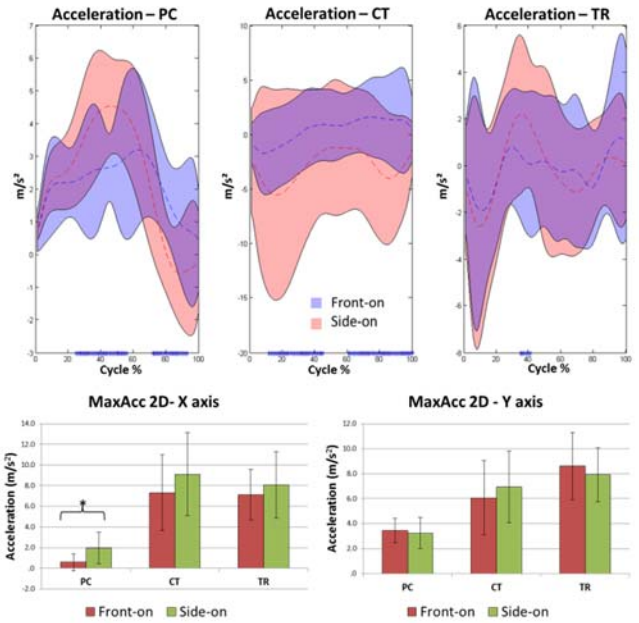

Figure 1: Acceleration normative bands (mean±SD) computed along running path, and maximum acceleration along x (medio-lateral) and y (forward-back) axis (*=* = $p<0.05$).

RESULTS AND DISCUSSION

Results presented in Figure 1, showed significant differencesin CM acceleration between front-on and side-on tackling technique. On X axis higher acceleration were detected on side-on tackle in each analysed phase, while on Y axis higher acceleration were detected on front-on tackle apart from CT.

CONCLUSIONS

The present experimental setup was able to distinguish tackler behavior at different level of impacts and in different key phases of the task. Coaching staff could use this information to evaluate tackler performances. A 2D approach was adopted in order to keep the computational process quick and affordable, however 3D data are also available.

ACKNOWLEDGEMENTS

The authors acknowledge the FIR academy for athletes and rugby field availability.

THE RELATIONSHIP BETWEEN IMPACT AND BALL FLIGHT CHARACTERISTICS IN FOOTBALL KICKING: INTRA-INDIVIDUAL ANALYSIS OF ANKLE MOTION DURING IMPACT

[1] **James Peacock**, [1]Kevin Ball and [1]Simon Taylor
[1]College of Sport & Exercise Science, Institute for Sport, Exercise & Active Living, Victoria University, Footscray, Australia
Corresponding author email: james.peacock@live.vu.edu.au

INTRODUCTION

Kicking is an important skill for the football codes. During impact, the ankle has been found to passively abduct, evert and plantarflex[1], and reduced plantarflexion is associated with increased ball velocity[2,3]. Ankle angle at impact start has also been found to influence subsequent motion with greater plantar flexion at impact start associated with an increased rigidity[3].

While ankle motion seems to be emerging as influential to kick performance, the analysis has largely been limited to the saggital plane. Further, the performance indicator has been limited to ball velocity. This evaluation needs to move to three-dimensional (3d) analysis of ankle motion and to other flight characteristics kick which will also affect the outcome, such as spin rate and angle of trajectory. The aim of the present study was to identify the relationship between 3d ankle motion and flight characteristics.

METHODS

Three amateur football players completed 30 kicks toward a target 30m away with an Australian Football, representing three separate kicking analyses. The intra-individual analysis was the most appropriate method to identify the effects of impact characteristics on kick outcome, and avoid confounding the analysis with different player characteristics (e.g. mass, foot length and shoe type).

Change in ankle angle and initial ball flight characteristics (azimuth angle, elevation angle, spin rate and spin axis) were captured using three high-speed-video cameras (4,000 Hz). Data were smoothed with a Butterworth, low-pass filter (280 Hz). The choice of cut-off frequency was based upon direct fourier transform, previoius literature[1,2] and visual inspection of the data comparing different frequencies. Relationships between ankle motion and flight charactersitics were evaluated using 1st, 2nd or 3rd order regression equations with the choice of the most appropriate regression based on r^2 value, visual inspection of the scatterplots and significance ($p < 0.05$).

RESULTS AND DISCUSSION

Ankle motion during impact varied within the players. Across the trials, all participants displayed both plantar and dorsal flexion, both inversion and eversion, and both adduction and abduction, excluding Player 2 that displayed only abduction and no adduction. Previous group analyses of the sagittal plane identified different techniques between players; to either plantar or dorsal flex or no change[1,3]. Shinkai et al (2009)[1] also identified abduction and eversion for instep kicking. The individual analysis of the present study identified players are able to produce techniques of plantar and dorsal flexion, but also inversion/ eversion and adduction/ abduction.

The relationships between ankle motion and flight characteristics varied on an individual level. A positive linear relationship between inversion with azimuth ball trajectory was consistent for all players. Otherwise, flight characteristics were associated with at least one ankle motion across the participants. For example, only Player 1 demonstrated a relationship between change in plantarflexion with elevation angle, and only Player 3 demonstrated a relationship between adduction and azimuth angle. This indicates that variation existed between players with ankle motion and flight characteristics.

A positive linear relationship existed between inversion with ball azimuth trajectory for all players (Figure 1), meaning ankle rigidity is beneficial to kicking accuracy, similar to the association with velocity. The direction of the relationship is particularly interesting because it is consistent to the current understanding by coaches, that the ankle was passively inverted/ everted in the opposite direction to the kick. All players displayed this relationship, indicating inversion/ eversion rigidity is associated with azimuth ball flight and therefore kicking accuracy. Peacock et al., (2017)[3] identified plantar/ dorsal rigidity was actively decreased under an accuracy based task, and suggested this was a strategy to either enhance accuracy or decrease the elevation angle of the ball. The present study indicates an increased rigidity is associated with accuracy. Furthermore, Player 1 displayed a relationship between plantarflexion with elevation angle, also suggesting the decreased plantarflexion observed by Peacock et al.,[3] was more likely to be associated with a lower trajectory than enhanced accuracy.

