Heat Roadmap Europe

Towards a sustainable, resilient and competitive heating sector
by 2050 – Data and country profiles

This report is a supplementary report to the Heat Roadmap Europe – Main report. This report shows how ambitious heat savings, large-scale district heating expansion to a 55% market share, and smart electrification can reduce EU primary energy use, eliminate reliance on fossil fuels, and enhance competitiveness. More than 3 PWh of waste and renewable heat potentials have been identified, of which at least 650 TWh are assessed as usable. By integrating renewable and waste heat into adaptive, low-temperature networks, supported by large-scale heat pumps and thermal storage, Europe can achieve a sustainable and resilient heating sector by 2050. Smart electrification and district heating go hand in hand. The report focuses on the EU level but also provides exploitable country-level results.

This report builds primarily on analyses conducted within the EU-funded project sEEnergies (Grant Agreement No 846463). It was prepared with support from Euroheat & Power and carried out in 2024–2025. The report forms part of the Heat Roadmap Europe project series and is the fifth in the series (heatroadmap.eu). It consists of a main report and a supplementary report, which complements the main report by providing additional EU-level and country level data on primary waste heat potentials, as well as downloadable maps in PNG format.

I Introduction

This report is part of the Heat Roadmap Europe series' fifth study. This supplementary report complements the main report by providing additional EU-level and country-level evidence on primary waste-heat potentials and district heating. It combines spatial mapping across different district-heating deployment levels, including city-focused results and detailed maps showing where recoverable waste heat can be integrated into adaptive, low-temperature district-heating networks. By linking these mapped potentials to pathways for district-heating expansion, supported by large-scale heat pumps and thermal storage - the aim is to strengthen the empirical basis for planning, investment, and implementation at EU, national, and city scales.

The supplementary report presents waste-heat shares and potentials under different district-heating market-share assumptions at both EU level and for individual countries. When linking waste and renewable heat potentials to an EU-level district-heating share, the results reflect a top-down spatial modelling approach in which lower-cost and larger opportunities are prioritized first. This is necessary because there are no consistent EU-wide data describing the locations or extents of existing district-heating networks. As a result, country-level results, where district heating may rely on waste heat, geothermal energy, or solar thermal, and where cost structures vary are not directly comparable with EU-level optimization. For example, an EU-wide district-heating share of 33% may correspond to only 5% district-heating penetration in a given country if lower-cost expansion options exist elsewhere.

To strengthen this analysis, the report incorporates extensive technical data on future heat sources and district-heating potentials. It includes technical district-heating potentials (TWh) at a 55% EU27 market share across a broad range of waste-heat and renewable-heat categories; projected waste-to-energy and waste-treatment potentials for 2020–2050; total waste volumes (million tonnes); expected heat production (TWh/y); and available data centre waste heat under multiple scenarios. The assessment also examines global and European nuclear capacities and estimates of nuclear waste-heat availability in 2023 and 2050. Industrial waste-heat potentials at 25°C, 55°C, and 95°C are quantified for each EU27 + UK country, with further detail for selected Member States.

Additional modelling covers national-level district-heating network costs, the identification of the most suitable cities for district-heating expansion based on cost and heat-source availability, and country-level overviews of district-heating shares and mapped waste-heat sources. The spatial modelling methodology includes heat-demand estimation using building-stock and population data, district-heating potential derived from heat-demand and floor-area grids, the mapping of future heat sources, and the calculation of full and technical potentials (TWh/y). A scenario-based prioritization allocates heat sources sequentially to baseload demand, with solar thermal evaluated separately before integration. Finally, the report provides key modelling inputs, costs, capacities, and scenario-specific assumptions used to link these spatial and technical findings to broader energy-system analyses.

2 Waste heat potential and data for EU

2.1 Technical potentials of district heating at 55% EU27 market share in TWh.

Table 1: Technical potentials of district heating at 55% EU27 market share in TWh, divided on each EU27 country and the 10 sources of heat.

2.4 Nuclear assessment

The next table tries to summarize key data about the nuclear energy infrastructure for different countries. In the table you can see the total number of nuclear plants of each country with a distinction on how many they are operational. As well as the ones under construction and the proposed to be built in the future because the horizon for the project is 2050. In that sense the age or lifetime expectancy is also taken into consideration to estimate if the plant will be operating still in 2050. The column labelled as EU27 filters out whether a country is part of the European Union or not, in order to use the data for these countries which is particularly relevant for the analysis of the EU27 case study. In conclusion, this table offers valuable insights into global nuclear energy strategies and future capacity changes, enabling to assess energy supply and to picture how nuclear fits within the broader energy mix. It is also important to mention that the distribution profile for the nuclear energy to know its hourly behaviour in time the historic distribution was taken from Energy Charts. As it can be expected, for the countries that have no nuclear energy in their energy mix the distribution file is a constant of zero.

Table 7: The countries globally with nuclear based power plants and their capacities.

| Country | Plants | Proposed | Operational | Under construction | 2023 Net capacity | Age of operation 2023 | 2030 Net capacity | Age of operation 2030 | 2040 Net capacity | Age of operation 2040 | 2050 Net capacity | Age of operation 2050 |

2.5 Industry waste heat aggregated

This section presents the aggregated industrial waste heat at 25°C, 55°C, and 95°C for each EU27 + UK country, based on the studied scenarios and summed across all source subcategories. Low temperature waste heat (25°C) consists of waste heat from industry, metros, supermarkets and baseload. Medium temperature waste heat (55°C) originates from industry, wastewater treatment and baseload. High temperature waste heat (95°C) consists of waste heat from industry, waste-to-energy and baseload. The relation between the base year of 2015 and 2050 is calculated, to show the expected development of available waste heat.

Table 9: This section presents the aggregated industrial waste heat at 25°C, 55°C, and 95°C for each EU27 + UK country, based on the studied scenarios and summed across all source subcategories.

| Waste heat available UNIT: TJ | Temp | Base year | Frozen efficiency | | | BAT (No extra recycling) | | BAT (high recycling) | BAT (high recycling) | 2015/2050 |
|----------------------------------|-----------|-------------|-------------------|-------------|-------------|--------------------------|-------------|----------------------|----------------------|-----------|
| | | | 2030 | 2050 | 2030 | 2050 | 2030 | 2050 | Relation % | |

2.7 Industry waste heat – sub-sectors 55°C

This section presents industrial waste heat at 55°C divided into sources for each the selected countries of France, Germany Hungary, Poland and Spain, based on the studied scenarios and summed across all source subcategories.

Table 11: The industrial waste heat at 55°C divided into sources for each the selected countries of France, Germany Hungary, Poland and Spain, based on the studied scenarios.

| 55°C: | Waste heat available UNIT: TJ | Product | Base year | Frozen efficiency | | | BAT (No extra recycling) | | BAT (high recycling) | | 2015/2050 |

2.8 Industry waste heat – sub-sectors 95°C

This section presents industrial waste heat at 95°C divided into sources for each the selected countries of France, Germany Hungary, Poland and Spain, based on the studied scenarios and summed across all source subcategories.

Table 12: The industrial waste heat at 95°C divided into sources for each the selected countries of France, Germany Hungary, Poland and Spain, based on the studied scenarios.

| 95°C: | Waste heat available UNIT: TJ | | Base year | Frozen efficiency | | BAT (No extra recycling) | | BAT (high re-cycling) | BAT (high re-cycling) | 2015/2050 |
|---------|-------------------------------|----------------------------|-----------|-------------------|--------|--------------------------|-------|-----------------------|-----------------------|------------|

3.8 Industry share of total demand

The table shows the share of the industrial demand over the total demand per country. This was used to determine the district heating distribution files.

Table 22: The table shows the share of the industrial demand over the total demand per country. This was used to determine the district heating distribution files.

| Country | The total district heating demand | Country | The total district heating demand | Country | The total district heating demand |
|----------|-----------------------------------|-------------|-----------------------------------|----------------|-----------------------------------|
| Austria | 2,75% | Germany | 2,82% | Poland | 3,14% |
| Belgium | 1,61% | Greece | 1,03% | Portugal | 1,91% |
| Bulgaria | 5,68% | Hungary | 4,28% | Romania | 5,79% |
| Croatia | 1,83% | Ireland | 3,27% | Slovakia | 1,60% |
| Cyprus | 0,00% | Italy | 3,24% | Slovenia | 2,57% |
| Czechia | 8,58% | Latvia | 0,15% | Spain | 0,92% |
| Denmark | 0,64% | Lithuania | 2,06% | Sweden | 2,40% |
| Estonia | 2,79% | Luxembourg | 0,17% | United Kingdom | 0,48% |
| Finland | 5,16% | Malta | 0,00% | EU27 | 2,62% |
| France | 0,73% | Netherlands | 4,97% | EU27 + UK | 2,35% |

4 City level results

Identification of optimal cities for district heating development

This appendix identifies the most suitable cities for the development of (district heating systems by integrating high shares of waste heat from various investigated sources. The analysis focuses on the largest urban areas with significant contributions from high-temperature industrial waste heat, medium- and low-temperature waste heat, and geothermal and solar potential. While the district heating model delineates suitable district heating areas within cities based on heat density, this section consolidates these distinct areas into a unified framework at the city level. By aggregating the heat demand and waste heat potential of individual district heating areas to city-level combined zones, the analysis reduces the number of data entries, thereby enhancing the clarity and efficiency of the assessment at both the EU and national scales.

The analysis further emphasizes larger urban centers, focusing on cities with populations exceeding 45,000 inhabitants, where the implementation of district heating systems is more feasible and economically viable. Figure 3-6 illustrate the cities with the highest shares of heat demand covered by waste heat from various sources - namely, high-temperature industrial processes, medium- and low-temperature activities, and geothermal energy - relative to city size.

In these visualizations, the size of each bubble reflects the proportion of heat demand covered by the corresponding waste heat source, with larger bubbles representing coverage levels exceeding 75% of the heat demand. The bubble colors denote the population size of the respective cities, providing an additional layer of insight. For clarity, the maps highlight the names of the largest cities exhibiting the highest heat demand shares covered from waste heat sources.

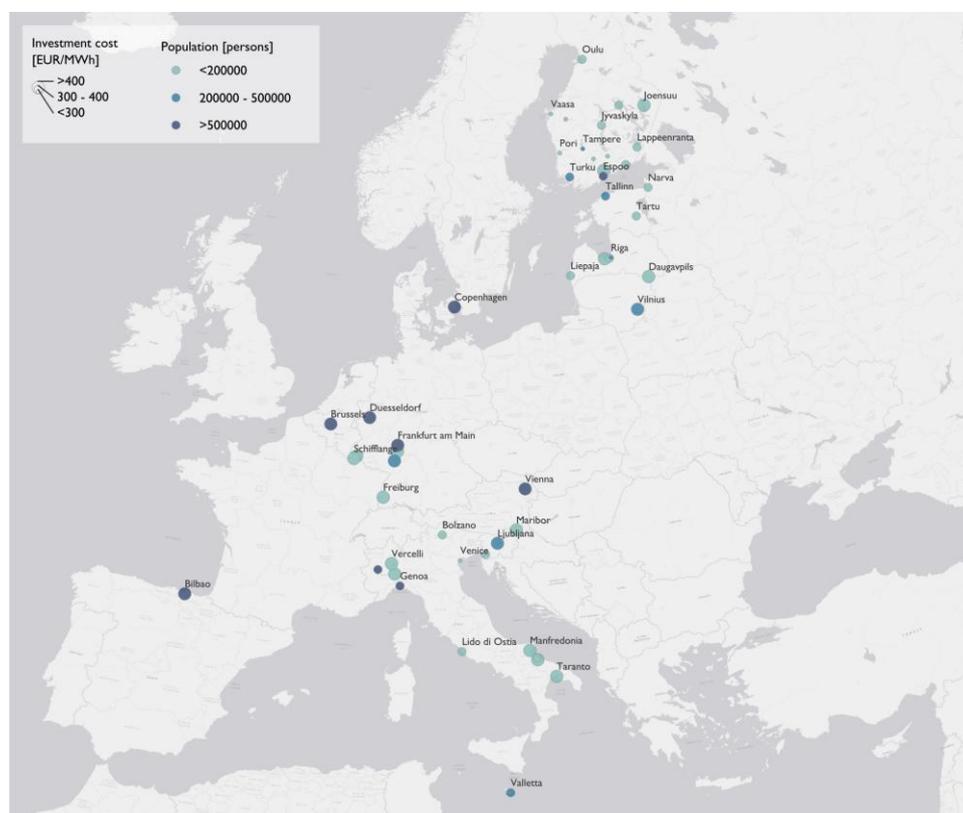

Figure 3 The 50 most suitable cities for the development of district heating based on investment costs.

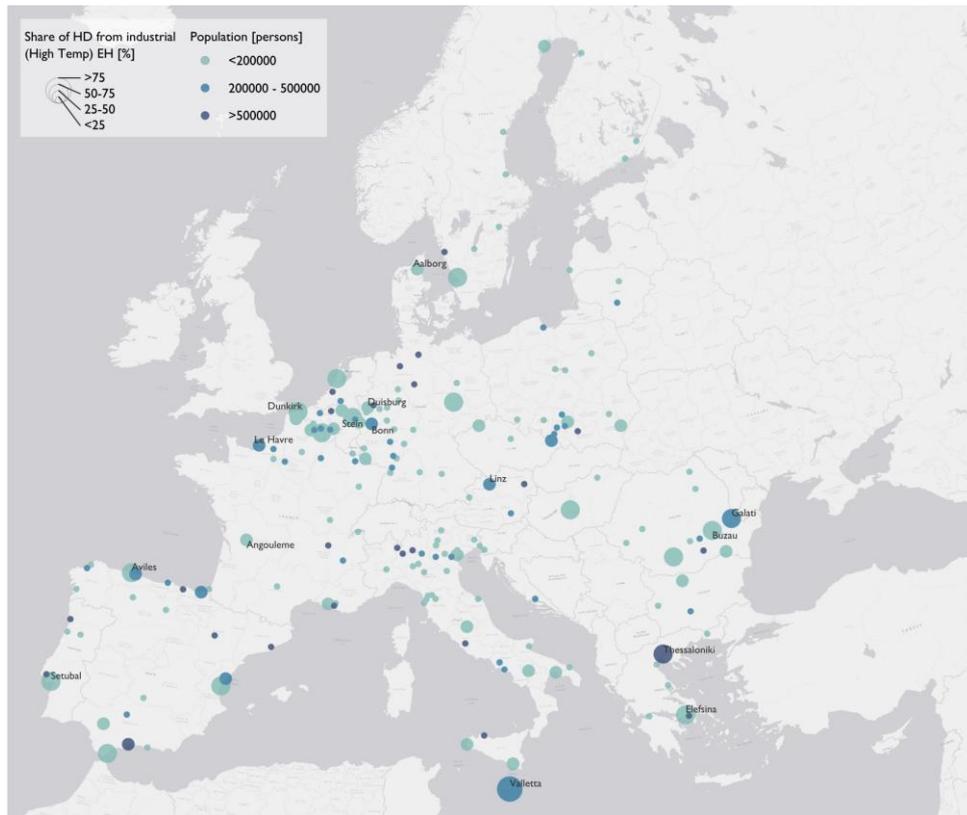

Figure 4 Mapped share of heat demand covered from high temperature industrial waste heat in comparison to the city's population.

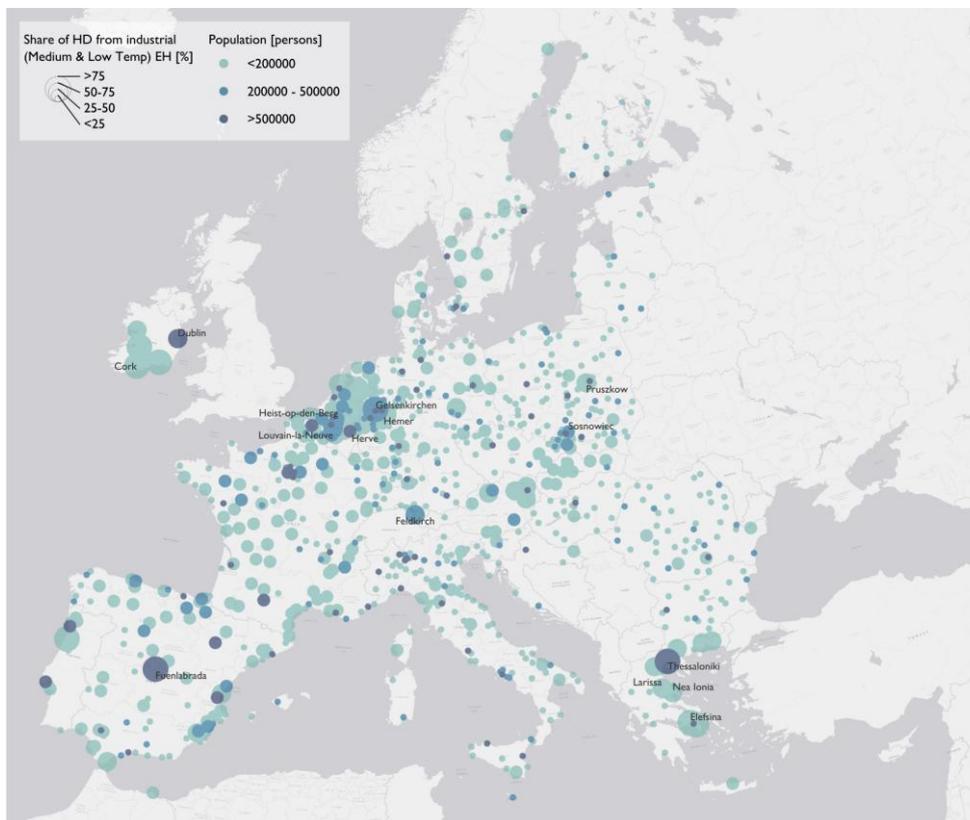

Figure 5 Mapped share of heat demand covered from medium and low temperature industrial waste heat in comparison to the city's population.

