Abstract—Cardio Respiratory Fitness (CRF) is a strong predictor of mortality. Because of this the American Heart Association recommends that ideally all patients should have measured CRF with a maximal effort test on a regular basis. However, this is not practically possible. Seismocardiography (SCG) is a measure of the vibration produced by the beating heart, measured on the sternum. This study investigates the correlation between amplitudes in the SCG and VO₂-max from 17 females and 9 males. All amplitudes investigated correlated significantly with VO₂-max.

I. INTRODUCTION

According to an American Heart Association (AHA) Scientific Statement from 2016, CRF is potentially a stronger risk predictor of mortality than smoking, diabetes and hypertension [1]. CRF can be estimated by maximal oxygen consumption (VO₂-max) with a maximal effort cycle ergometer test. This test is not well suited for the elderly or obese patients. In this study we investigated using recordings of vibrations on the chest produced by the beating of the heart, SCG, and its correlation to VO₂-max. SCG is a deterministic signal recorded non-invasively on the sternum with an accelerometer [2].

II. METHODS

Seventeen females and 9 males were recruited for the study. All subjects signed written informed consent form. Demographic data, SCG and electrocardiography (ECG) was recorded for 5 minutes at rest. VO₂-max was measured with a Vyntus CPX during a maximal effort cycle ergometer test. The female subjects participated in a follow up recording session, after 8 weeks of structured high intensity training for 2 hours a week. Based on the ECG R-peak, the SCG was divided into individual beats and one mean SCG beat was calculated for each subject. From the mean SCG beats the peak-to-peak amplitudes between the location of the mitral valve closure (Eₕ) and the following valley Fₕ, Fₛ to aortic valve opening (Gₛ), aortic valve closure (Bₛ) to the following valley Cₛ and lastly Cₐ to Dₐ was measured (see Fig I) [3]. The amplitudes were correlated with the VO₂-max using the Pearson’s Correlation.

III. RESULTS

The mean VO₂-max for the females was 28.7 (± 4.5) (mL/kg)/min prior to the 8 weeks of training, compared to 31.2 (± 6.5) (mL/kg)/min after training (p < 0.05). The mean VO₂-max for the males was 40.1 (± 8.4) (mL/kg)/min. The correlations between the amplitudes of the valve events and VO₂-max are listed in Table I.

IV. DISCUSSION & CONCLUSION

The amplitude of Cₐ to Dₐ could be caused by the heart moving towards its apex when the aortic valve closes [2]. The amplitude of this event could be manipulated by the speed of the pressure drop in the left ventricle. Faster ventricular relaxation has previously been shown in athletes compared to normal subjects.

This study shows a correlation between amplitudes measured in the SCG and VO₂-max, presenting a novel non-exercise method for estimating CRF.