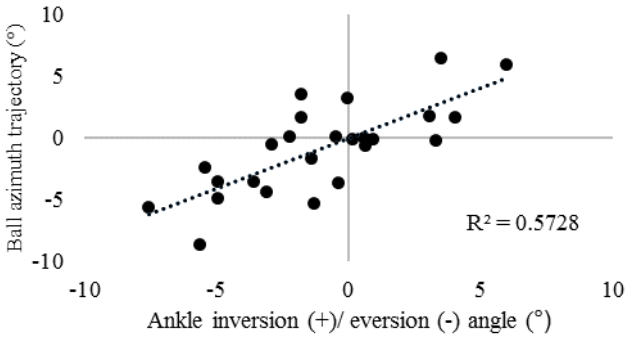

Figure 1: The relationship between inversion/ eversion with ball azimuth trajectory for one player ($P < 0.0001$).

CONCLUSIONS

Ankle motion varied within players, and the relationship with flight characteristics differed on an individual level, highlighting individual ankle motion influenced ball flight. All players displayed a positive relationship between inversion and azimuth angle, indicating that rigidity was beneficial to accuracy, similar to the association with velocity.

DIFFERENCES BETWEEN THREE-DIMENSIONAL TRUNK KINEMATICS WHILE PERFORMING A MAXIMAL INSTEP KICK WITH THE PREFERRED AND NON-PREFERRED LIMB

Jamie Gosling, Robert A. Needham and Nachiappan Chockalingam
Staffordshire University
Corresponding author email: r.needham@staffs.ac.uk

INTRODUCTION

In association football, the power generated during a maximal instep kick (MIK) relates to the formation and fast release of a 'tension arc' (TA) [1]. The active creation of the TA originates from maximal hip extension (MHE) of the kicking leg and rotation of the trunk towards the non-kicking side. Whereas the release aspect of the TA involves a 'quasi-whip-like' action of the kicking leg and trunk rotation towards the supporting leg [1].

While the characteristics of trunk kinematics play an important role in the TA process, there is scarce research that detail the movement patterns of the trunk during a MIK. In addition, dominant (DOM) and non-dominant (ND) kicking legs display different kinematics [2]. Yet it is unknown how these inter-limb differences influences movement strategies in the trunk region. Therefore, this study investigated the differences between three-dimensional trunk kinematics while performing a MIK with the preferred and non-preferred limb.

METHODS

Ten male university football players participated in this study (21.5 ± 5 years, height: 181.38 ± 23.2 cm, mass: 74.54 ± 19.01 kg). Ethical approval was sought and granted by the University Research Ethics Committee. An 18-camera motion capture system (VICON, Oxford, UK) collected kinematic data of the maximal instep kick at 200Hz. The marker configuration used was in accordance with Leardini and Colleagues [3]. Ten trials were collected on the DOM and ND side. Data was normalised for time from kicking leg toe off (KLTO) to maximal hip flexion (MHF) of the kicking leg. Statistical parametric mapping (SPM) analyses were applied to kinematic waveform data to compare trunk kinematics between the DOM and ND condition [4].

RESULTS AND DISCUSSION

SPM1D *t*-tests revealed no significant difference in mean trunk kinematic waveforms between the DOM and ND condition across all three planes of motion (Figure 1B, D and F). A visual inspection of the mean sagittal plane waveform and the associated standard deviation band for the DOM condition, display greater trunk flexion during the formation (KLTO to MHE) and release (MHE to ball contact (BC)) of the TA in comparison to the ND condition (Figure 1A). A similar observation was noted on trunk rotation in the transverse plane (Figure 1E). Since trunk flexion and rotation are key characteristics of the TA [1], the impact of these highlighted differences between the DOM and ND condition on MIK performance variables (kicking leg velocity, ball speed etc.) warrants further investigation.

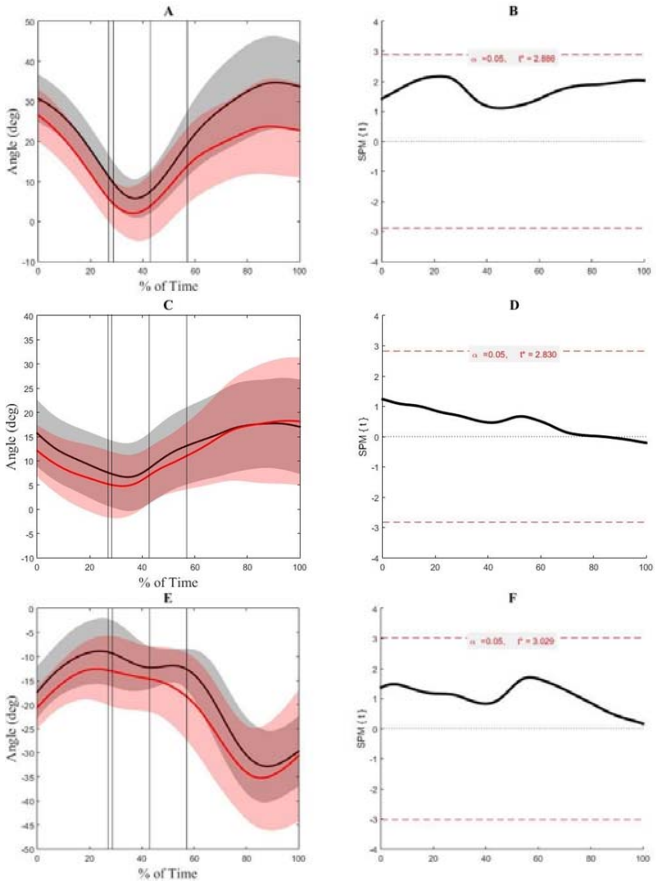

Figure 1: Mean trunk kinematic waveforms in the sagittal (A), frontal (C), and transverse plane (E) (black - DOM / red – ND / shaded area denotes standard deviation across time) representing MIK data from 10 participants. SPM *t*-test outputs for the sagittal (B), frontal (D) and transverse plane (F) are presented. The vertical lines on A, C, and E highlight events during the MIK - KLTO (0%), MHE (26%), standing leg heel strike (28%), max kicking leg knee flexion (42%), ball contact (57%) and MHF (100%).

CONCLUSIONS

The present study found that performing the MIK with the preferred and non-preferred limb did not significantly influence three-dimensional trunk kinematics. However, there were subtle differences in the kinematic waveforms between the DOM and ND conditions. Since the data represented relative movement, it was not possible to distinguish whether these differences in movement strategies were due to changes in thorax or pelvis movement. An understanding of segmental angle and the coordination pattern between the thorax and pelvis may inform on performance characteristics such as the TA and on injury risk.