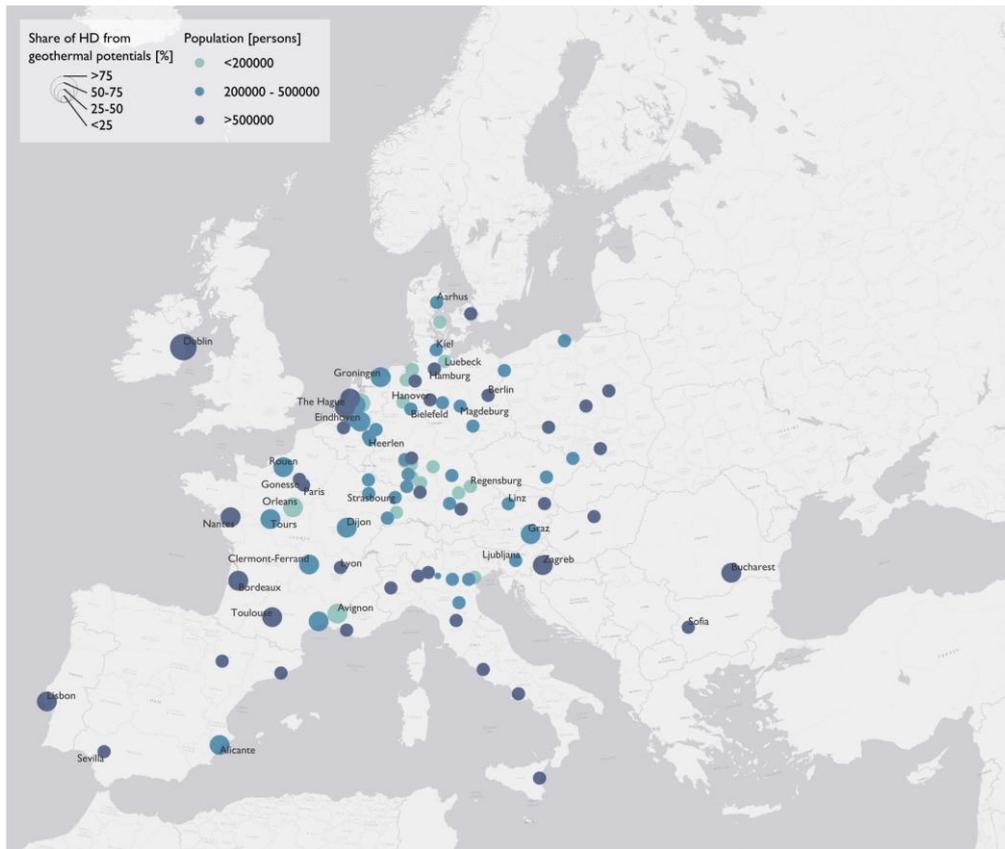

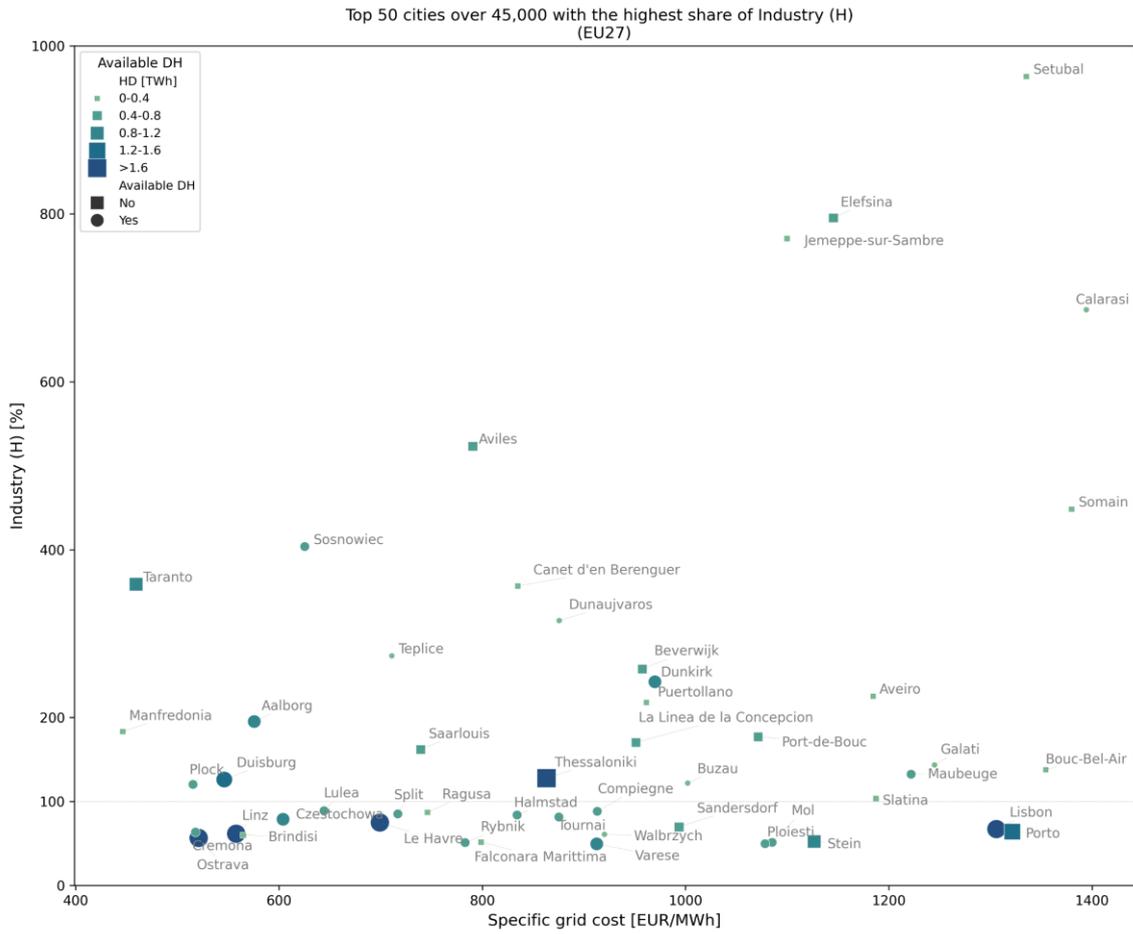

Figure 6 Mapped share of heat demand covered from geothermal potential in comparison to the city's population.

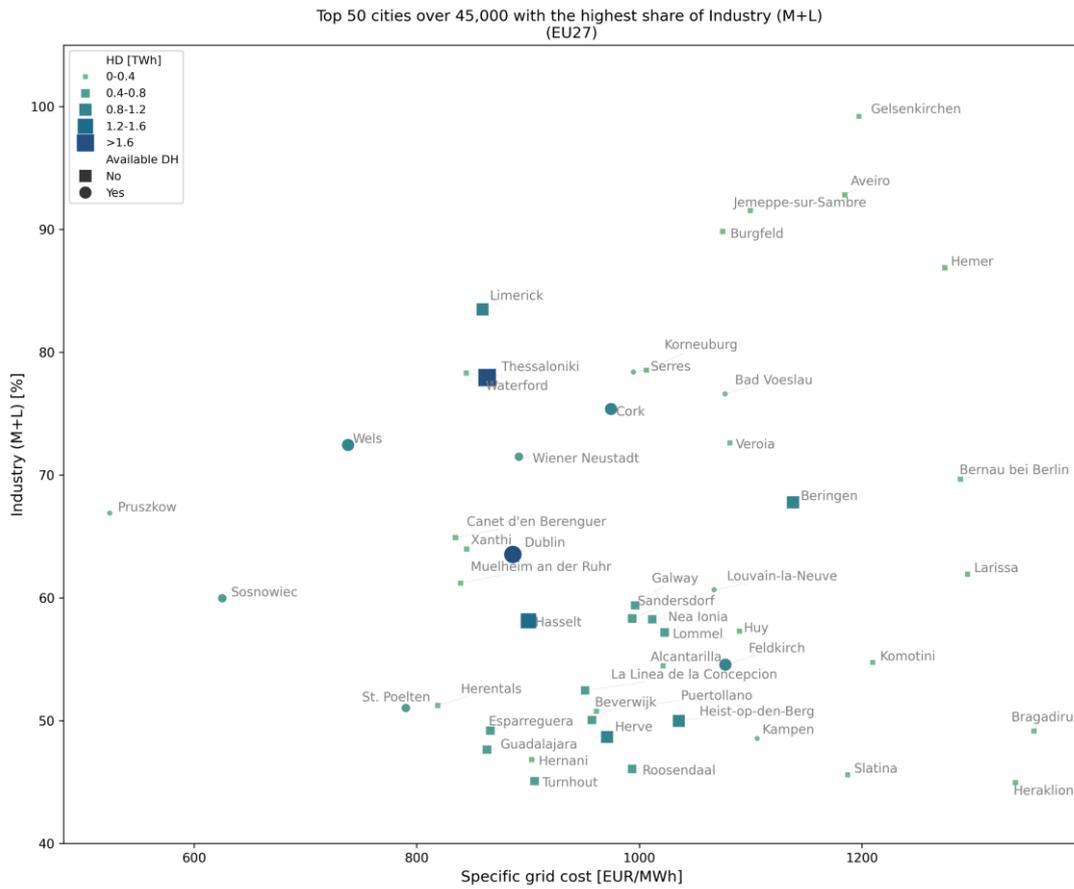

Figure 8 Scatterplot of the share of heat demand covered from medium and low temperature industrial surplus heat in comparison to the investment cost.

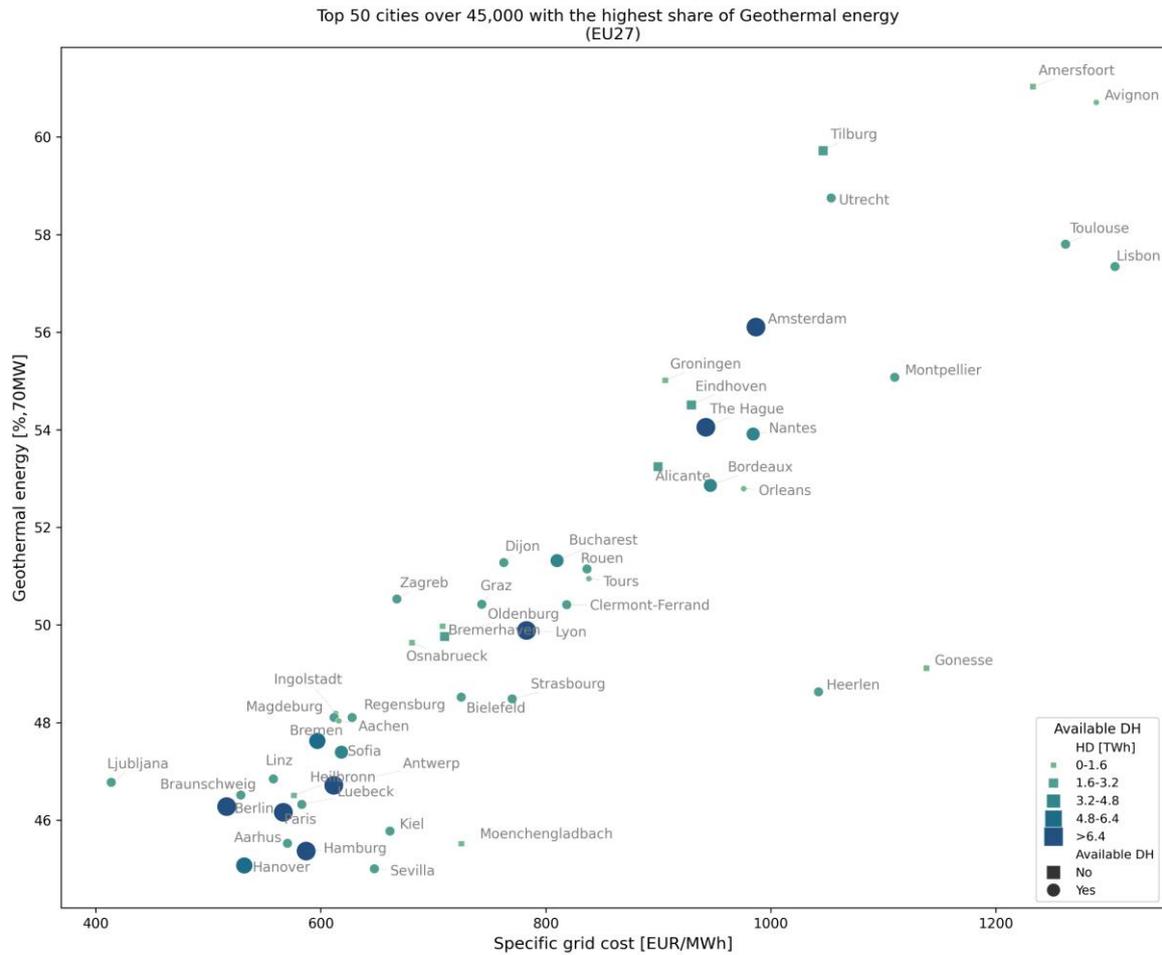

Figure 9 Scatterplot of the share of heat demand covered from geothermal potential in comparison to the investment cost.

Table 23 The 50 cities in EU27 with the highest shares of heat demand in district heating covered by high temperature industrial waste heat.

| City | Country | Heat demand [TWh] | Investment cost [EUR/MWh] | Waste heat from Industry (H) [TWh] | Share of heat demand by high temp industrial waste heat | Available district heating | Available geothermal |

5 National-level waste heat and renewable heat potentials

This section contains an overview for each country studied in the Heat Roadmap Europe main report. The overview consists of table showing the district heating shares and the related sources of waste heat. It is important to understand that these shares differ from the shares presented in the EU27 market share assessment. Further the potential for each waste heat source, is visualized on maps. When applicable, the following sources of waste heat are geolocated:

1. Geothermal energy (Baseload of district heating area, capacity >40MW).
2. Geothermal energy (Baseload of district heating area, capacity >70MW).
3. Baseload high temperature waste heat
4. Baseload low temperature waste heat
5. Baseload medium temperature waste heat
6. High temperature from industry
7. High temperature from waste-to-energy
8. Low temperature from industry
9. Low temperature from metros
10. Low temperature from supermarkets
11. Medium temperature from industry
12. Medium temperature from wastewater treatment

In this appendix, some graphs from the different countries, as the ones shown in the main report for the EU27 will be presented. They represent a comparison of the different scenarios in two aspects: the biomass consumption and the general cost of all the system. Several modifications could be done with the cost as a sensitivity analysis was done, however the basic cost was chosen so no scenario has any advantage over the others, more than the natural advantage of the system itself. For all the countries and graphs there are two sections in each scenario: the three first columns of the graph, represents the 3rd generation district heating grid, and the 3 last columns with a transparency, show the results of the 4th generation.

5.1 Austria

Table 26: District heating shares specific to Austria and the corresponding heat sources to the heat demand.

| Country | District heating_shares_goal [%] | District heating_shares_closest [%] | Heat demand [TWh] | Waste to energy (TWh) | Industrial Waste High Temp (TWh) | Industrial Waste Medium Temp (TWh) | Industrial Waste Low Temp (TWh) | Waste Water Treatment (TWh) | Waste heat from Supermarkets (TWh) | Waste heat from Metros (TWh) | District heating Solar Thermal (TWh, c=20MW) | District heating Solar Thermal (TWh, c=70MW) | District heating Geothermal (TWh, c=40MW) | District heating Geothermal (TWh, c=70MW) |
|---------|----------------------------------|-------------------------------------|-------------------|-----------------------|----------------------------------|------------------------------------|---------------------------------|-----------------------------|------------------------------------|------------------------------|--|--|---|---|
| Austria | 5 | 18,77 | 12,07 | 1,05 | 0,84 | 0,76 | 1,19 | 1,31 | 0,12 | 0 | 0 | 0 | 0 | 0 |
| | 10 | 18,77 | 12,07 | 1,05 | 0,84 | 0,76 | 1,19 | 1,31 | 0,12 | 0 | 0 | 0 | 0 | 0 |
| | 15 | 18,77 | 12,07 | 1,05 | 0,84 | 0,76 | 1,19 | 1,31 | 0,12 | 0 | 0 | 0 | 0 | 0 |
| | 20 | 23,06 | 14,84 | 1,32 | 1,89 | 0,76 | 1,19 | 1,31 | 0,12 | 0 | 0 | 0 | 0 | 0 |

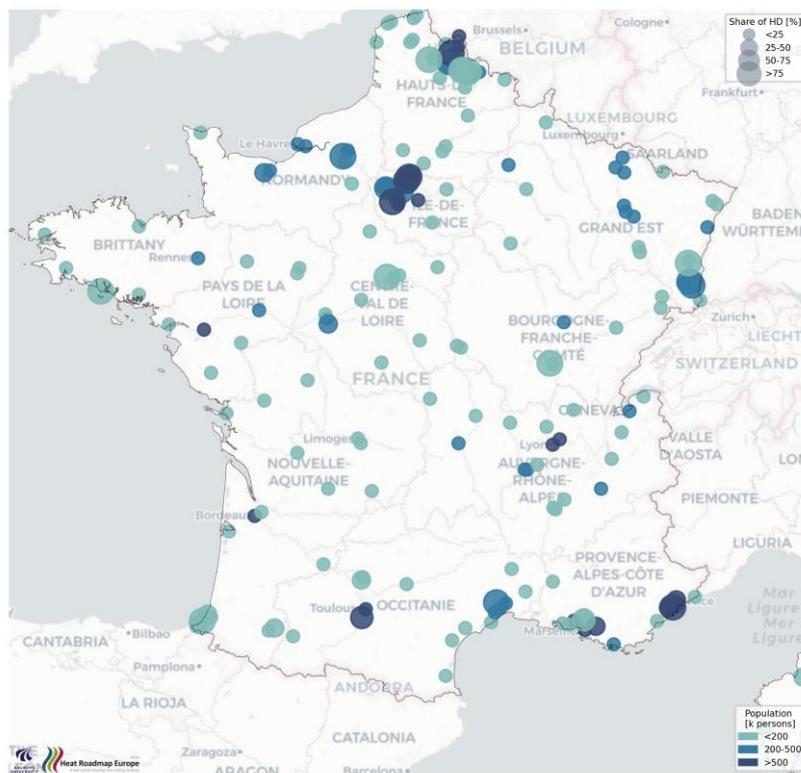

Figure 110: Medium temperature from wastewater treatment for France.

For the case of France, the recommended District heating share for 2050 is ~ 50% District heating which is illustrated below:

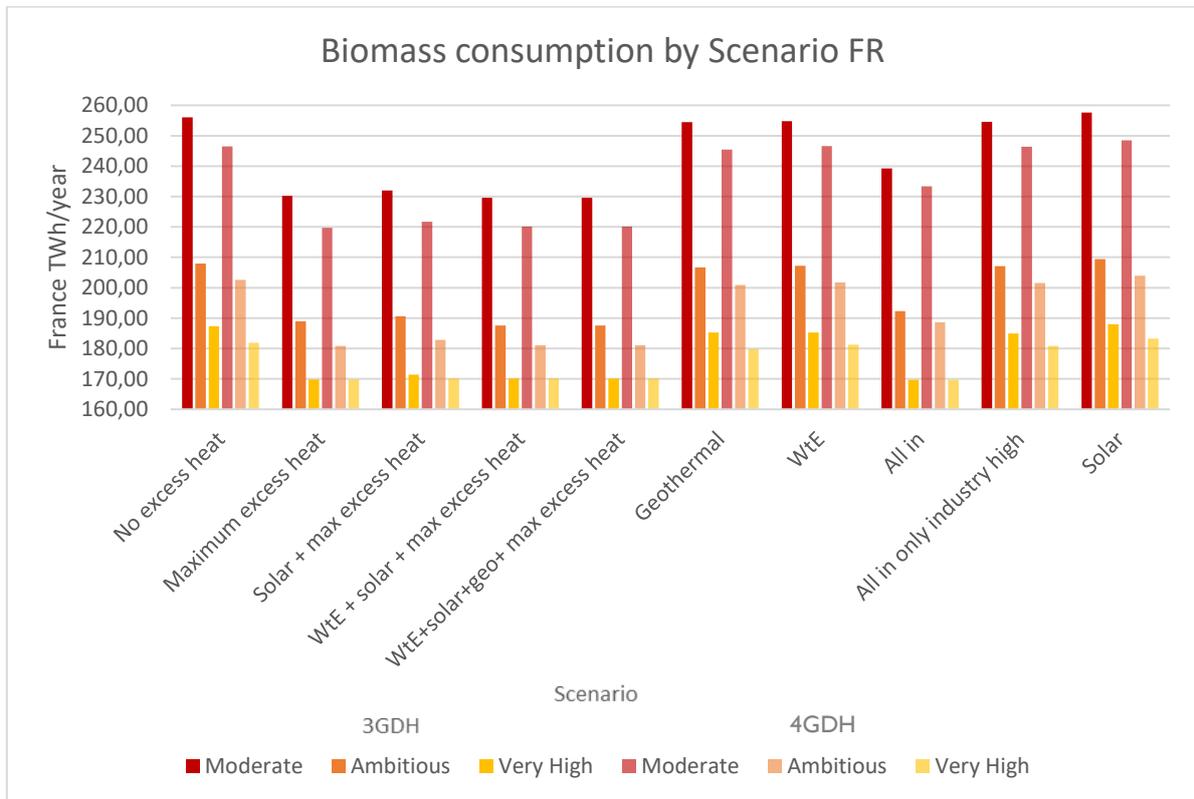

Figure 111: Biomass consumption in TWh/year for different district heating shares and heat source for 3GDH and 4GDH, in the case of France..

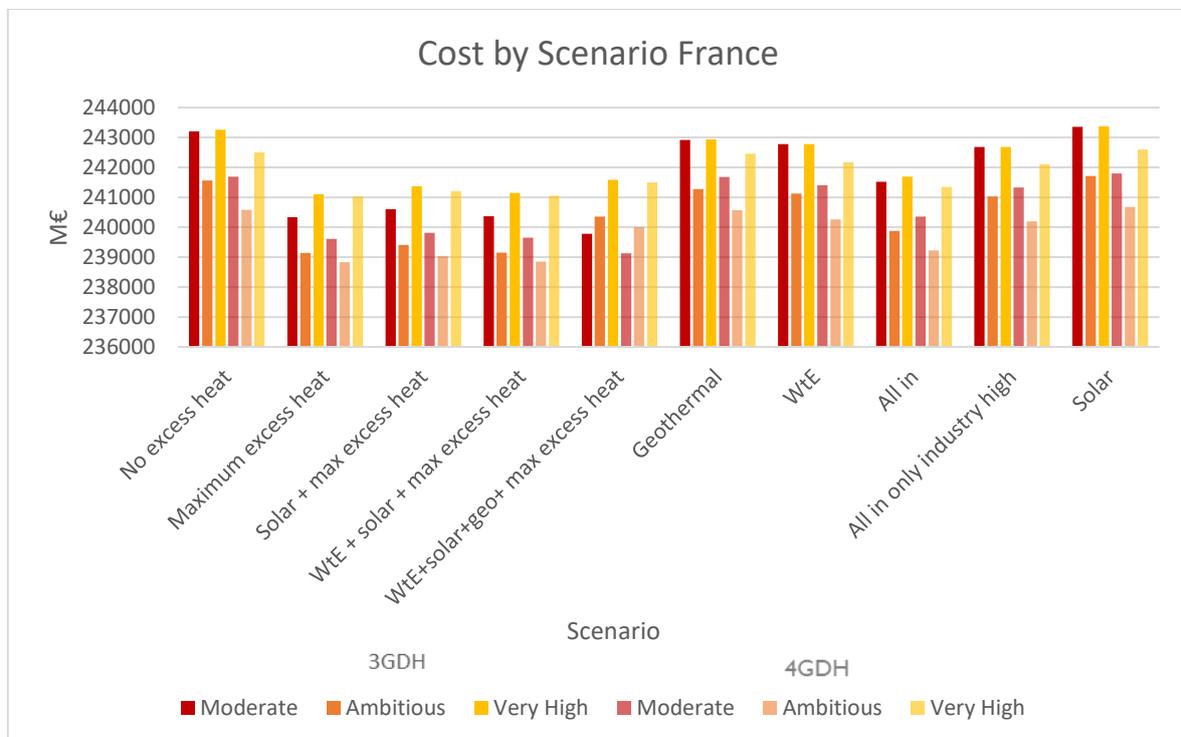

Figure 112: Cost in M€ for each scenario of district heating system at 50% district heating share for both 3GDH and 4GDH, in the case of France.

There is a clear saving potential of the biomass use with measures to reduce the heat demand, that can be seen in all cases where the very high savings, have the lowest biomass consumption, while the Moderate savings scenarios just consume the most biomass. Regarding the cost, a valley is formed for both the 3rd and the 4th generations: the cheapest option in the different heat prioritization is the Ambitious savings, while an increase in the cost happens when the saving levels goes to the Very high levels due to all the measures to reduce the demand. On the other side, in the 4th generation, all of the cases are cheaper than their parallel in the 3rd generation, showing that even with the upgrade on the system, it will end up being cheaper after all. The most expensive system would be the just Solar due to the still big use of other technologies and insufficient solar potential alone to overcome the heat demand. On the contrary, the cheapest system is the mix of heat sources (All in), reducing the system's cost over all the saving scenarios and generations of the system.

Table 35: : Biomass consumption in TWh/year for different district heating shares and heat source for 3GDH and 4GDH, in the case of France and Cost in M€ for each scenario of district heating system at 50% district heating share for both 3GDH and 4GDH, in the case of France.

| Solar | 243.359 | 241.709 | 243.378 | 241.803 | 240.677 | 242.599 |

As the previous tables show, the biggest difference in biomass consumption from the Moderate savings is found in the Very High savings, with a save close to 30% compared to the 20% of the Ambitious savings. An extra step on this is when the system is upgraded to a 4th generation system, allowing the system to save even more. When comparing the simulations with the scenario 0 as a starting point, the scenario with the biggest

reduction, discarding the free heat scenarios, is the scenario D, with all the heat mix available which can reduce up to a 10%. In this case, the Very high savings scenario D in the 3rd generation allows for more savings than their parallel scenario in the 4th generation, this is due to the better starting point it is compared to from the beginning, so there is less room for improvement. However, it needs to be mentioned that upgrading the system's generation alone, does not benefit a lot as it only saves around a 3% of the biomass.

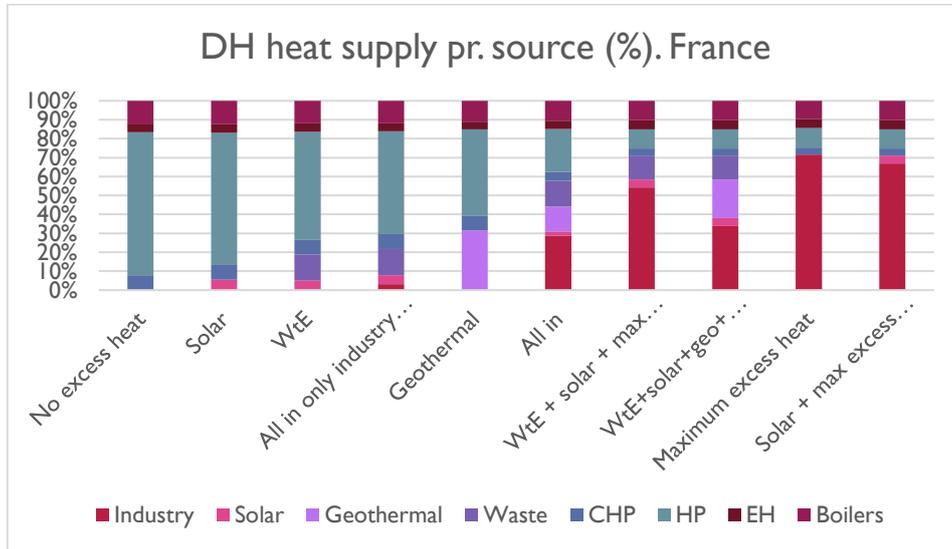

Figure 113: District heating heat supply pr. source in percentage for each scenario in the case of France.

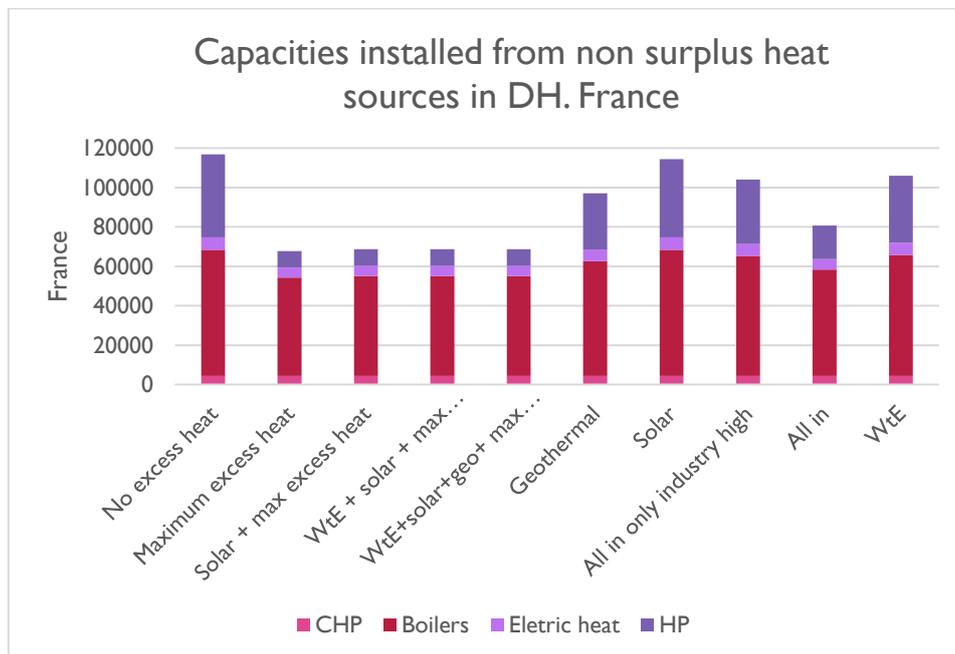

Figure 114: Installed capacities in MW from non surplus heat sources in district heating in France.

The scenarios where the lowest HP capacity is found in the scenarios with “free” surplus heat, however, when we take those scenarios out of the equation, the scenario All in where all the heat surplus sources are present has the lowest HP capacity installed. This highlights, once again, the importance of having a good mix of sources to use the available heat in a smart way.

5.10 Germany

Table 36: District heating shares specific to Germany and the corresponding heat sources to the heat demand.

| Country | District heating_shares_goal [%] | District heating_shares_closest [%] | Heat demand [TWh] | Waste to energy (TWh) | Industrial Waste High Temp (TWh) | Industrial Waste Medium Temp (TWh) | Industrial Waste Low Temp (TWh) | Waste Water Treatment (TWh) | Waste heat from Supermarkets (TWh) | Waste heat from Metros (TWh) | District heating Solar Thermal (TWh, c=20MW) | District heating Solar Thermal (TWh, c=70MW) | District heating Geothermal (TWh, c=40MW) | District heating Geothermal (TWh, c=70MW) |

Germany: a recommended district heating share of 64,6. Results shown: simulation for 60% district heating share:

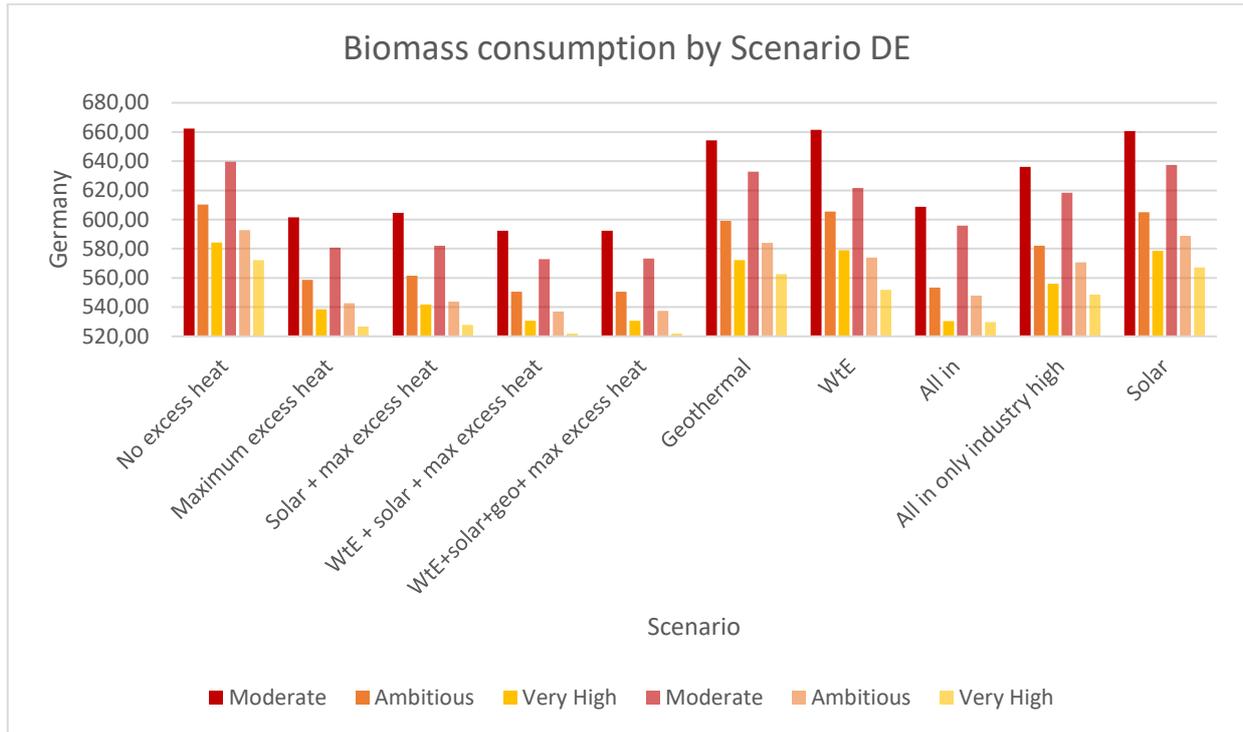

Figure 127: Biomass consumption in TWh/year for different district heating shares and heat source for 3GDH and 4GDH, in the case of Germany.

This graph represents the biomass consumption in the different scenarios for Germany. There is a clear trend that shows the higher the saving levels, so the lower the demand, the less biomass it is consumed. Also, a higher efficiency of the system, as the different district heating generations, affects the biomass consumption, as it can be seen, in any scenario, the more productive generation of the system, the lower the biomass consumption. So, basing the decision just and only on the biomass consumption, it would be sensible to say that the higher the saving level and in a 4th generation system is recommended, while mixing the most amount of heat sources (All in heat prioritization scenario), which brings a lower biomass level in any of the cases.

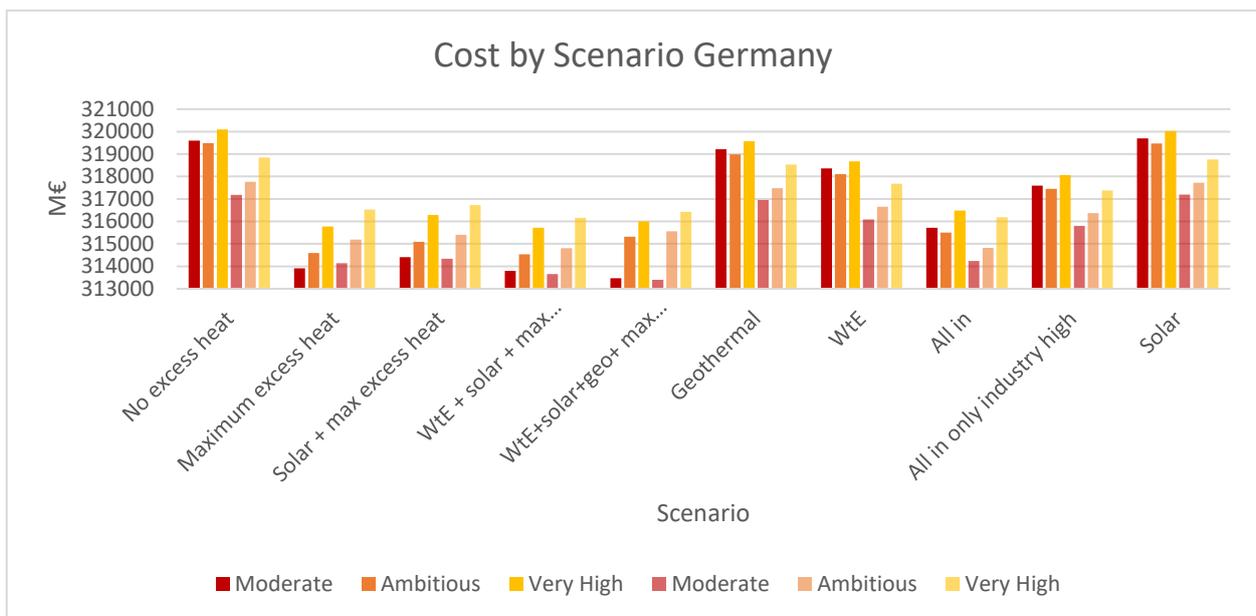

Figure 128: Cost in M€ for each scenario of district heating system at 50% district heating share for both 3GDH and 4GDH, in the case of Germany.