HIP ADDUCTOR MUSCLE STRESS DURING SHORT PASSING IN SOCCER

[1]**Filip G Lysdal**, [1]Kristian R L Mortensen, [2]Thomas Dupré, [2]Johannes Funken, [2]Ralf Müller, [3]Jan Mayer, [2]Hartmut Krahl, [1]Uwe G Kersting and [2]Wolfgang Potthast

INTRODUCTION

Muscle injuries are the most common injury in professional soccer accounting for up to 37% of all time-loss injuries [1,2]. The hip adductors are the second-most injured muscle group in soccer constituting up to 35% of all muscle injuries. A larger proportion of groin injuries may however be adductor related [2]. Musculoskeletal modeling may offer a valuable tool for quantifying muscle loading.
The objective of the study was to model the muscle stress in adductor longus due to a perceived high eccentric loading during the swing phase of a kick [3] and gracilis due to the highest stress presented in a pilot study [4].

METHODS

Seventy-three elite male soccer players (age = 15.6 ± 3.7 years, height = 170.4 ± 13.0 cm, mass = 61.6 ± 14.7 kg) participated in the study that took place inside the Footbonaut™ at the training facilities of TSG 1899 Hoffenheim (Zuzenhausen, Badem-Württemberg, Germany). The Footbonaut™ is a soccer specific training device consisting of a 14×14 m playing field surrounded by eight ball machines and 64 ball receivers. The Footbonaut™ can pass balls from four different directions and vary the passes in terms of speed, angle and spin. Subsequently the player has to pass the ball into one of the 64 targets surrounding the playing field. All ball machines and targets have a dimension of 1.3×1.3 m and are equipped with photoelectric sensors to register whenever a ball is dispensed or received.

Each subject received a total of 32 footballs at ground level with a speed of 40 km/h. The subjects were instructed to pass the ball using the inside of the foot. The dispensing of footballs and subsequent targets followed the same sequence to standardize the protocol for all participating subjects in the present study.

A 3D motion capture system composed of 16 high-speed infrared cameras (Vicon MX-F40, Vicon Motion Systems Ltd., Oxford, Great Britain) was used to capture kinematic data from 61 retro-reflective markers. The kinematic data were low-pass filtered using a 4th order Butterworth-filter with a cut-off frequency of 12.5 Hz.

Ten random passes from the subjects' dominant legs were chosen for further analysis [2]. Joint angles, joint moments and muscle forces were computed using the AnyBody Modeling System (Version 6.0, AnyBody Technology, Aalborg, Denmark). Inverse dynamics simulations were conducted using the Anatomical Landmark Scaled Model [5], a rigid-body musculoskeletal model that is individually scaled to the anthropometrics of each subject. The simulations were time normalized using MatLab 2015b (MathWorks Inc., Natick, Massachusetts, USA) and analyzed between toe-off and ball contact.

Muscle forces were normalized to body mass to account for the anthropometric differences between subjects. The respective physiological cross-sectional areas [6] were used to calculate muscle stress.

RESULTS AND DISCUSSION

Comparing the computed joint angles and moments, it became evident that the maximum joint moments occur during an eccentric contraction, with the hip abduction angle peaking at 73% of the swing phase.

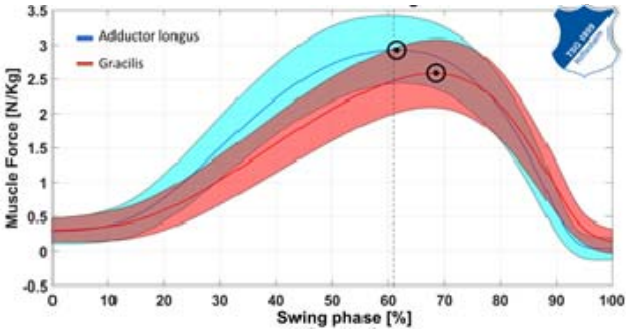

Figure 1: Muscle force during the swing phase [N/kg]. (The vertical dashed line indicates maximum hip extension).

Maximum muscle force in the adductor longus occurred at 61.5% of the swing phase (Figure 1) with a maximum stress of 2.1 kPa/kg (± 0.32). Maximum muscle force in the gracilis occurred at 68.0% of the swing phase with a maximum stress of 5.72 kPa/kg (± 0.97).

CONCLUSIONS

The nature of short passing places the hip adductors under great stress during the eccentric phase of the kick. The presented stress in gracilis is more than 2.5 times greater than in adductor longus and might also play an important role in groin related injuries and pain to the pubic bone.
This high eccentric stresses combined with the repetitive nature of passing in soccer might explain the high incidence of groin related pain and injuries.

TAEKWONDO AP CHAGI KICK'S COORDINATION VARIABILITY BY CONTINUOUS RELATIVE PHASE AND VECTOR CODING

[1] **Hamidreza Barnamehei**, [1]**Mohamad Reza Kharazi**, [2] **Mohamad Ali Safaei**

INTRODUCTION

Taekwondo techniques are inherently variable. A traditional perspective from Shannon's information theory (Shannon, 1948) argues that variability is synonymous with ''noise'' arising from errors, either in the performance of the movement or in the recording and treatment of the data (Fitts, 1954; Schmidt et al., 1979). Alternatively, dynamical systems theory argues that variability is not inherently good or bad, but reflects the variety of coordination patterns used to complete the task (Haken et al., 1985; Scho¨ner and Kelso, 1988).

Researchers have used different techniques of nonlinear dynamics to study the structure of variability in sports movement. The two most popular techniques for quantifying variability in human movement appear to be vector coding (Heiderscheit et al., 2002; Ferber et al., 2005; Wilson et al., 2008) and continuous relative phase (CRP) (Hamill et al., 1999; Irwin and Kerwin, 2007; Miller et al., 2008). Although both techniques involve the assessment of coordination by the quantification of phase plane trajectories, the phase planes constructed with these two techniques are fundamentally different. The vector coding phase plane contains only spatial information derived from positional signals, while the CRP phase plane contains both position and velocity signals, and provides spatiotemporal information.

In light of these differences, there is no assurance that vector coding and CRP convey similar information on the structure of variability when they are used to study a particular movement. In addition, a direct comparison between variability quantified by vector coding and by CRP has not been widely demonstrated in the biomechanics and motor control literature. Consequently, it is difficult to make comparisons between studies that use vector coding and those that use CRP. These comparisons are important if both techniques are to be used as measures of variability.