In regards to the costs of the system, it can be seen that the cheapest system is the all mix available heat sources, compared to the other heat prioritization. When comparing the scenarios by themselves, it can be concluded that the Very High savings is the most expensive but there is not a relationship between the saving level and the cost directly, as the cheapest is not the scenario where less measures are done, it is the Ambitious savings for the 3rd generation district heating system. On the other hand, the 4th generation system has a more direct relation between the saving level and the cost as they increase with every saving level.

Table 37: Biomass consumption in TWh/year for different district heating shares and heat source for 3GDH and 4GDH, in the case of Germany and Cost in M€ for each scenario of district heating system at 50% district heating share for both 3GDH and 4GDH, in the case of Germany.

| WtE | 318.364 | 318.105 | 318.679 | 316.092 | 316.653 | 317.674 |
| All in | 315.721 | 315.497 | 316.487 | 314.232 | 314.821 | 316.191 |
| All in only industry high | 317.590 | 317.448 | 318.068 | 315.806 | 316.367 | 317.382 |
| Solar | 319.700 | 319.463 | 320.026 | 317.198 | 317.718 | 318.759 |

For the biomass consumption, any action taken for a reduction of the demand is beneficial for reducing the biomass usage, also improving the system's generation. The most beneficial improvement to do would be to step up the generation of the system and also taking measures to reduce the system's heat demand. As an overall comparison, the All in heat prioritization is the one that uses less biomass across all heat saving scenarios.

Not only scenario All in is the cheapest standing in front of the others, but it is also the one that brings a biggest positive change, the biggest reduction compared to the no-surplus-heat scenario. This contrasts the scenario of only solar which has the biggest increase in all saving levels and generations. There it can be concluded, based on this, that only solar is not a feasible choice but the mix of the surplus heat sources helps to reduce the cost of the system. Regarding the saving level, it becomes cheaper to improve the generation of the system over taking measures to reduce the demand. In case that reducing the demand is the only option, it is recommended that only one step is taken to stay at the Ambitious savings.

Another result shown for EU27 is how the heat supply is formed with all the different sources. For the case of Germany:

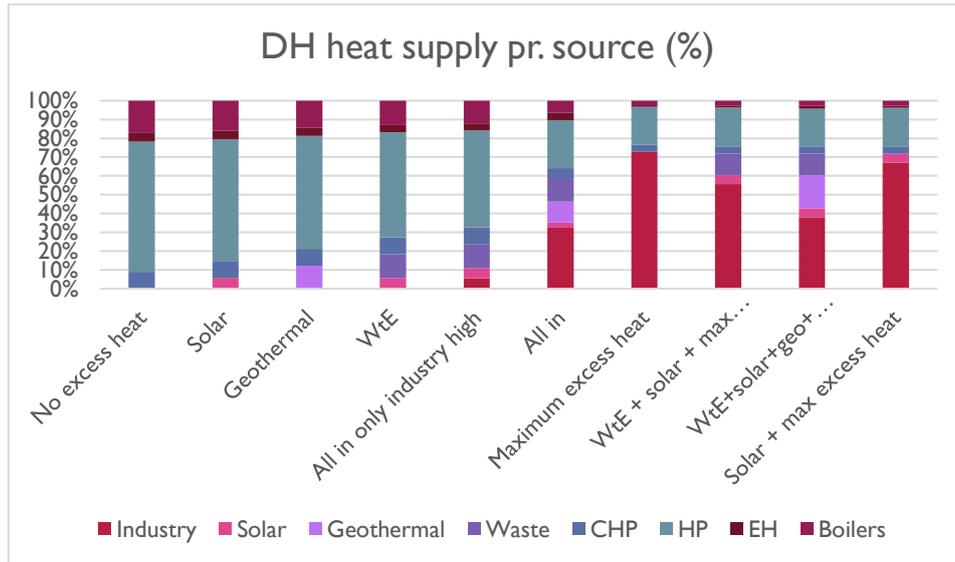

Figure 129: District heating heat supply pr. source in percentage for each scenario in the case of Germany.

This graph shows how the different heat sources are fueling the system. The light blue features the Waste to energy potential and in all the scenarios and priorities, it is used its full potential, highlighting its easiness to be integrated to the district heating system in any case. The scenarios Geothermal and Solar show that only solar and geothermal alone have not enough potential to even cover 15% of the demand. The scenario where there is less usage of heat pumps, is the scenario All in, where all the waste heat is available.

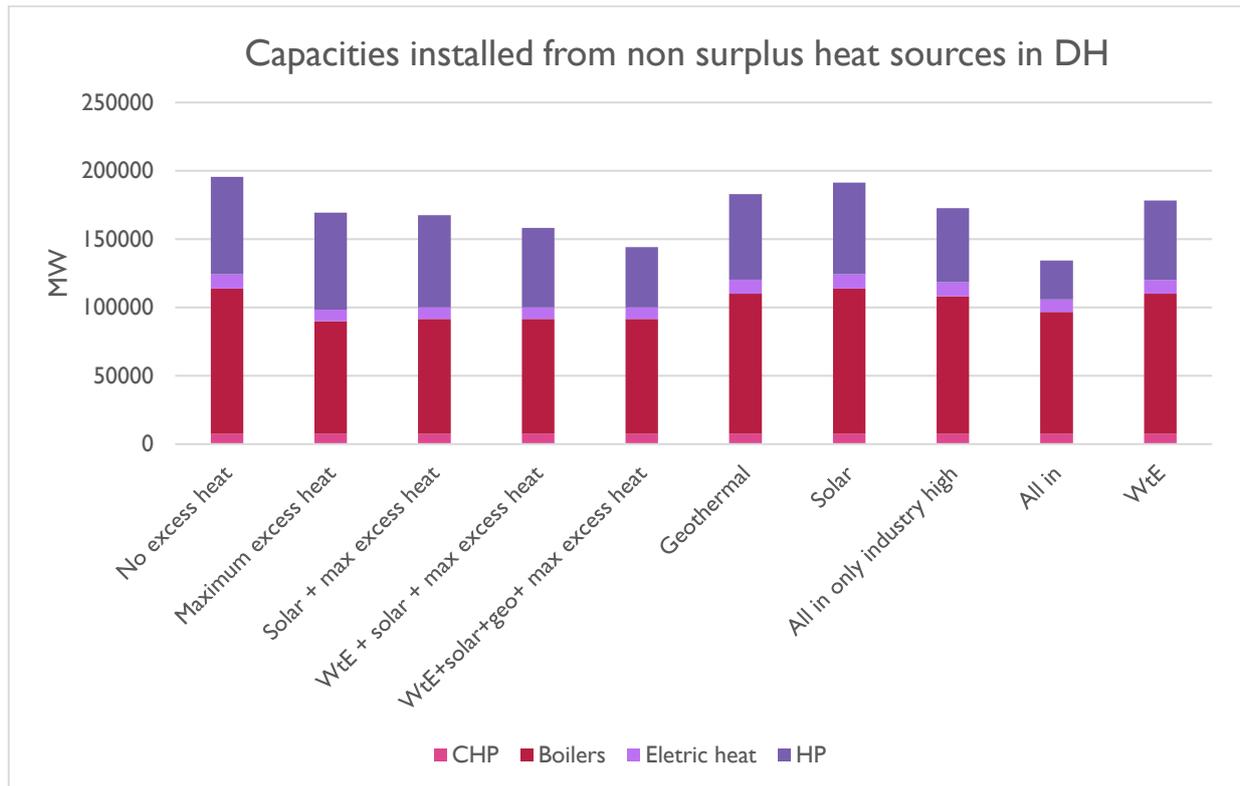

Figure 130: Installed capacities in MW from non surplus heat sources in district heating in Germany.

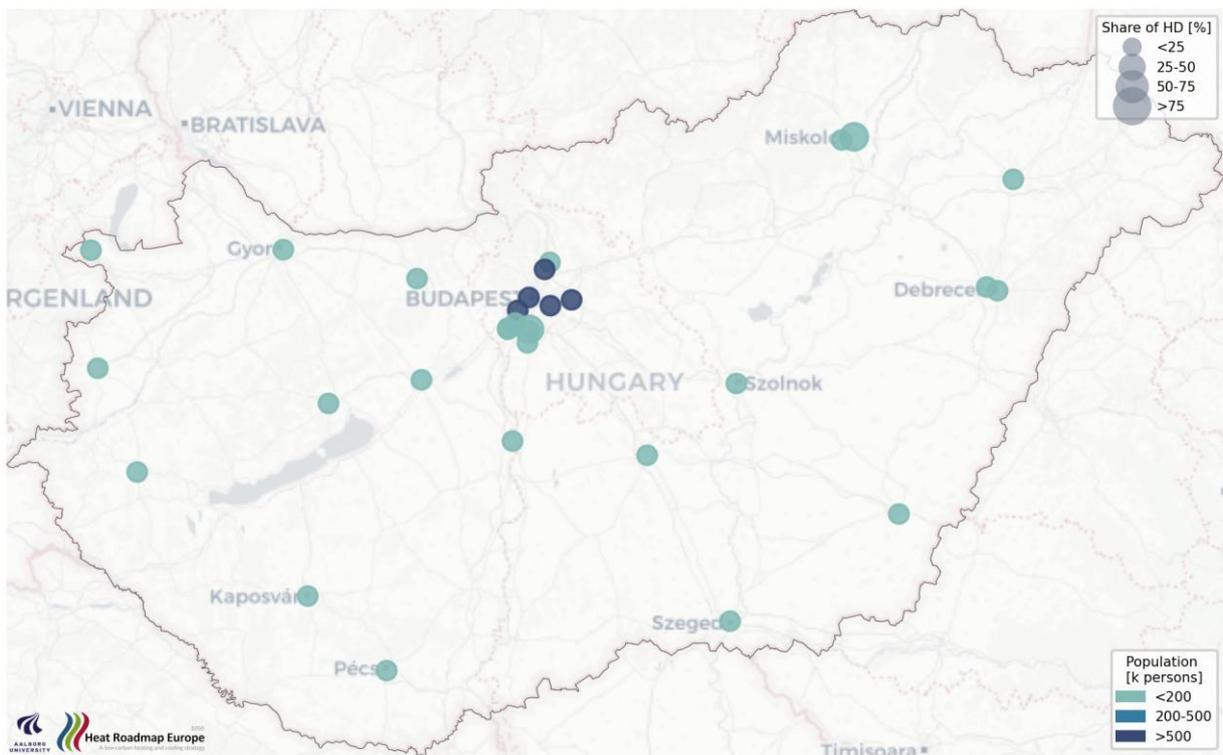

Figure 150: Low temperature from supermarkets for Hungary.

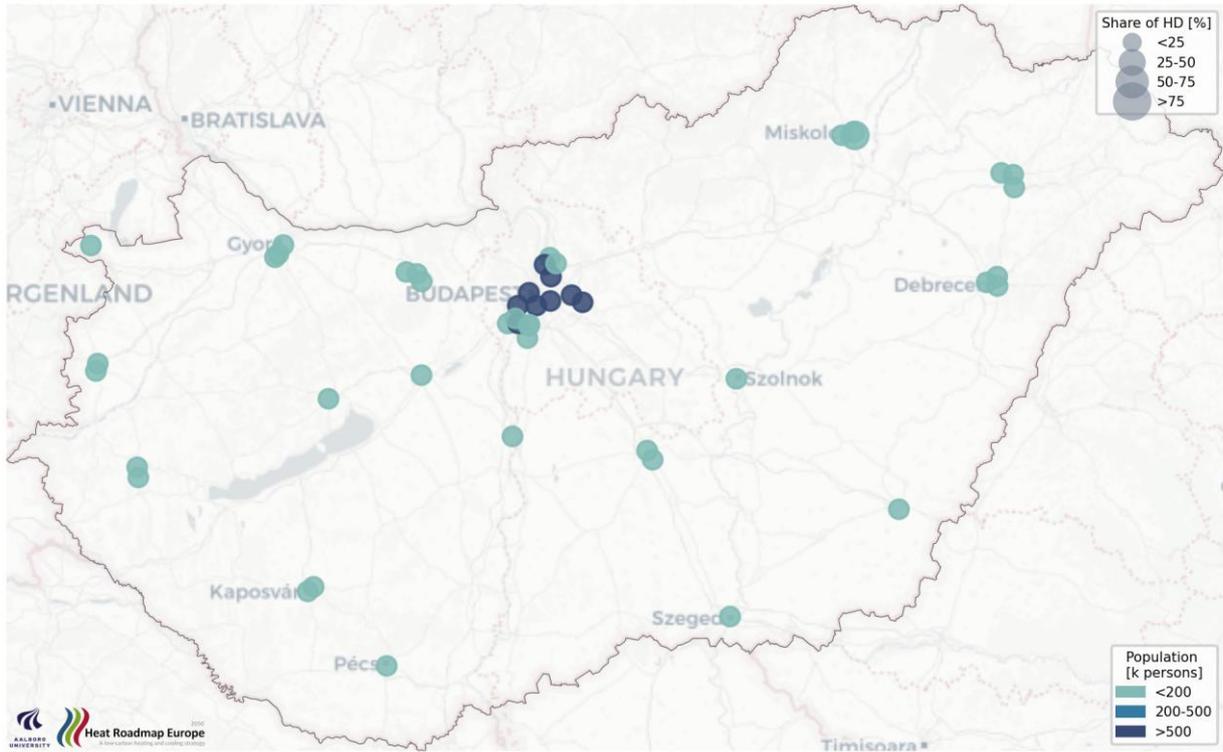

Figure 151: Medium temperature from industry for Hungary.

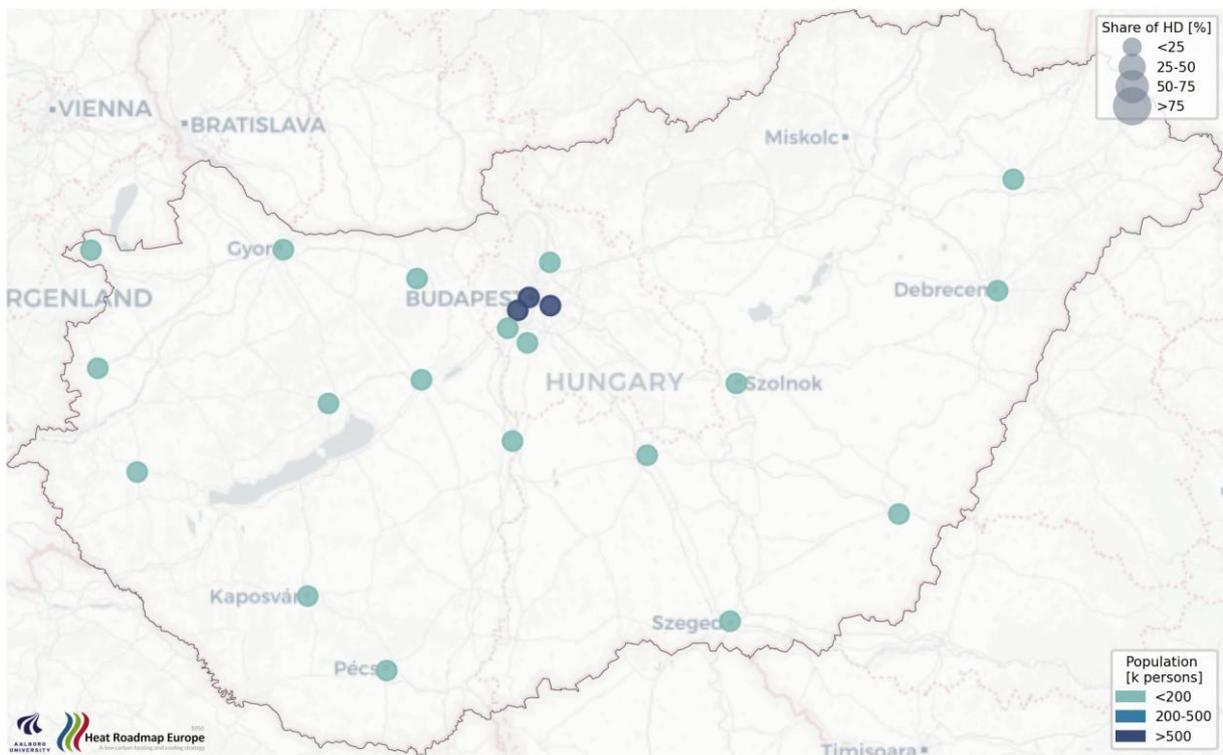

Figure 152: Medium temperature from wastewater treatment for Hungary

For Hungary the recommended district heating share is 46,59%, so the simulation for the 50% is taken.

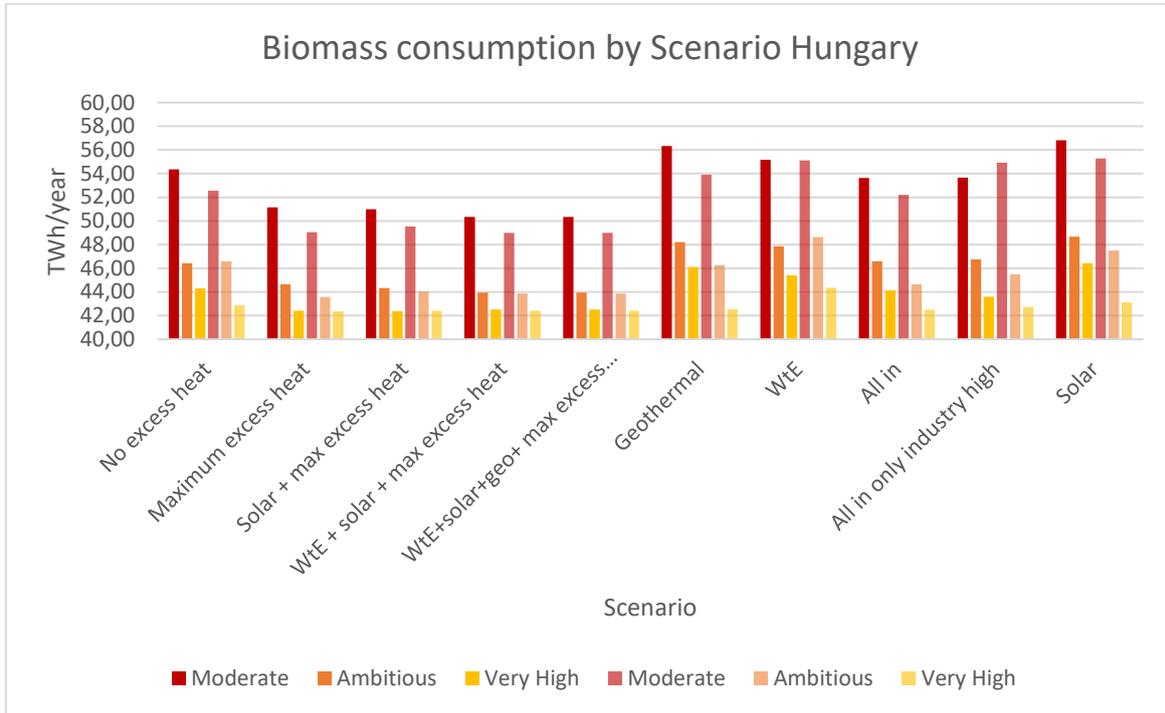

Figure 153: Biomass consumption in TWh/year for different district heating shares and heat source for 3GDH and 4GDH, in the case of Hungary.

As a rule, for Hungary, the consumption of the biomass is the minimum when the heat demand is. That happens across all scenarios and system generations. As it is logical, the high demand scenarios are the ones with more biomass consumption.

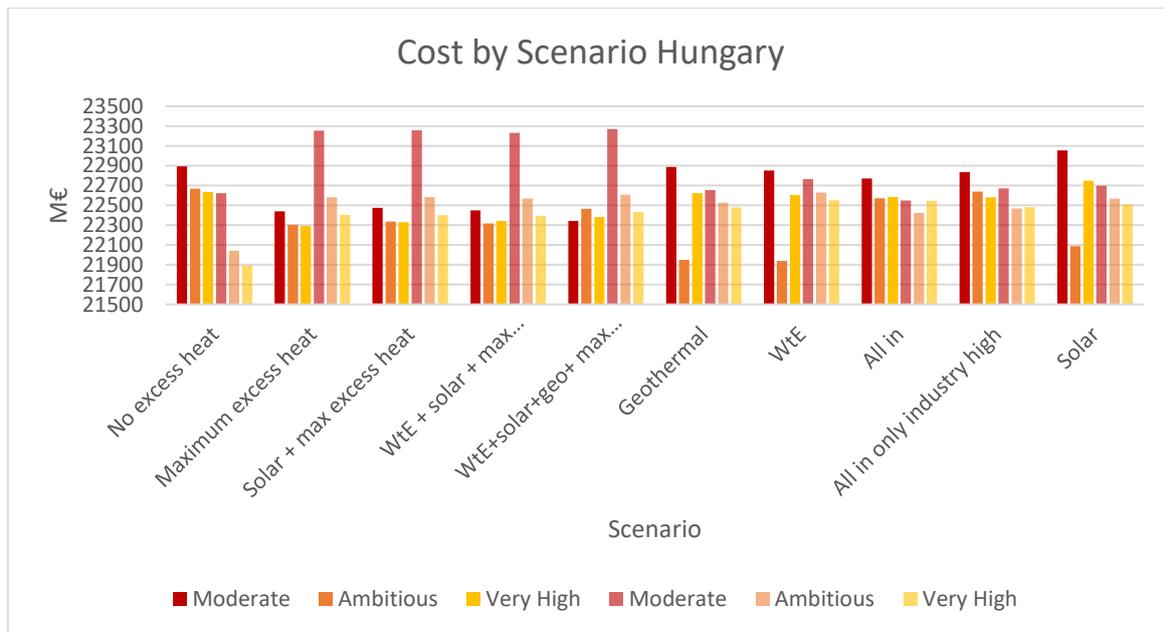

Figure 154: Cost in M€ for each scenario of district heating system at 50% district heating share for both 3GDH and 4GDH, in the case of Hungary.

The high peaks on the 4th generation on the scenarios of max availability is due to the undersize of the biomass boiler, so a compensation is added. Discarding that, the more expensive scenarios are the ones with the higher heat demand. An anomaly is seen in the Ambitious saving for the scenarios with a single heat source for the 3rd generation. For the single heat source scenarios, there is the trend that brings the cost down as the demand goes down for the 4th generation.

Table 40: : Biomass consumption in TWh/year for different district heating shares and heat source for 3GDH and 4GDH, in the case of Hungary and cost in M€ for each scenario of district heating system at 50% district heating share for both 3GDH and 4GDH, in the case of Hungary.

In the case of the biomass, its consumption can be reduced up to a 24% if measures are taken to reduce the heat demand and if the generation of the system is improved. There is only one case of increasing the biomass: when the system generation is improved with no other measures to reduce the demand are implemented in the scenario All in only industry high, for the rest, any step means a reduction in the biomass consumption. For the cost it happens a similar pattern, in any heat prioritization whatever action is taken to improve the system or reduce the demand is translated into

a reduction of the cost. However, the reduction is not a big step as the average reduction is lower than a 2% in the whole cost. Another way of justifying the actions to improve the system and the demand is that with that improvement there will be huge positive consequences for the biomass and for the environment and also for the economy.

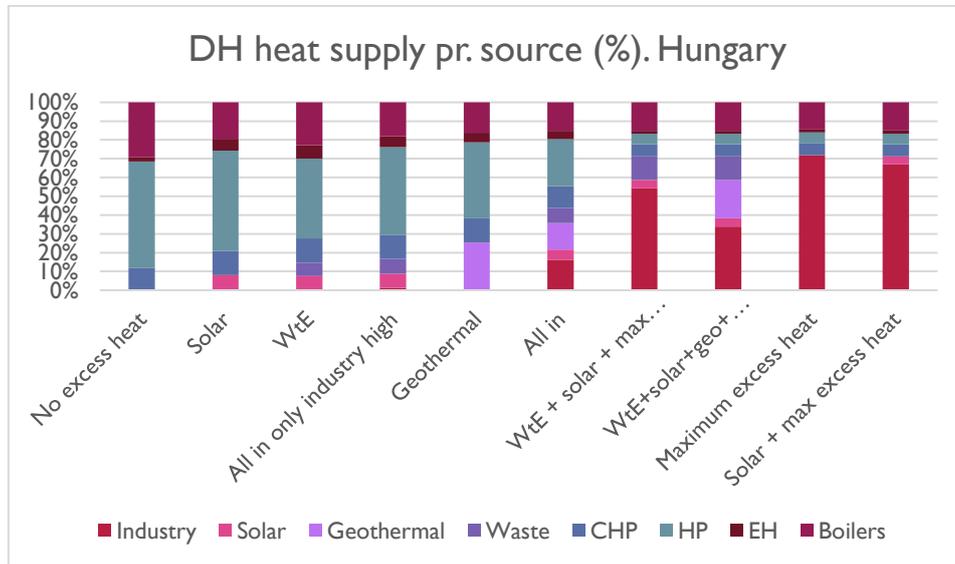

Figure 155: District heating heat supply pr. source in percentage for each scenario in the case of Hungary.

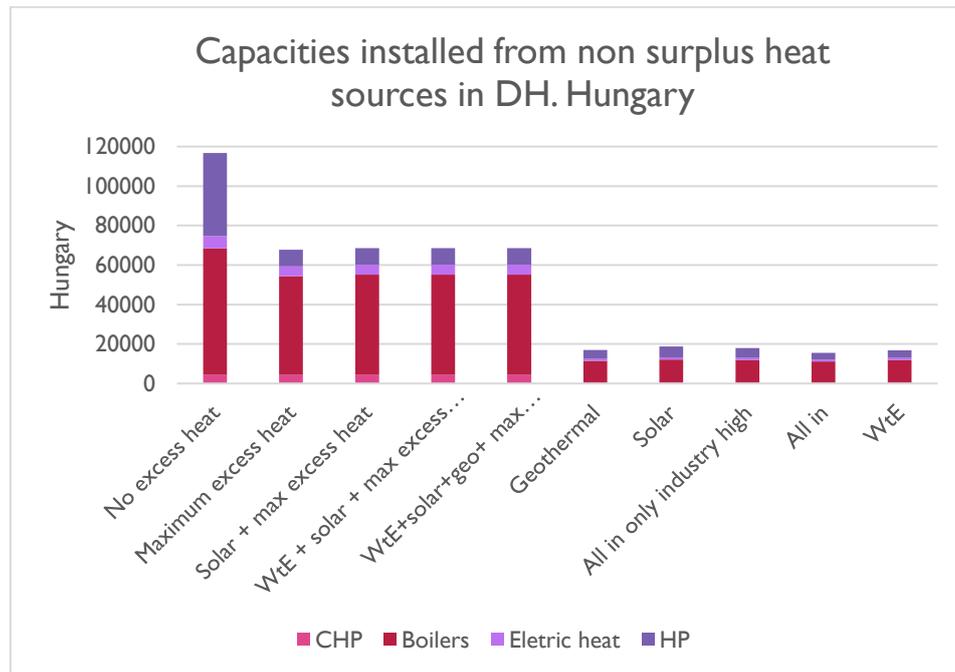

Figure 156: Installed capacities in MW from non-surplus heat sources in district heating in Hungary.

The case of Hungary resembles more to France than to Spain or Germany. In this case there is a lot of geothermal potential, that is why the geothermal scenario is the second with less HP installed (taking out the max availability scenarios). However, as it seems to be a rule now, the scenario heat prioritization with less HP installed is the one with the mix heat sources. Regarding that scenario, there is still some geothermal potential that is not exploited, that must be due to the criteria of choosing the cheapest option first, and it happens the same with the solar potential. As a standout, compared to other countries, the full potential of the waste to energy is not used in all the scenarios.

5.13 Ireland

Table 41: District heating shares specific to Ireland and the corresponding heat sources to the heat demand.

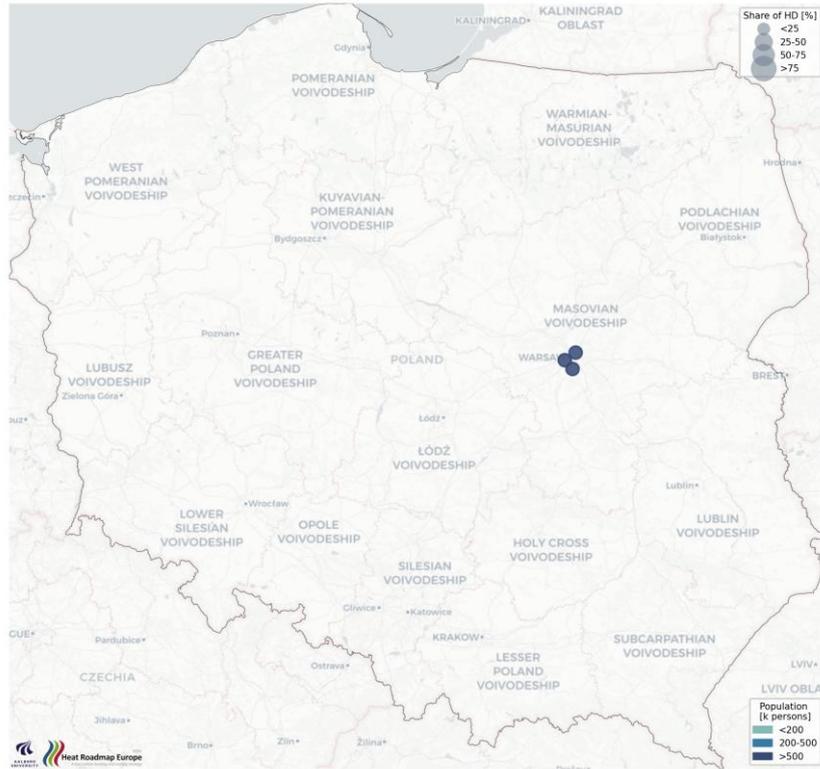

Figure 234: Low temperature from metros for Poland.

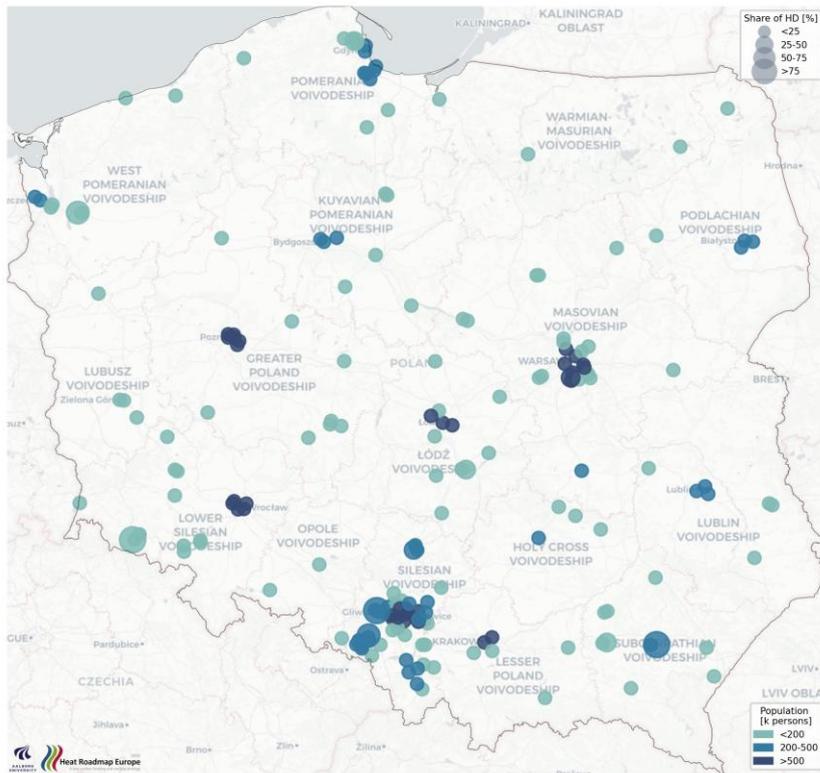

Figure 235: Low temperature from supermarkets for Poland.

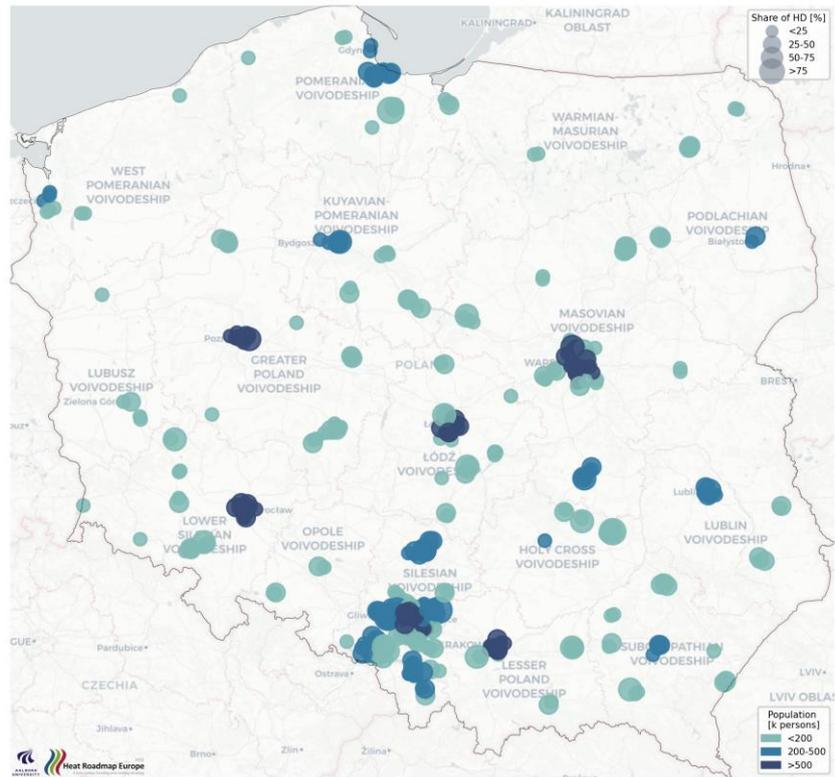

Figure 236: Medium temperature from industry for Poland.

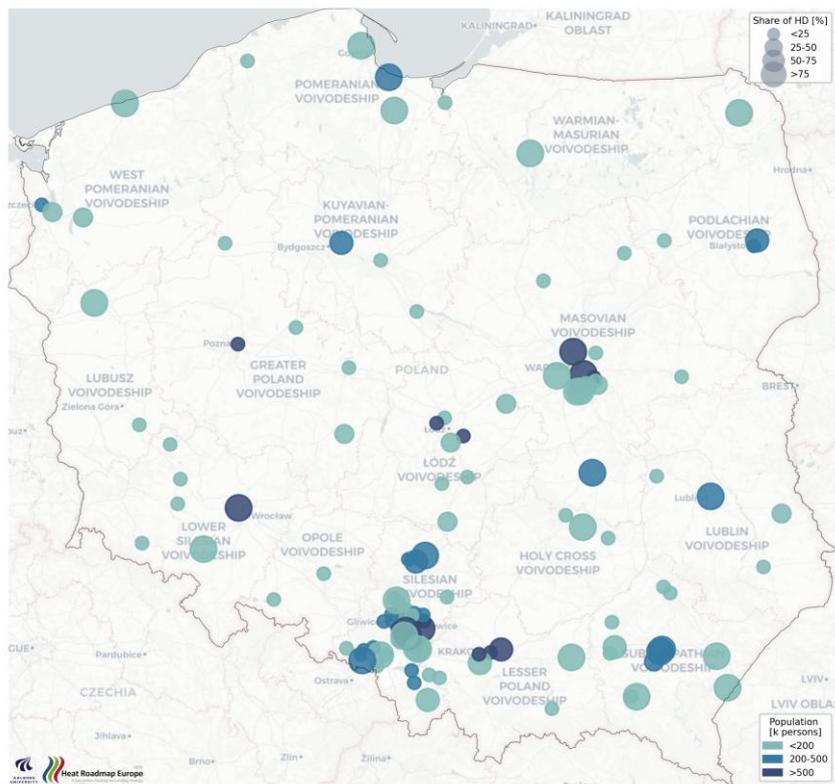

Figure 237: Medium temperature from wastewater treatment for Poland.

For Poland, the recommended district heating share is 47,58% so the one being used from the simulations is 50%.