Therefore, the purposes of the study were to directly compare Ap Chagi kick's variability quantified by vector coding and CRP in Taekwondo, and to determine if these techniques convey similar information on variability.

METHODS

Six elite athletes of National Taekwondo Team of Iran who won many medals of Taekwondo games at international level. In experimental setup, we chose the Ap Chagi kick being testing movement, which is the most frequently used technique in competitions, the Motion Analysis System with 5 high speed cameras (S Infrared, Vicon camera, Oxford metrics, Oxford, UK) were used to collect the kinematics data (sampling rate at 200 Hz) through tracking the 22 makers automatically, and then the joint velocity and angular velocity for each lower limb were derived from the time series. The movement time was calculated from toe-off to the ground contact.

In all the examples that follow, the coupling between two time-varying signals θ_1 and θ_2 was assessed. The two signals were always of equal length, sampled n times at the same points in time.

2.1. Vector coding

Vector coding was performed using the method of Sparrow et al. (1987). A phase plane was constructed, consisting of θ_1 on the x-axis and θ_2 on the y-axis. Coupling between θ_1 and θ_2 was quantified by the coupling angle θ_{VC} between consecutive coordinates in the phase plane

$$\theta_{VC}(i) = \tan^{-1}\left[\frac{\theta_2(i+1)-\theta_2(i)}{\theta_1(i+1)-\theta_1(i)}\right], \quad i = 1,2,\ldots,n-1$$

Where *i* indicates the point within the time series.

2.2. Continuous relative phase

Continuous relative phase (CRP) was performed using the method of Hamill et al. (1999). The state of each signal was assumed to be described by two state variable $\tilde{\theta}$ and $\tilde{\omega}$ with amplitude A and frequency f

$$\tilde{\theta} = A\cos(f\emptyset)$$
$$\tilde{\omega} = A\sin(f\emptyset)$$

A phase plane was constructed with $\tilde{\theta}$ on the x-axis and $\tilde{\omega}$ on the y-axis.

$$\emptyset(t) = \tan^{-1}\left[\frac{\tilde{\omega}(t)}{\tilde{\theta}(t)}\right]$$

Coupling was quantified by the CRP angle θ_{CRP}, which is the difference between the phase angles of two signals

$$\theta_{CRP}(t) = |\emptyset_1(t) - \emptyset_2(t)|$$

Where $\emptyset_1$ and $\emptyset_2$ are the phase angles for the first and second signals, respectively.

RESULTS AND DISCUSSION

In this paper, first calculate angle of lower limb joints and then calculate the angular velocity of them. With sketch the angle-angle and angle- angular velocity diagram, analysis to be perfect. Figure1, show the angel-angular velocity diagram of Hip and Knee. Figure2, show the angle-angle diagram of Knee and Hip.

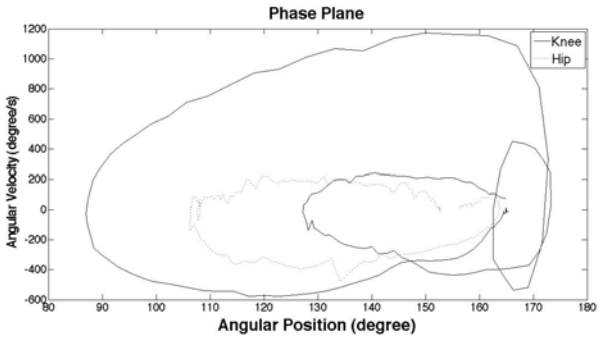

Figure 1: Angular Position-Angular Velocity of Hip and Knee joints

The pattern of inter-joint coordination of CRP and VC was compared by descriptive descriptions with in phase (CRP = 0° or ± 360°; VC = 45° or 225°) and out of phase (CRP = ± 180°; VC = 135° or 315°). The variability of inter-joint coordination of CRP and VC was calculated as the average standard deviation of all points on the ensemble CRP and VC curves over a Ap Chagi's Taekwondo for each subject, namely the deviation phase (DP). DP values represent the turn to return variability and a lower DP value indicates a more repeatable coordination between two joints.

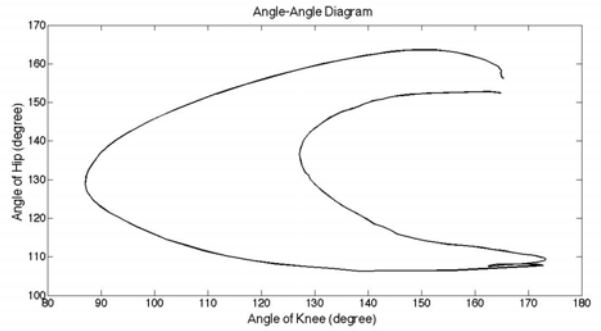

Figure 2: Angle (Knee)-Angle (Hip) Diagram

The alternations of coordination patterns between in phase and out of phase were generally in similar fashion in both techniques, except the initial contact of hip-knee coordination. While VC seemed to have greater ranges of fluctuations on the patterns than CRP, CRP seemed to have sharper inflexion points on knee-ankle inter-joint coordination than VC. The DP values for both hip-knee and knee-ankle inter-joint coordination were similar using both techniques, respectively (Table 1).

Table 1: DP values of inter-joints coordination (degrees)

Inter Joints	CRP	VC
Hip-Knee	0.17±1.23	0.77±0.11
Knee-Angle	0.15±1.03	0.83±0.09
Angle-Hip	0.02±0.96	0.82±0.11

CONCLUSIONS

In figure1, the loop of the knee is larger than to hip and it shows range of motion and angular velocity range of knee are greater than hip because in Ap Chagi kick's Taekwondo, knee joint play important role in attack.

In addition, in figure1 and 2, all curved are loop because in this study Ap Chagi kick is cyclic technique and the leg of attach return to initial position. Figure2 has 2 step that relate to turn and return and consequently all from in-phase to out-phase and vice versa. In ideal state turn and return curved are unique and in this state player has full stable condition.