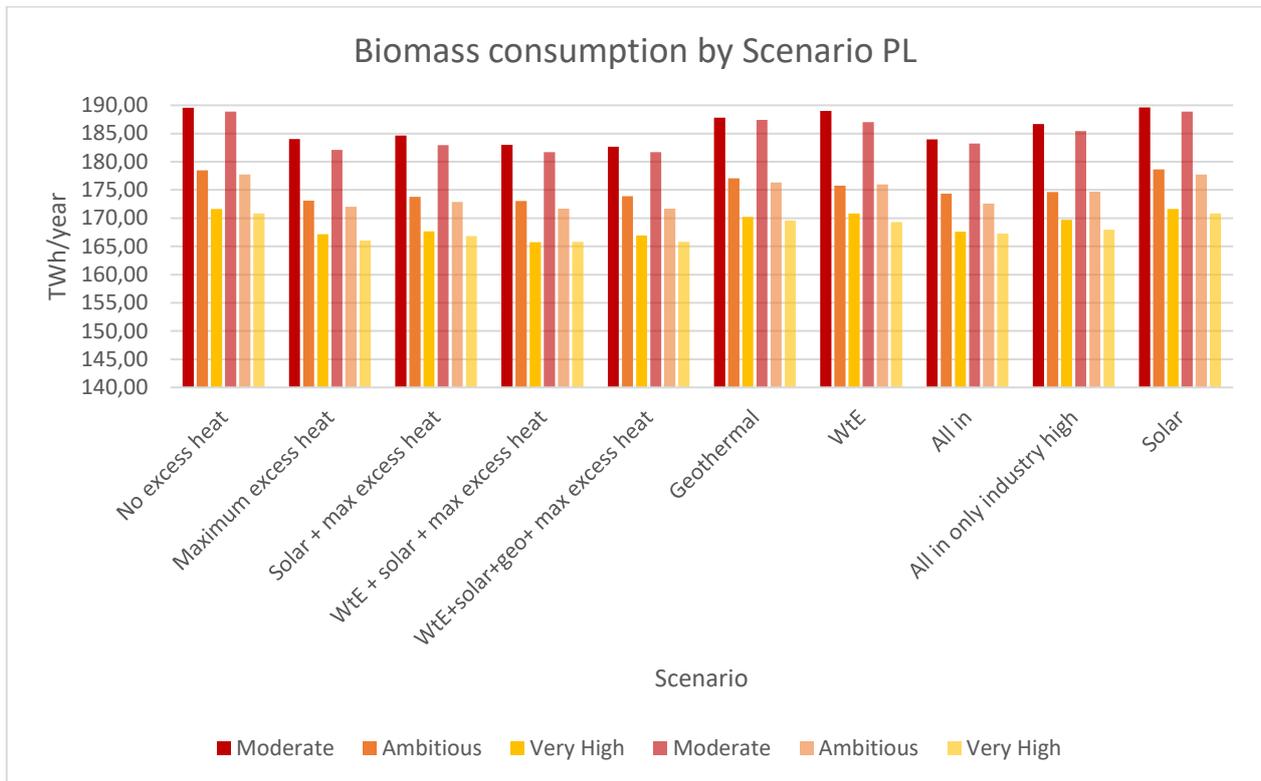

Figure 238: Biomass consumption in TWh/year for different district heating shares and heat source for 3GDH and 4GDH, in the case of Poland.

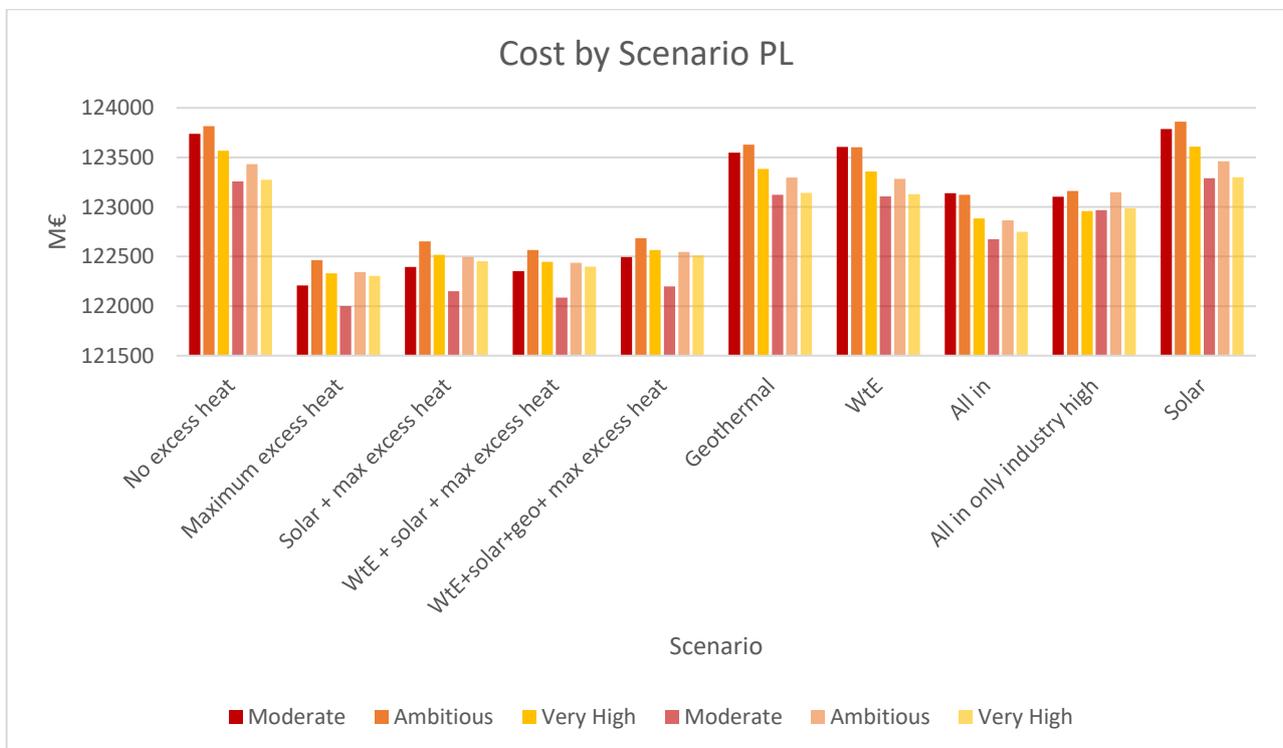

Figure 239: Cost in M€ for each scenario of district heating system at 50% district heating share for both 3GDH and 4GDH, in the case of Poland.

In the case of Poland, the biomass consumption peaks at the Moderate saving in all cases and gets reduced with any upgrade, either a higher saving level or a better generation for the district heating system, being the lowest the Very High savings from the 4th generation, and more specifically the ones from the mix heat prioritization scenario. As just mentioned, all action taken benefit the biomass consumption, however, if a single action should be taken, then a heat demand improvement should be the way to go as it has a greater effect on the biomass consumption, which is less when a step is taken in the demand reduction when compared to the previous one than comparing it to their parallel scenario in the 4th generation district heating.

In the case of Poland, the costs are differently affected compared to the other countries. Here it can be seen that an upgrade to the 4th generation is economically beneficial in any case. However, when comparing the different generations the results differ: in the case of the 3rd generation it is cheaper to go for the very high savings, while in the 4th generation the moderate savings are just a bit cheaper than the very high savings. In any case, the mix heat prioritization is the cheapest option, it is the one that reduces more the cost followed by the All in only industry high case which holds the second most number of heat sources.

Table 49: Biomass consumption in TWh/year for different district heating shares and heat source for 3GDH and 4GDH, in the case of Poland and cost in M€ for each scenario of district heating system at 50% district heating share for both 3GDH and 4GDH, in the case of Poland.

| All in only industry high | | 123.102 | 123.160 | 122.959 | 122.968 | 123.150 | 122.987 |
| Solar | | 123.785 | 123.862 | 123.610 | 123.289 | 123.460 | 123.301 |

For the biomass consumption there is a clear tendency towards lower levels of its use, the higher the heat savings are, also there is a slight upgrade between the 3rd generation and the 4th generation. When quantifying these improvements, they range from 1%, when upgrading the generation of the system, to 10% when upgrading up to Very High savings. However, it is cheaper to upgrade the system than to improve the saving measures, even though the differences are so small that they could be neglected.

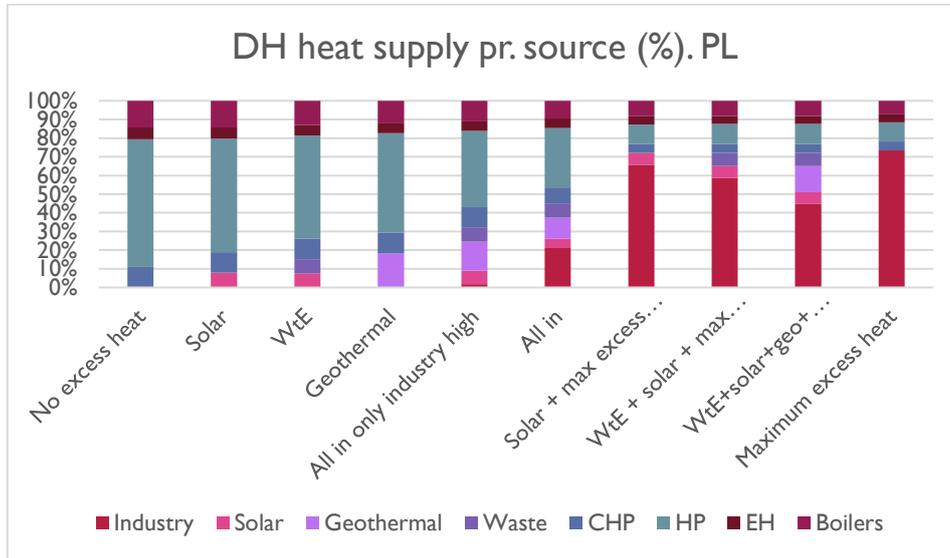

Figure 240: District heating heat supply pr. source in percentage for each scenario in the case of Spain.

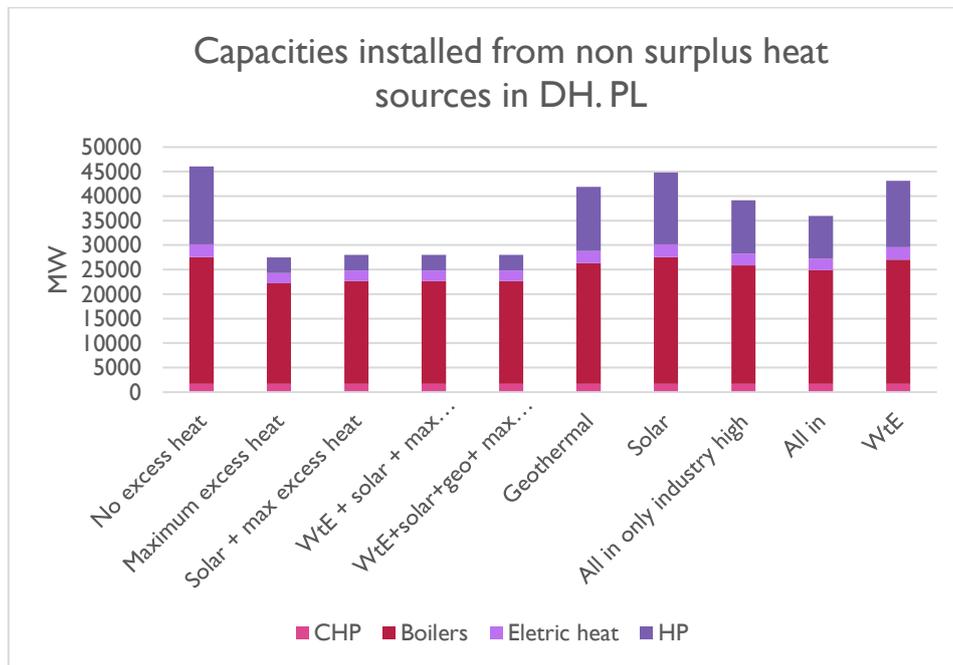

Figure 241: Installed capacities in MW from non surplus heat sources in district heating in Poland.

The HP capacity installed follows the same pattern as the cost reduction. The lowest is the surplus heat mix sources followed by All in only industry high, which is the prioritization with the second most number of surplus heat sources. Also, the highest happens to be the scenario Solar where only solar is used both in HP capacity and cost.

5.21 Portugal

Table 50: District heating shares specific to Portugal and the corresponding heat sources to the heat demand.

| Country | District heating_shares_goal [%] | District heating_shares_closest [%] | Heat demand [TWh] | Waste to energy (TWh) | Industrial Waste High Temp (TWh) | Industrial Waste Medium Temp (TWh) | Industrial Waste Low Temp (TWh) | Waste Water Treatment (TWh) | Waste heat from Supermarkets (TWh) | Waste heat from Metros (TWh) | District heating Solar Thermal (TWh, c=20MW) | District heating Solar Thermal (TWh, c=70MW) | District heating Geothermal (TWh, c=40MW) | District heating Geothermal (TWh, c=70MW) |

Figure 296: Low temperature from supermarkets for Spain.

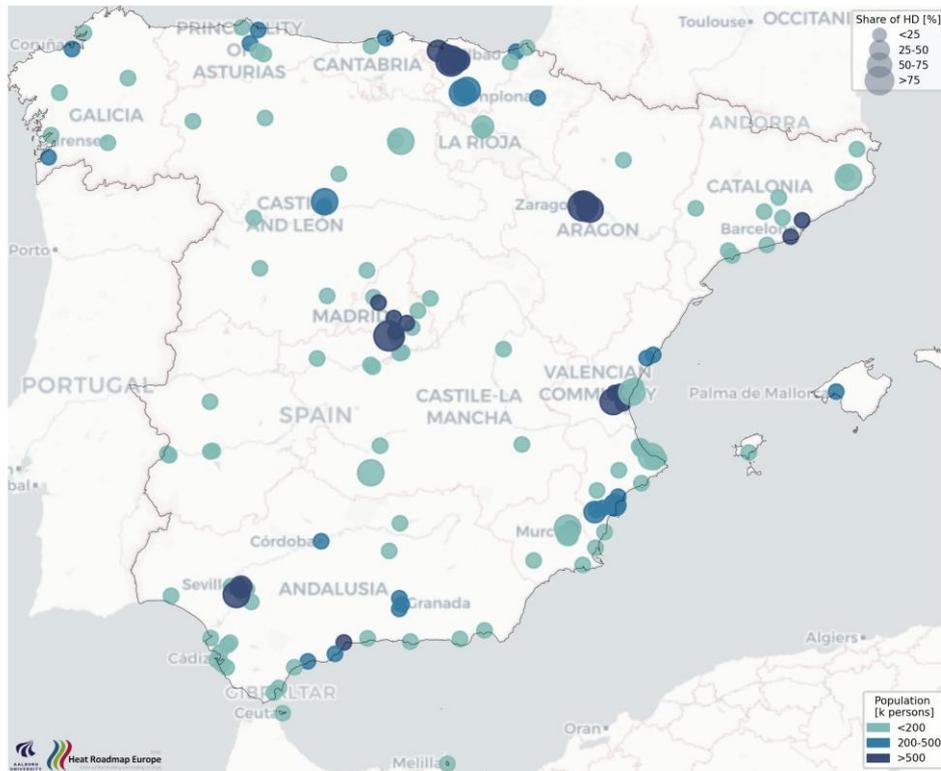

Figure 297: Medium temperature from industry for Spain.

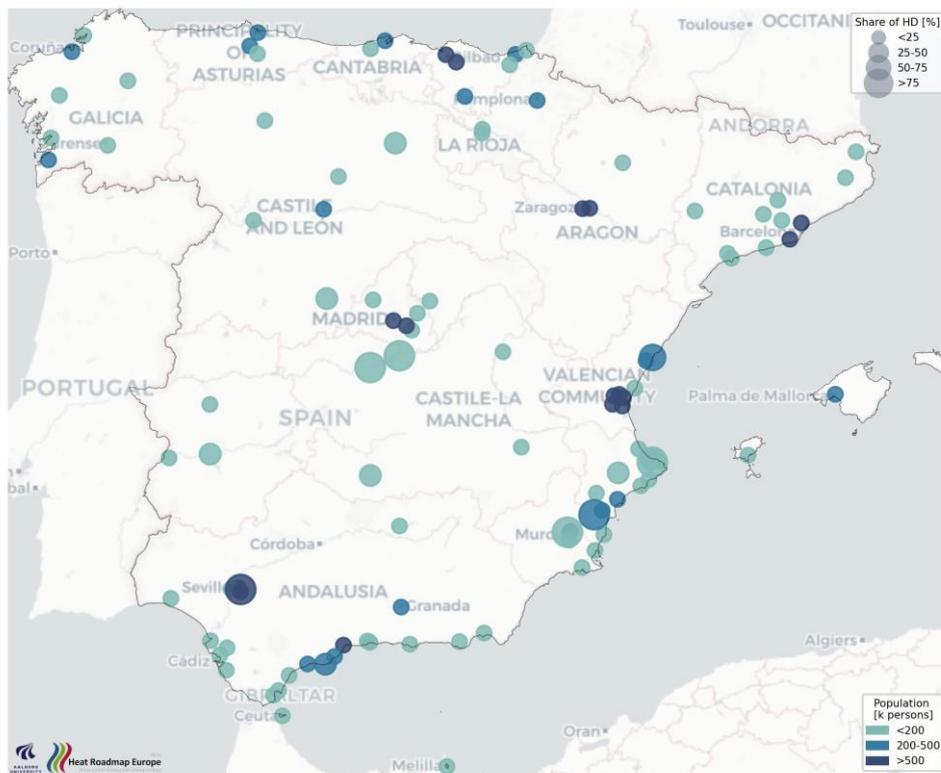

Figure 298: Medium temperature from wastewater treatment for Spain.

For Spain, the recommended District heating share for 2050 is 61,29 so the results from the simulations are taken from the 60% District heating share:

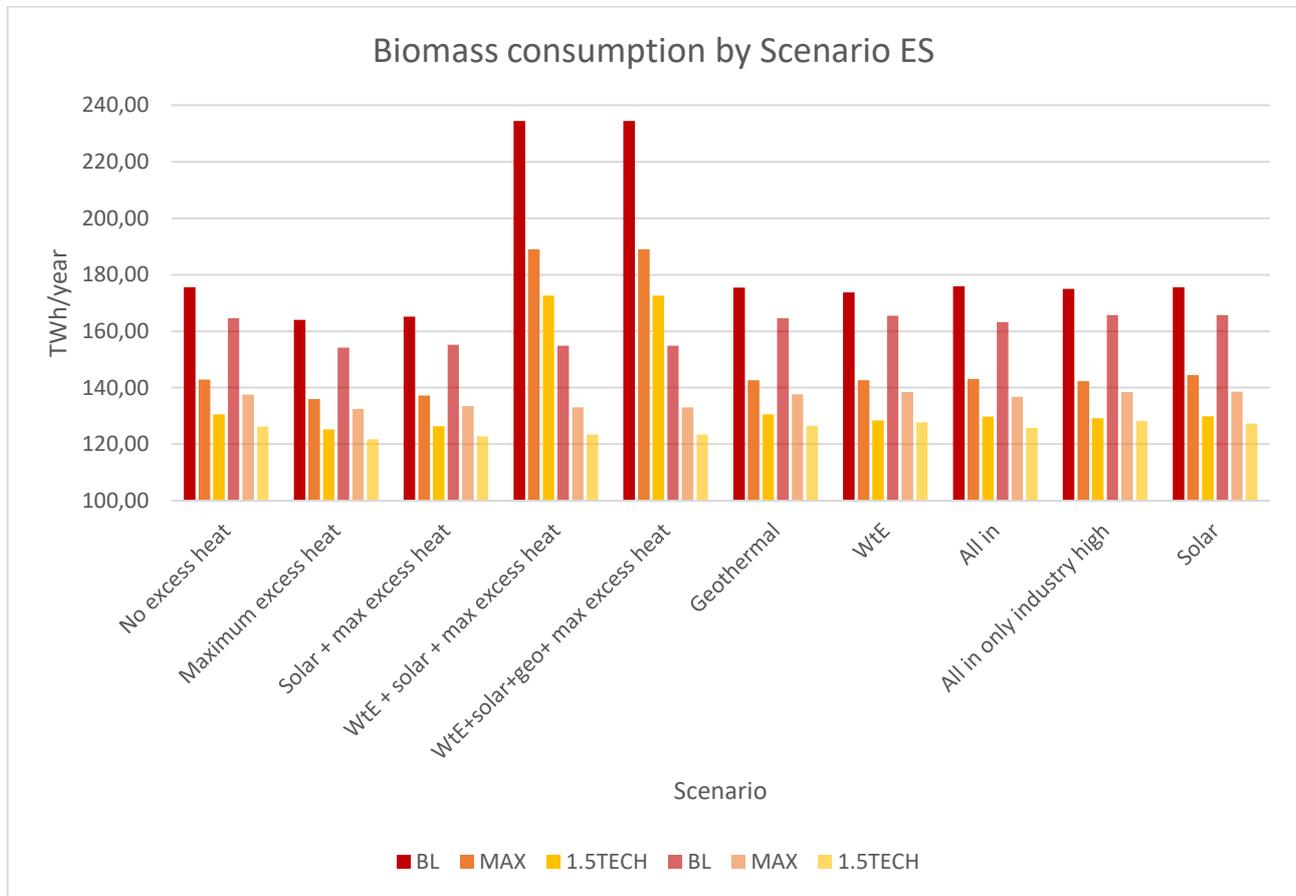

Figure 299: Biomass consumption in TWh/year for different district heating shares and heat for 3GDH and 4GDH, in the case of Spain.

In the case of Spain, for the biomass consumption, there is a pattern for all the scenarios, where the lowest heat saving scenario has the highest biomass consumption and it gets lowered the higher the saving demand is. There is not such big differences between the same saving levels across scenarios comparing with the case of Germany, for instance. The main impact on the biomass consumption is not the heat prioritization, then, it is the saving level and the generation of the grid generation. Spain highlights the importance of having a robust system, both in efficiency in the delivery of heat and in the demand side. Between these two aspects, the system's generation and the saving level, it is more effective to increase the saving level than upgrading the grid generation if only one action should be taken. Of course, this is only based on the biomass consumption, with a multicriteria analysis, the conclusion would be different.

The lowest of all the cases is in the 4th generation and in the scenario with max availability, followed by the scenario of all heat sources and the very high saving levels.

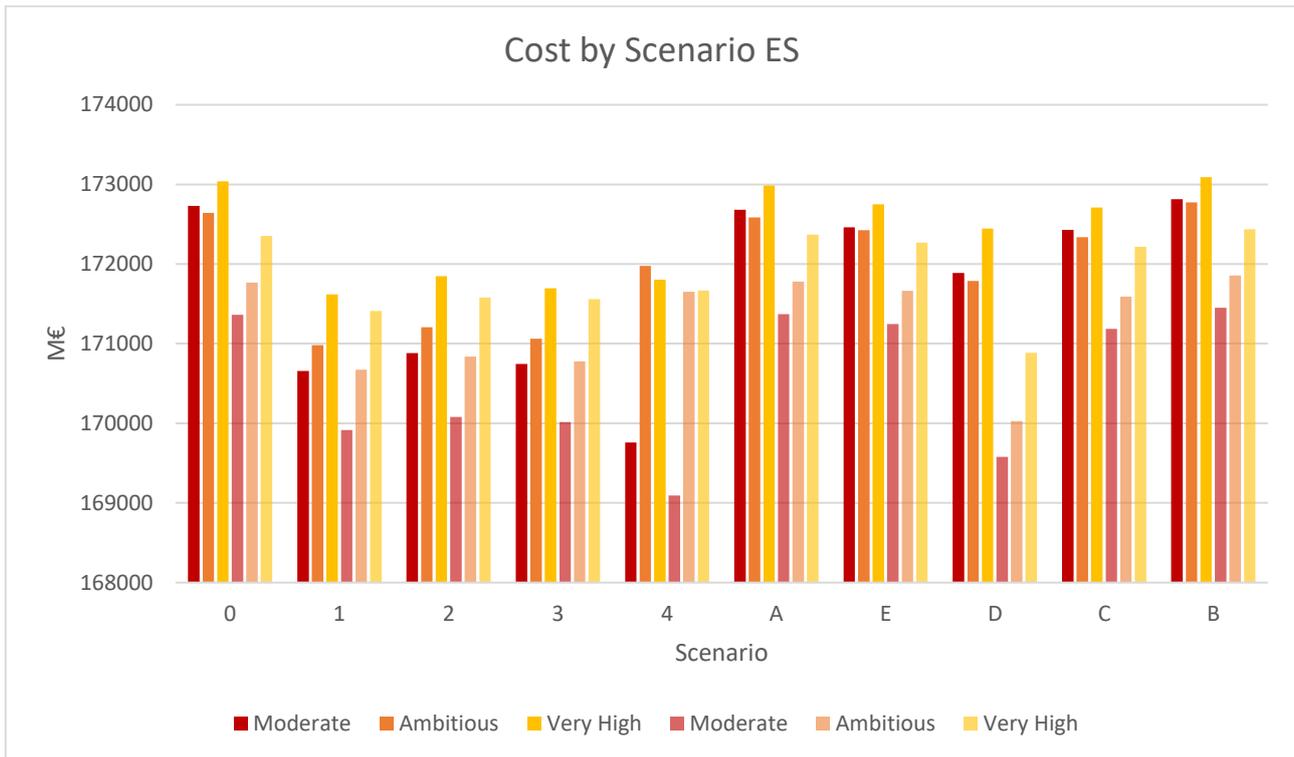

Figure 300: Cost in M€ for each scenario of district heating system at 50% district heating share for both 3GDH and 4GDH, in the case of Spain.

In the case of the cost, in contrast with the biomass consumption, it can be said that upgrading the generation of the system is cheaper than the saving levels for its benefits to the system. For the 3rd generation system, it tends to be that the moderate savings are a bit higher than the ambitious savings and then the very high savings is the highest of them all. On the other hand, there is the 4th generation, where the trend changes to the higher the saving level, the higher the cost for all scenarios.

Table 55: Biomass consumption in TWh/year for different district heating shares and heat for 3GDH and 4GDH, in the case of Spain and cost in M€ for each scenario of district heating system at 50% district heating share for both 3GDH and 4GDH, in the case of Spain.

| 61,29 | 3rd | | | 4th | | |
|------------------------------|----------|-----------|-----------|----------|-----------|-----------|
| Biomass | Moderate | Ambitious | Very High | Moderate | Ambitious | Very High |
| No waste heat | 175,54 | 142,90 | 130,55 | 164,55 | 137,54 | 126,31 |
| Maximum waste heat | 164,02 | 136,01 | 125,22 | 154,19 | 132,43 | 121,78 |

As mentioned before, in the case of the biomass, upgrading the saving measures saves up more than just upgrading the generation of the system. Taking the depart point as the moderate saving for both system's generation, in the case of the 3rd it is saved up to 18% to 26%, whether it is applied ambitious or very high saving measures, respectively. Changing the priorities of the heat supply would only save a 6% as a maximum compared to the scenario of not using any surplus heat.

In the case of the cost, there are not big differences between scenarios, by upgrading the generation it can be saved up to a 1%, so the difference is not as big compared to the base line %wise, however when speaking of small percentage in that type of scales it becomes a large number at the end.

Spain has way less industrial waste heat potential compared to Germany, that leads to a higher HP and boilers installed. The waste to energy is still running at its full potential, showing it is a valuable surplus heat source that can be integrated in any type of system.

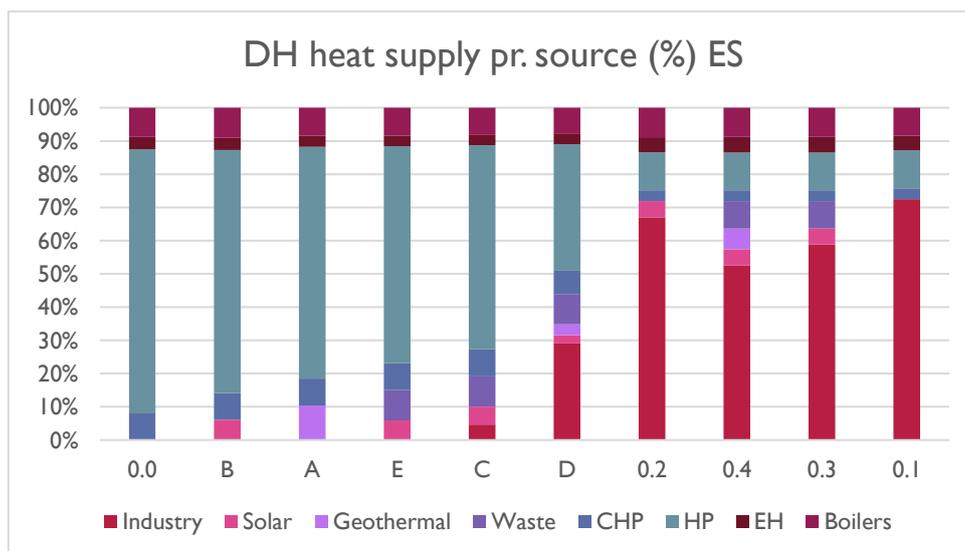

Figure 301: District heating heat supply pr. source in percentage for each scenario in the case of Spain.

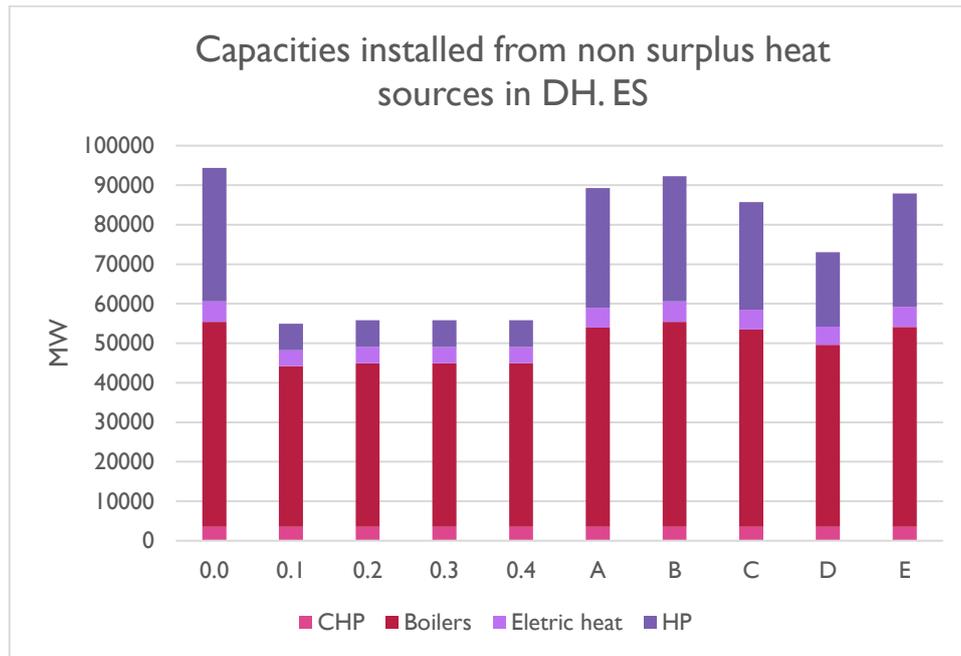

Figure 302: Installed capacities in MW from non surplus heat sources in district heating in Spain.

As it can be seen in this graph, the scenarios with less surplus heat potentials, have more installed capacity from non-waste heat sources, as it is logical.

5.26 Sweden

6 Spatial modelling

This appendix describes the methods used to map the heat demand in residential and service buildings in Europe, the distribution of district heating areas based on the above, and the heat potential from waste heat sources. The models, originally developed in the Heat Roadmap Europe project (Persson et al., 2017), were improved in the sEEnergies project (Möller et al., 2022) and are now being further improved with a focus on an open-access development approach. The models are developed in Python using open-source libraries and are made openly through github. Each of the models is described in detail in the following subsections, along with the required data and data sources.

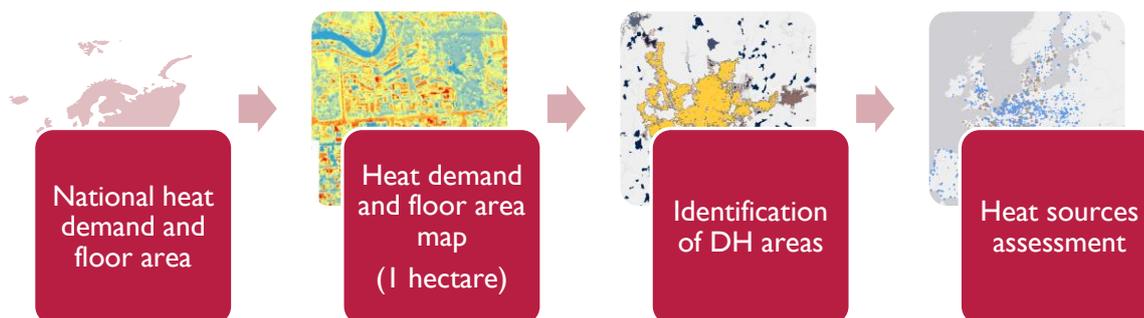

Figure 325 Workflow of GIS analysis including heat mapping, mapping district heating areas and heat sources.

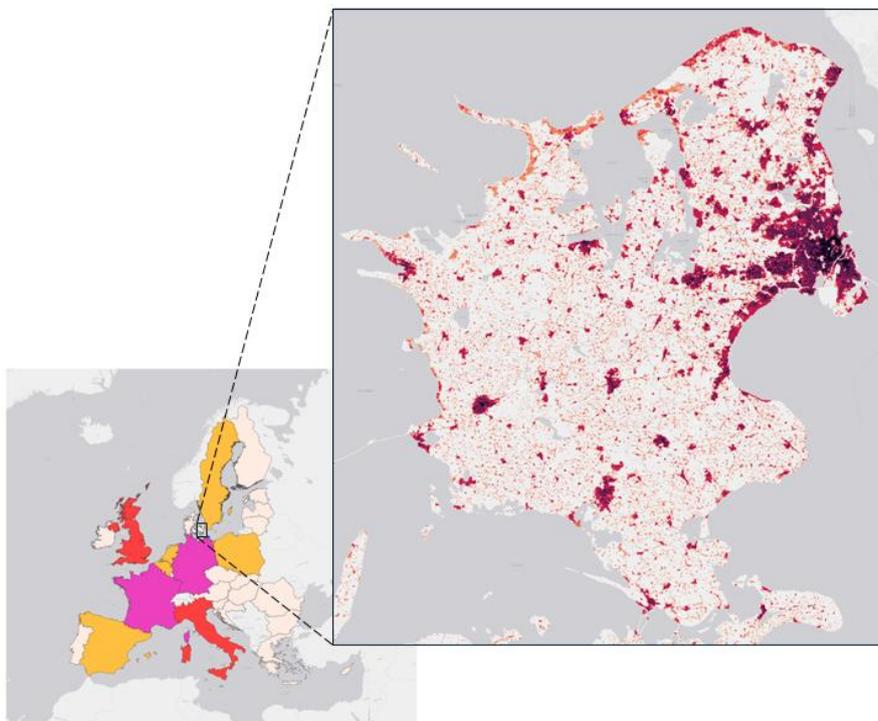

Figure 326 Disaggregation of heat demands.

6.1 Heat demands

The present heat demand model estimates detailed representations of current heat demands. It takes into account the building age classes (i.e. the proportion of buildings in the area built before 1975, between 1975 and 1990, between 1990 and 2015 and after) and therefore allows for the inclusion of energy efficiency potential by construction period. The method is based on the downscaling of the national counts of heat demands and floor area to the 1 ha grid level using the methods of the sEEnergies project (Möller et al., 2022). The code is openly available at <https://github.com/mgeorgati/heatingatlas>. Two scenarios are examined in this case, namely the baseline scenario and the frozen efficiency, where no efficiency potentials are assumed. The data necessary for the estimation of the heat demands at European level is presented in Table 1.

Specifically, the national counts of heat demand and floor area (presented in Figure 327, Figure 328 and Figure 329) are downscaled to the finer resolution of 1 hectare for each building sector and construction period. Then the heat demand per square meter of floor area is calculated for each sector and construction period. This involves integrating additional data representing the built-up area factor (GHS_BUILT) – a dataset produced by the Hotmaps project (Mueller, 2019) based on the Global Human Settlement Layer (GHSL) by the Joint Research Centre (JRC (EC), 2022).