Our findings suggested that there was a slight difference in the pattern and variability of inter-joint coordination presented by CRP and VC. This difference may be caused by the velocity (temporal evolution) and the normalization procedure involved in calculating CRP. The coordination information obtained from CRP and VC might be comparable with cautions. However, movement velocities were found to play an important role in finding the relationships between electromyography (EMG) and the joint kinematics properties on a phase portrait. Previous studies had successfully demonstrated that the control of human movement can be validated by using phase portraits of the motions of joints or segments. Hurmuzlu et al. (1994) has suggested that observing joint positions alone may be enough to identify the movement equilibrium during walking, however, phase portraits can be considered as useful tools to monitor the properties and changes of joints over time as they directly correlated the joint angles with respect to joint velocities. Since it has been indicated that the afferent fibers in muscle receptors work most efficiently by sensing joint position and velocity and a parameter missing the temporal evolution may potentially reduce its sensitivity to the variability, CRP may provide a higher level assessment of neuromuscular control as it can define joint position and direction of motions across multiple points of a gait cycle when compared to VC. Therefore, in the dissertation, we used CRP to investigate the inter-joint coordination.

HIGH-SPEED DUAL FLUOROSCOPY MEASUREMENT OF ISCHIOFEMORAL SPACE IN RECREATIONALLY ACTIVE ADULTS DURING DYNAMIC ACTIVITIES

[1] **Penny R. Atkins**, [1]Niccolo M. Fiorentino, [1]Stephen K. Aoki, [1]Christopher L. Peters,
[1]Travis G. Maak, and [1]Andrew E. Anderson

INTRODUCTION

Ischiofemoral impingement (IFI) is a recently recognized cause of extra-articular hip pain, most commonly found in females. IFI is believed to occur during hip extension, adduction, and external rotation due to close approximation between the lesser trochanter of the femur and the ischium of the pelvis. While IFI is a dynamic process, diagnosis guidelines for this condition use a measurement of the distance between the lesser trochanter and ischium on static, supine magnetic resonance imaging (MRI) scans. Recently, two studies measured ischiofemoral space (IFS) at specific angles of internal-external rotation and abduction-adduction of the femur while supine using MRI and ultrasound [1,2]. To establish a baseline measurement of IFS during dynamic activities of daily living, we quantified in-vivo hip motion and IFS by coupling patient-specific computed tomography (CT) generated 3D models with dual-fluoroscopy (DF) in asymptomatic control subjects. Using this data, we evaluated the relationship of dynamic measurements with gender, hip kinematics, and IFS measured from axial MRI.

METHODS

Eleven young, asymptomatic, recreationally active adults (5 females, aged 23±2 years, BMI of 21.1±1.9 kg/m2) were recruited in this institutional review board approved study. CT and MRI images were acquired and 3D reconstructions of the pelvis and femur were generated. DF images were acquired at 100 Hz during a static standing trial, external rotation, level treadmill walking and inclined (5 degrees) treadmill walking at a self-selected speed (1.29±0.11 m/s) [3]. Projections of the 3D bone reconstructions were aligned with DF images, using a process termed model-based tracking (previously validated to an error ~ 0.6 mm) [4], to define the 3D orientation of each bone in-vivo. The transformations from model-based tracking were applied to the 3D bone reconstructions to recreate motions of the femur and pelvis. Bone-to-bone distance between the lesser trochanter and ischium was measured for each video frame of the dynamic motions in PostView (v. 1.9.0, www.febio.org). Using the MR images two measurements of IFS were obtained: first, from an axial slice, as is commonly used in diagnosis clinically, and, second, using 3D surface reconstructions in PostView, as described for the DF data. The minimum and range of IFS were compared across activities and between genders using a paired and two sample Student's T-test, respectively, with Holm's correction for multiplicity. The relationship between IFS and hip joint angles was evaluated using Pearson's Correlation Coefficient.

RESULTS AND DISCUSSION

Minimum IFS occurred during the external rotation activity for 10/11 subjects and inclined walking for 1/11 subjects. Measurements of IFS from axial MRI (mean (95% CI); 23.6 (19.4-28.5) mm) were significantly greater than minimum IFS observed during external rotation (10.8 (8.4-13.7) mm, $p<0.001$), level walking (15.5 (11.4-19.7) mm, $p=0.016$), and inclined walking (15.8 (11.6-20.1) mm, $p=0.011$), but not supine or standing positions. The range of IFS measured during level walking (27.4 (24.6-30.1) mm) was less than inclined walking (32.5 (29.5-35.2) mm, $p=0.045$) and rotation (33.0 (30.3-35.6) mm, $p=0.033$) (Figure 1).

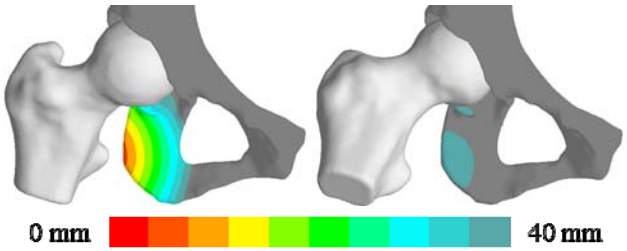

Figure 1: Measurement of IFS in a representative female subject from CT reconstructions. Dual-fluoroscopy determined positions of minimum (left) and maximum (right) IFS during level walking are shown.

Findings confirmed that minimum IFS was smaller in females than males for standing (mean (95% CI); 20.9 (19.3-22.3) vs. 30.4 (27.2-33.8) mm, $p=0.034$), level walking (8.8 (7.5-9.9) vs. 21.1 (18.7-23.6) mm, $p=0.001$), and inclined walking activities (9.1 (7.4-10.8) vs. 21.3 (18.9-24.1) mm, $p=0.003$). IFS was strongly correlated with flexion-extension ($r=0.83$), and moderately correlated with abduction-adduction ($r=0.57$) and internal-external rotation angles ($r=0.49$) ($p<0.001$ for all). There were no significant kinematic differences between genders.

CONCLUSIONS

Strong correlations between IFS and flexion-extension suggest that greater extension, rather than adduction or external rotation, should be incorporated into imaging and clinical exams to determine minimum IFS. The large variation in IFS measurements observed both across and within activities suggests that IFS measurements from static imaging, especially in a neutral orientation, do not accurately represent IFS during dynamic activities and may not improve the diagnosis of IFI.

TARGETING AND REDUCING THE NUMBER OF STEPS BEFORE HITTING FORCE PLATES IN OVER-GROUND WALKING HAS NO EFFECT ON GAIT PARAMETERS IN ORTHOPEDIC PATIENTS

[1]Katrin Bracht-Schweizer, [1]Marie Freslier, [1]Sebastian Krapf and [1]**Jacqueline Romkes**

INTRODUCTION

Three-dimensional instrumented clinical gait analysis usually includes recording multiple trials with kinematic and kinetic data during over-ground walking. A challenge is to acquire clean force plate hits (kinetics) of a patient in a limited amount of time. In a clinical environment, the physical constitution in some patients may limit the number of walking trials and walking distance during data acquisition. Recording a certain number of clean force plate hits can therefore be time consuming and an optimal recording protocol is desirable. Visual targeting the force plate or reducing the number of steps when approaching the force plate may increase the rate of clean force plate hits. No studies found in the literature investigated the influence of different walking distances or of targeting versus non-targeting conditions for the major gait parameters during over-ground walking: spatio-temporal parameters, full body kinematics, and lower body kinetics simultaneously. Therefore, the aim of this study was to compare gait parameters of three measurement protocols to make kinetic data collection during clinical gait analysis more time-efficient.

METHODS

In 15 patients (age range: 8.4-45.0 years) with different orthopedic diagnoses, three walking conditions in over-ground walking were compared: 1) approaching the force plates with 4 steps, 2) with 6 steps, and 3) with 4 steps while hitting a target one step before the first force plate. The starting position was individually adapted for each patient, to minimize the need for stride length adjustments or control for gait velocity prior to the target. Kinematic and kinetic data were collected simultaneously by a motion capture system (Vicon, Oxford, UK) and two force plates (Kistler Instrumente AG, Winterthur, CH). The full-body Plug-in-Gait model was used to obtain kinematics. The VICON-software was used for the pre-processing (i.e. filtering, calculating Plug-in-Gait joint kinematics and kinetics of the left and right steps hitting the force plates) and post-processed with the MATLAB software (such as time normalization to a gait cycle, subtract parameters of interest, statistics). The rate of clean force plate hits, spatio-temporal parameters, full body gait kinematics, and lower body kinetics were analyzed. The Shapiro-Wilk-Test (normality test), paired-sample t-test, and one-dimensional Statistical Parametric Mapping were used for the statistical analysis (alpha-level: 0.05).

RESULTS AND DISCUSSION

The rate of clean force plate hits was highest (6.8 clean hits out of 8.1 trials on average per patient) in the condition with 4-steps and visual targeting. Considering the rate of clean force plate hits, this condition seems to be the most efficient and therefore the least time consuming method. This condition had 17% more clean trials than the condition 4-steps without visual targeting and 26% more clean trials than in approaching the force plate with 6 steps. These results are in line with Nicholson et al. [1] who found a reduction in trial numbers by reducing the distance to a plantar pressure plate or by targeting the plate.

Left hip adduction and rotation, right shoulder flexion, and total left hip power were the only gait parameters with statistical significant differences between the 4-step approach and the 6-step approach. These differences were too small to be of clinical relevance. In absence of differences in the spatio-temporal parameters, we see no problem in restricting orthopedic patients to approach the force plate with 4 steps instead of 6.
The average walking distance per trial across patients for the 4-step approach was 6.4 m (range 5.0-7.7 m), starting 2.1 m (range 1.4-3.1 m) prior to the force plate. For the 6-step approach this was 8.9 m (range 8.2-9.5 m) with a starting position of 3.4 m (range 2.9-3.9 m) prior to the force plate.

Left cadence, right step time, left thorax lateroflexion, left shoulder abduction, total right knee power, as well as hip rotation, thorax tilt, head tilt of both sides were statistically different between the 4-step approach with and without visual targeting. However, except for the head tilt in the targeting condition (due to looking at the target on the floor), the differences were very small and none were of clinical relevance.
In this study, visual targeting prior to the force plate does not seem to affect the gait pattern of the strides hitting the force plates. This is in contrast to the literature [2]. However, we placed the target one step prior to the force plate instead of directly on to the force plate.

One study limitation is that the three walking conditions did not place very high demands on the coordination of our patient population (i.e. mildly impaired orthopedic patients). The conditions may be more demanding for patients with more severe gait disorders, such as neurologic patients with cerebral palsy and/or mental retardation, or children under 10 years of age due to an immature development of the corticospinal tract [3].

CONCLUSIONS

For mildly impaired patients we recommend to initiate walking 4 steps prior to the force plates and to hit a target one step before the first force plate. This can increase the efficiency of collecting clean force plate hits in clinical gait analysis. The applicability of this method in more severe impaired patients remains to be tested.

INTRODUCTION

In economically developing countries (EDCs) like India, the small-scale rehabilitation clinics do treat gait abnormalities but the outcomes are not always reliable. These clinics have poor to no access (67% rural population) to the efficient state-of-the-science 3D clinical gait analysis techniques due to high instrumentation and maintenance costs involved in setting up these labs. On the other hand, recent studies have reported that 2D planar kinematics is easy to interpret and can reliably determine the extent of walking disability [1]. Thus, the aim of this project was to develop a low cost and easy to use portable 2D videography system to be used as a complementary but reliable support to the clinicians working in rural part of India to treat walking abnormalities.

METHODS

Ten healthy volunteers (23.5±5.3years) signed informed consent and participated in this study that was approved by the ethical committee of the institute. Two types of mobile cameras were used to capture the videos - one having 5MP resolution (speed = 15 frames per second) and another having 13MP resolution (speed = 30 frames per second). Two sets of markers (size of 2.2cm and 3.5cm) were prepared by using waste paper, 1 inch screws, and radium strips (8 blue, 8 red and 3 green). Markers were bilaterally placed on shoulder, sacrum, ASIS, hip, medial and lateral knee, medial and lateral ankle, heel, and toe. The videos were taken in sagittal and frontal planes with opposite side of the camera covered by black cloth to avoid the interference of any other color than the marker colors. To calculate the parallax error for sagittal camera, multiple parallel strips, two inches apart from each other, were placed on the pathway.

Each volunteer performed two static trials (one for each side) and five walking trials on the pathway. For each walking trial, the entire to and fro motion was captured by the cameras. The videos were converted to frames and for each trial, gait cycle was identified. Intensity based marker detection method was used to automatically detect markers in each frame using Matlab (Mathworks Inc., Natick, MA, USA). The RGB images were converted to L*a*b images. The L*a*b space is perceptually uniform while RGB space is not. The 'L' channel specifies the luminosity in the range of 0 to 100, 'a' channel specifies red and green colors with values in the range -128 to 0 for green and 0 to 128 for red, 'b' channel specifies blue and yellow colors with values in the range -128 to 0 for blue and 0 to 128 for yellow (Figure 1). A stick figure was generated for the entire gait cycle (Figure 1), coordinates for all markers were found and then 2D joint angles were calculated for hip, knee, ankle and pelvic tilt for sagittal as well as frontal planes. To calculate parallax error, each volunteer stood on each of the parallel strips and a parallax trial was recorded. The measure of hip, knee and ankle angles was determined for each parallax trial and parallax error was determined for each marker. All the joint angle data was interpolated at every 1% gait cycle and parallax error values were either added or subtracted from the joint angles depending on the motion.

RESULTS AND DISCUSSION

Both 5MP and 13MP cameras could be successfully used for capturing the markers, however, 5MP camera required larger marker size (3.5cm) to effectively capture all the markers in all the time frames for entire gait cycle.

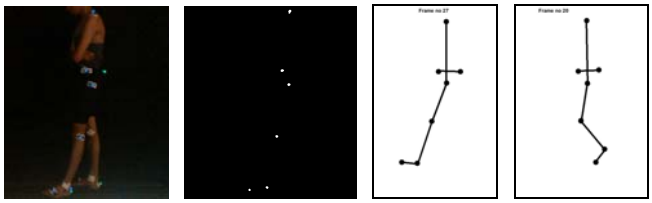

Figure 1: Marker detection using intensity identification and stick figure generation for data analysis.

Average joint angle data was found to be in good qualitative comparison (Figure 2) with 3D normative database [2]. However, more data will be collected to build the normative 2D gait database for clinical comparisons. Work is underway to determine the reliability of the system for its use in various static poses and dynamic trials.

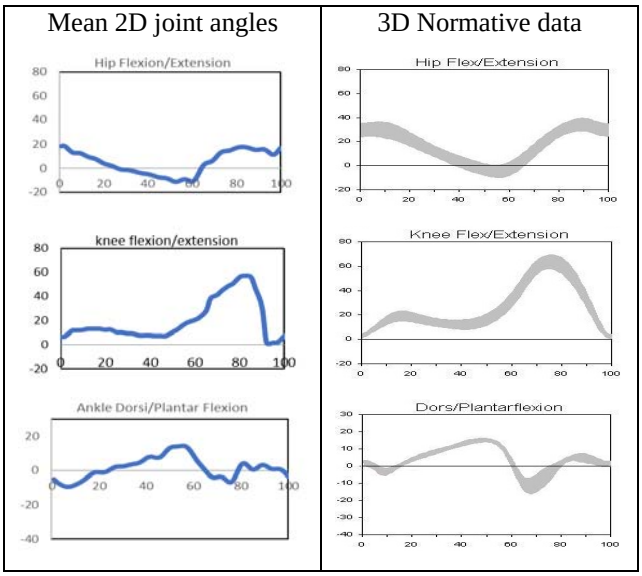

Figure 2: Comparison of 2D sagittal plane flexion/extension angles with 3D normative data reported earlier [2].

CONCLUSIONS

We have successfully developed a portable, low-cost 2D videography system to perform gait analysis in rural areas of India. Future work will be focused on evaluating the concurrent validity of the system, its implementation in rural clinics and its application for evaluating abnormalities.

KNEE RHYTHM DURING WALKING USING IN VIVO KINEMATICS FROM A BI-PLANE FLUROSCOPIC SYSTEM

[1] **Youngjun Koo**, [2]Yihwan Jung and [3]Seungbum Koo
[1]Chung-Ang University
Corresponding author email: skoo@cau.ac.kr

INTRODUCTION

Accurate joint kinematics is a fundamental element in studying joint kinetics [1] and musculoskeletal disease. While the anterior-posterior (AP) translation and internal-external (IE) rotation patterns in the knee have been reported in the literature [2,3,4], current musculoskeletal simulations use relatively simple joint type such as a hinge joint for the simplicity of calculation. Such a simple joint type would use inadequate moment arms of ligaments and muscles and degrade the quality of kinetics results. Previous studies formulated kinematics of the knee as a function of knee flexion angle using the data of cadaveric and non-ambulatory experiments [5,6]. Recently, bi-plane fluoroscopic (BPF) method has been introduced to measure in vivo skeletal kinematics [3,4,7]. Bi-plane fluoroscopic systems take skeletal images in vivo and calculate three-dimensional kinematics of joints with the state-of-the-art accuracy. The BPF-based skeletal kinematics includes AP translation, IE rotation and flexion-extension (FE) of joints. The purpose of this study was to formulate the knee rhythm during walking, which represent functional relationships among knee FE rotation, AP translation and IE rotation.

METHODS

This study was approved by IRB at Chung-Ang University. Seven healthy subjects (all males, age 23±2 years, 63±6 kg and 170±3 cm) without history of knee injury were participated in this study after informed consents were obtained. Kinematics of the right knee was measured during walking and standing using a BPF system. BPF images were obtained for a full gait cycle during treadmill walking but only the frames from mid-swing to mid-stance could be processed due to the overlap of the bones in images. Polygon models of the femur and tibia from CT images were registered to the fluoroscopic images of both walking and standing trials. Anatomical coordinate systems were determined in the distal femur and proximal tibia, and the knee kinematics were calculated according to the ISB recommendation. The standing trials were used as reference poses. The AP translation and IE rotation were presented as a function of flexion-extension (FE) angle for swing and stance phases of walking, separately. Regression equations were calculated to estimate AP translation and IE rotation from FE angle using generalized mixed effects model with consideration of subject effect. Also, corrected Akaike Information Criterion was calculated to determine the order of regression polynomial.

RESULTS AND DISCUSSION

AP translation and IE rotation were regressed as first order polynomial regression functions for both swing and stance phases. The tibia translated posteriorly and rotated internally with increase of knee flexion angle for both swing and stance phase. The regression lines for AP (y in mm) vs. FE (x in degree) were y=-0.367x-0.202 and y=-0.495x-2.395 for stance and swing phases, respectively. The regression lines for IE (y in degree) vs. FE (x in degree) were y=0.289x+1.769 and y=0.029x+0.442 for stance and swing phases, respectively.

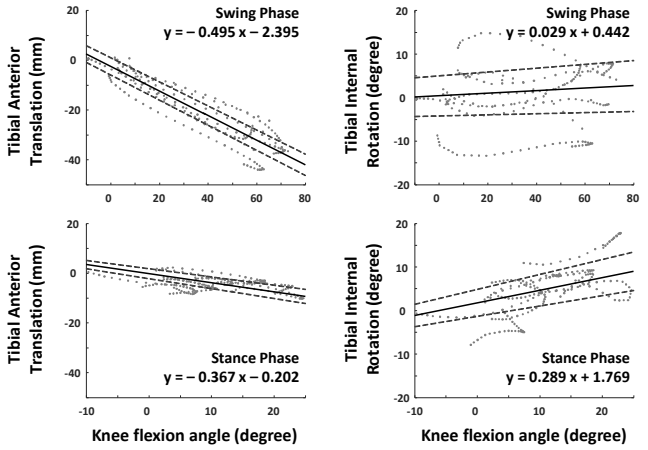

Figure 1: Knee kinematics from seven subjects were divided into swing (upper) and stance phases (lower). AP vs. FE (left) and IE vs. FE (right) data were regressed using a mixed effect model to obtain knee rhythm.

The curves during the stance phase conform to previous studies that the knee rotational center is in the lateral side of the knee during walking [2,3,4]. In previous studies [5,6] the function of IE vs. FE was not included in calculating three dimensional knee kinetics. The range of IE rotation is as large as 10º in the knee during stance phase and can affect moment arms of ligaments and muscles. Implementation of the regressed knee rhythm would help provide more accurate kinematics in the knee during walking and increase the accuracy of kinetics calculation in musculoskeletal simulations. Limitation of this study was that the knee kinematics was obtained only from mid-swing to mid-stance during walking.

CONCLUSIONS

The study calculated the knee rhythm that could estimate AP translations and IE rotations as a function of flexion angle, using the kinematics measured by a BPF system. The three-dimensional knee rhythm would increase the accuracy of knee kinetics calculation in musculoskeletal simulations.

EFFECT OF NOISE ON LOCAL DYNAMIC STABILITY MEASURES OF HUMAN MOVEMENT

[1]**Sina Mehdizadeh**, [2]Mohammad Ali Sanjari
[1]National Sports Institute of Malaysia
[2]Iran University of Medical Sciences
Corresponding author email: sina.m@isn.gov.my

INTRODUCTION

Largest Lyapunov exponent (LyE) has been proved to be a valid measure for quantifying human locomotion dynamic stability [1]. The LyE measures the exponential rate of divergence of neighboring trajectories of the state space constructed from human motion kinematic time series [2]. However, accurate calculation of LyE in experimental studies where experimental noise is omnipresent is a challenge. This noise can have adverse effects on the LyE value by increasing the possibility of picking false neighbors in the state space [7].

Rosenstein's [5] and Wolf's [6] methods are widely used to calculate LyE in studies of human movement. Although some studies [4] evaluated the robustness of these methods to noise in mathematical attractors such as Lorenz and Rössler, no study has investigated the effect of noise on LyE of time series associated with human movement.

The aim of this study was therefore to evaluate the effect of added experimental noise on LyE of time series associated with human locomotion (i.e. a passive dynamic walker) and also to compare Rosenstein's and Wolf's algorithms in estimating LyE of noisy time series.

METHODS

The LyE was calculated for the simplest passive dynamic walker model which has been widely investigated in the studies of bipedal locomotion [3]. The differential equations of the model were integrated to obtain hip joint angle while the model was walking down a slope of 0.009 rad.

To calculate the LyE, first, a state space with dimension of 4 and time delay of 100 samples was reconstructed using global false nearest neighbors and average mutual information methods, respectively. The LyE was calculated for hip angle time series with the length of 50 steps. Both Rosenstein's and Wolf's methods were used to quantify LyE for both noise-free and noisy time series. To determine the effect of noise on LyE, seven levels of Gaussian white noise (SNR=55dB to 25dB with 5dB steps) were added to the time series of hip angle. The percent error of the LyE of the noisy relative to that of noise-free value was also determined.

RESULTS AND DISCUSSION

The results showed that Rosenstein's and Wolf's methods calculated different values for the noise-free time series of the passive dynamic walker (Table 1). In addition, Rosenstein's method estimated the LyE for noisy time series lower than that of noise-free (negative %errors) in all noise levels. Furthermore, the mean %error was %-55.46 using Rosenstein's method. Considering Wolf's method, it estimated LyE for noisy time series lower than noise-free value for low levels of noise (55dB o 45dB); whereas for high levels of noise (40dB to 25dB), it estimated LyE higher than the actual value. The mean %error was also as high as %1063.65.

Table 1: LyE values and percent error calculated using Wolf's and Rosenstein's methods.

	LyE value (%Error)	
	Wolf's	Rosenstein's
no noise	1.36	0.34
55dB	0.39 (-71.57)	0.12 (-64.71)
50dB	1.04 (-23.66)	0.12 (-64.71)
45dB	0.54 (-60.03)	0.14 (-58.82)
40dB	6.73 (394.49)	0.15 (-55.88)
35dB	18.46 (1256.36)	0.16 (-52.94)
30dB	34.03 (2400.59)	0.18 (-47.06)
25dB	45.44 (3238.87)	0.19 (-44.12)

Our results show that neither of Rosenstein's or Wolf's methods are robust to experimental noise. It could be due the fact that in the presence of noise, possibility of picking false neighbors in the state space increases [7]. However, Rosenstein's method performed better than Wolf's method in the presence of noise (lower %error). Rispens, et al. [4] also demonstrated that the precision of Rosenstein's algorithm was greater than Wolf's algorithm for noisy Lorenz and Rossler attractors. In addition, in line with Rispens et al. [4] study, our results demonstrated that Wolf's algorithm is more accurate in low level compared to high level noise. One reason for Rosenstein's higher accuracy might be that it averages the divergence over the whole state space and thus eliminating the effect of noise [4].

CONCLUSIONS

Our findings suggest that neither of Rosenstein's and Wolf's algorithms calculate LyE accurately in the presence of noise although Rosenstein's algorithm is superior to Wolf's method in terms of robustness to experimental noise. Based on the results, caution should be taken in conducting experiments to reduce experimental noise in studies aiming to quantify walking dynamic stability. Furthermore, other algorithms of calculating LyE which are more robust to noise could be adopted to more accurately quantify dynamic stability of human walking.