Table 59 Overview of the data used in the spatial model for energy demands.

| Data | Abbreviation | Spatial resolution | Source | Description |
|------------------------------|--------------|--------------------|--|--|
| Heat demand | HD | Country | HRE (Persson et al., 2017) | Divided by buildings sector and construction period |
| Floor area | FA | Country | HRE (Persson et al., 2017) | Divided by buildings sector and construction period |
| Floor area | FA100 | 100 x 100m | sEEnergies/HRE (Persson et al., 2017) | Guide for disaggregating national FA for the estimation of plot ratios |
| Building shares by age class | GHS_BUILT | 100 x 100m | Hotmaps (Mueller, 2019)/JRC (JRC (EC), 2022) | Contains the estimated share of gross floor area per construction period |
| Heating index | NHI | NUTS3 | sEEnergies/HRE (Persson et al., 2017) — refined to complete spatial coverage | Based on the European Heating |
| Corine Land Cover | CLC | 100 x 100m | Copernicus (CORINE Land Cover — Copernicus Land Monitoring Service., 2021) | European land-use and land-cover classification dataset |
| GHSL population distribution | GHS POP | 100 x 100m | (JRC (EC), 2022) | Gridded population estimates |
| EUROPOPI9 | EUROPOPI9 | NUTS3 | (Eurostat, 2022) | EU regional population forecasts |

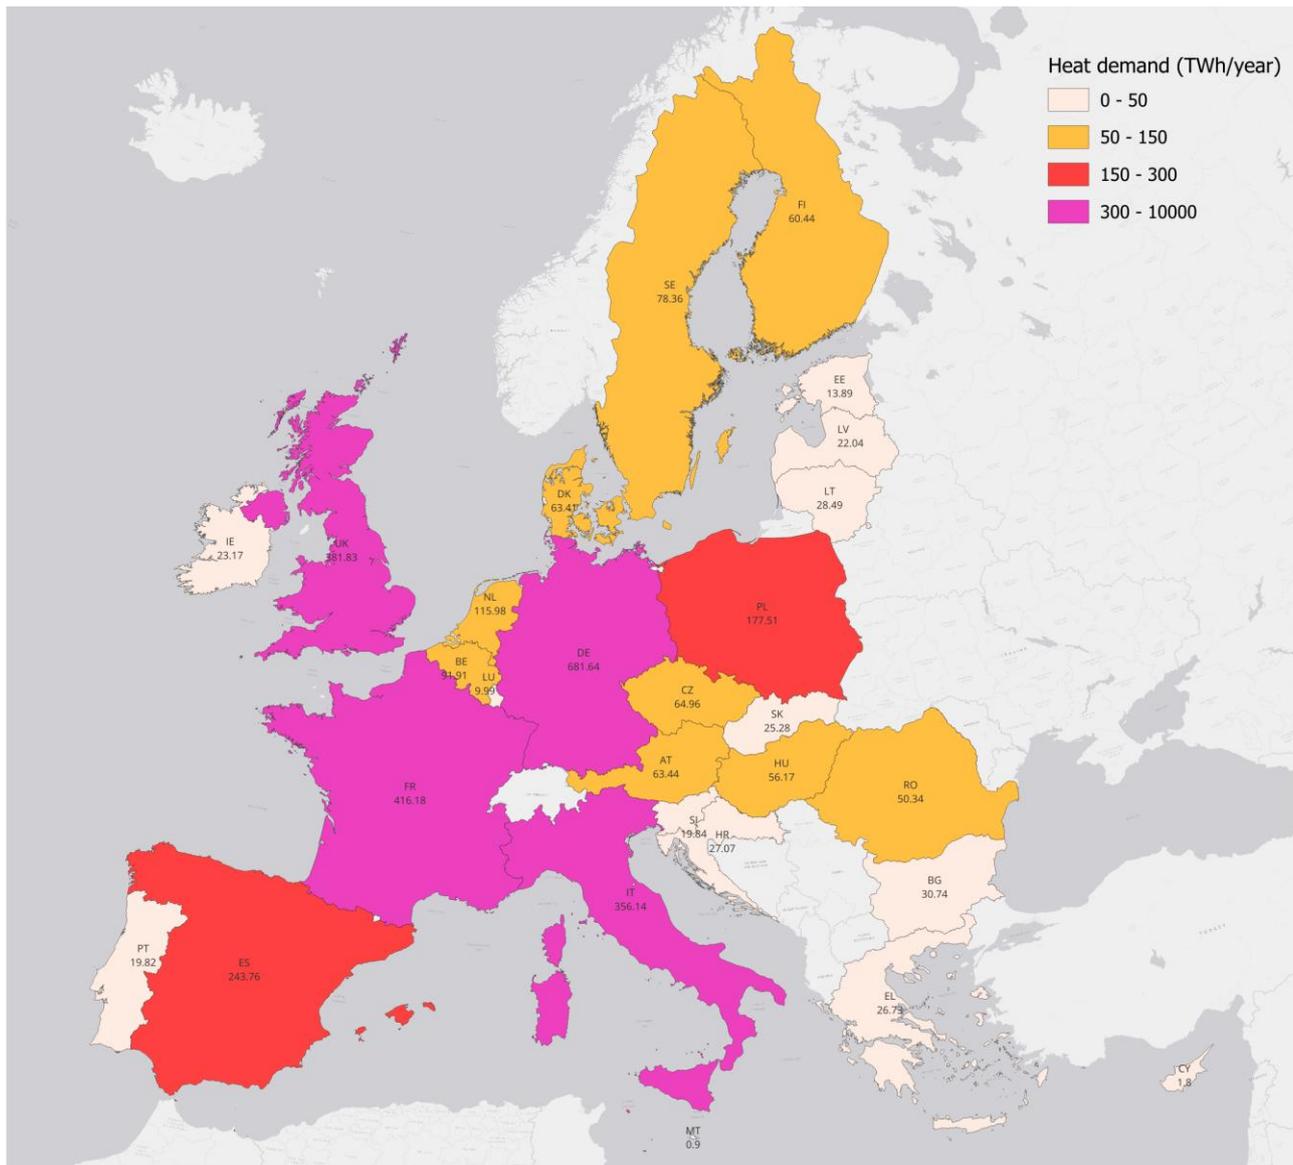

Figure 327 Estimated national heat demands in EU27 + United Kingdom in 2015.

The outcome is a set of raster layers indicating the heating demand per square meter or each sector and construction period. In the following step, the methodology refines the heat demand estimates by integrating factors, such as the national heat demand, floor area ratios and heating indices at a regional level. For the estimation of the floor area ratios, the sEnergies floor area local estimates were used as guides for the production of an enhanced layer based on dasymetric mapping. The total heat demand for each grid cell is then calculated by summing the adjusted heat demand values across all sectors. Figure 330 and Figure 331 illustrate the heat demand densities in 2015 in Copenhagen, Denmark; Madrid, Spain; and Hamburg, Germany.

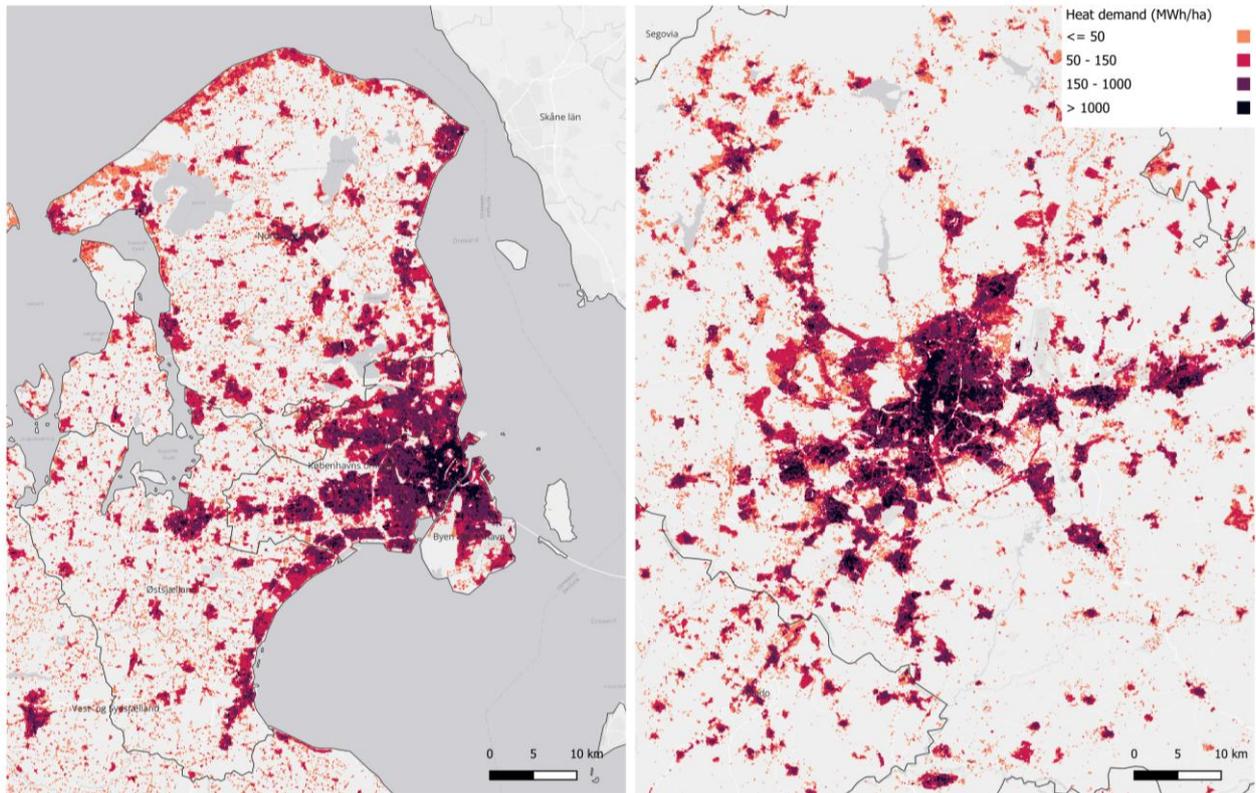

Figure 330 Heat demand in Zeeland, Denmark (left) and Madrid, Spain (right).

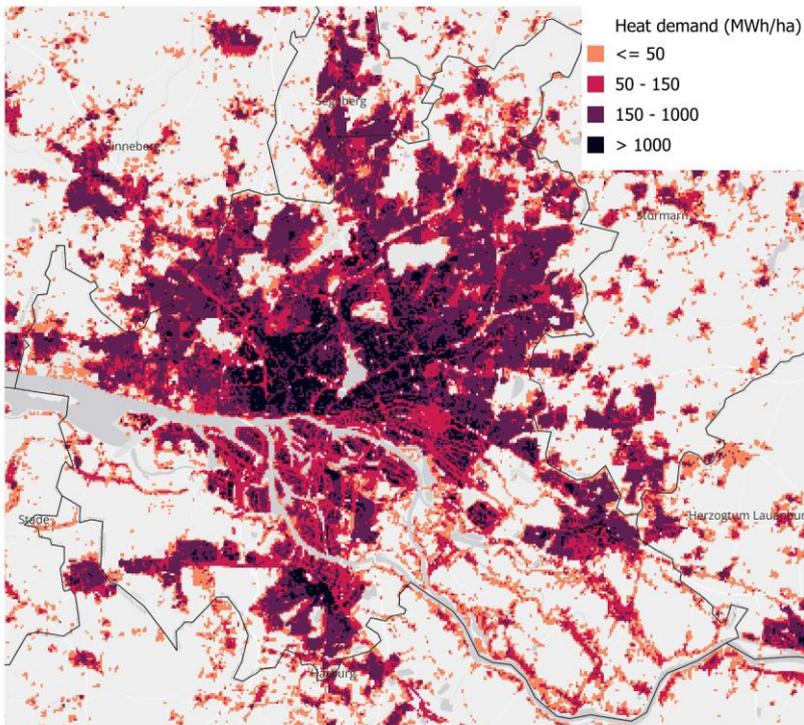

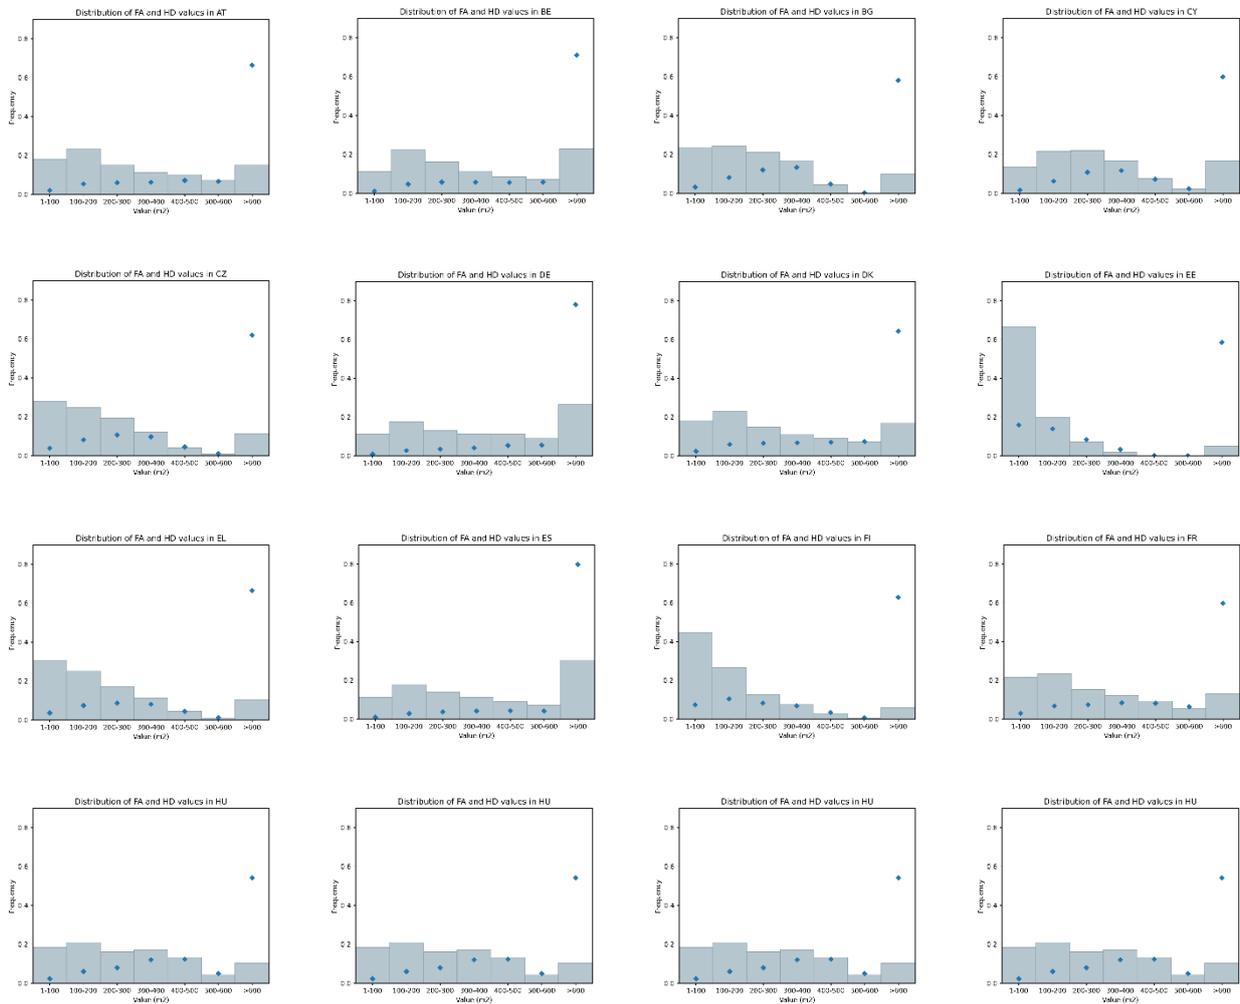

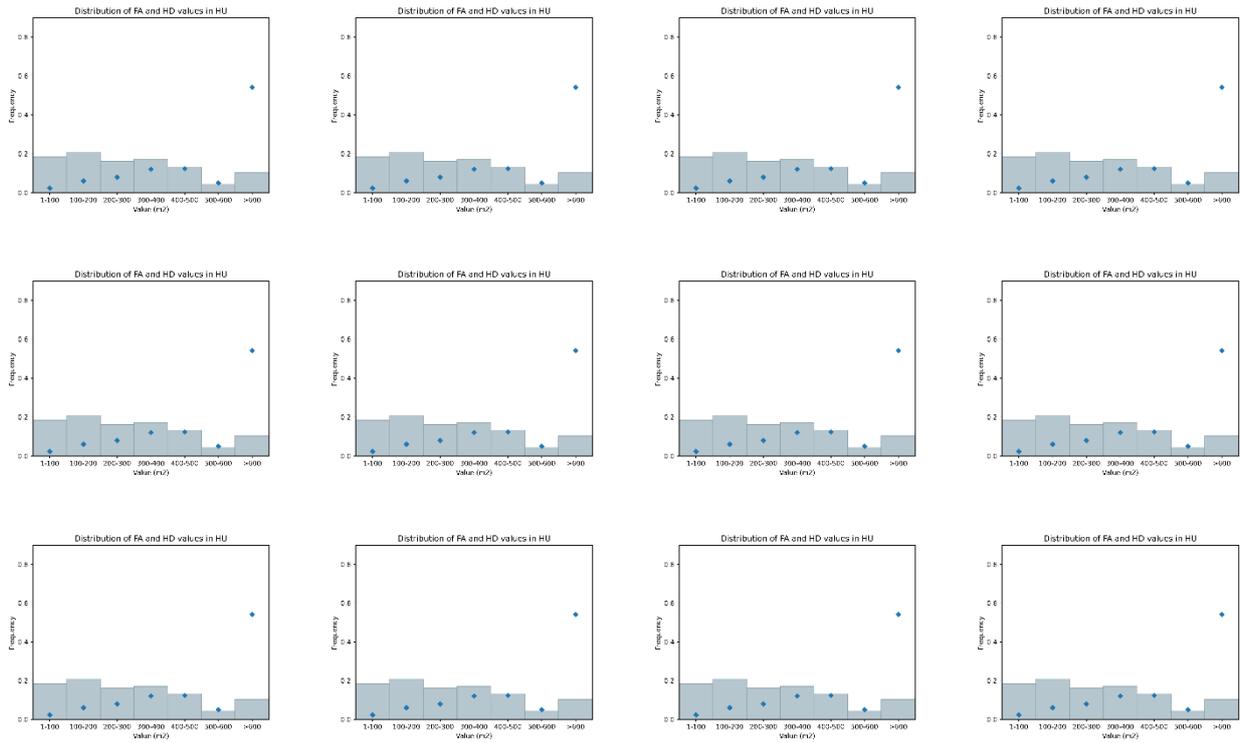

Figure 331 Heat demand in Hamburg, Germany.

6.2 District heating modelling

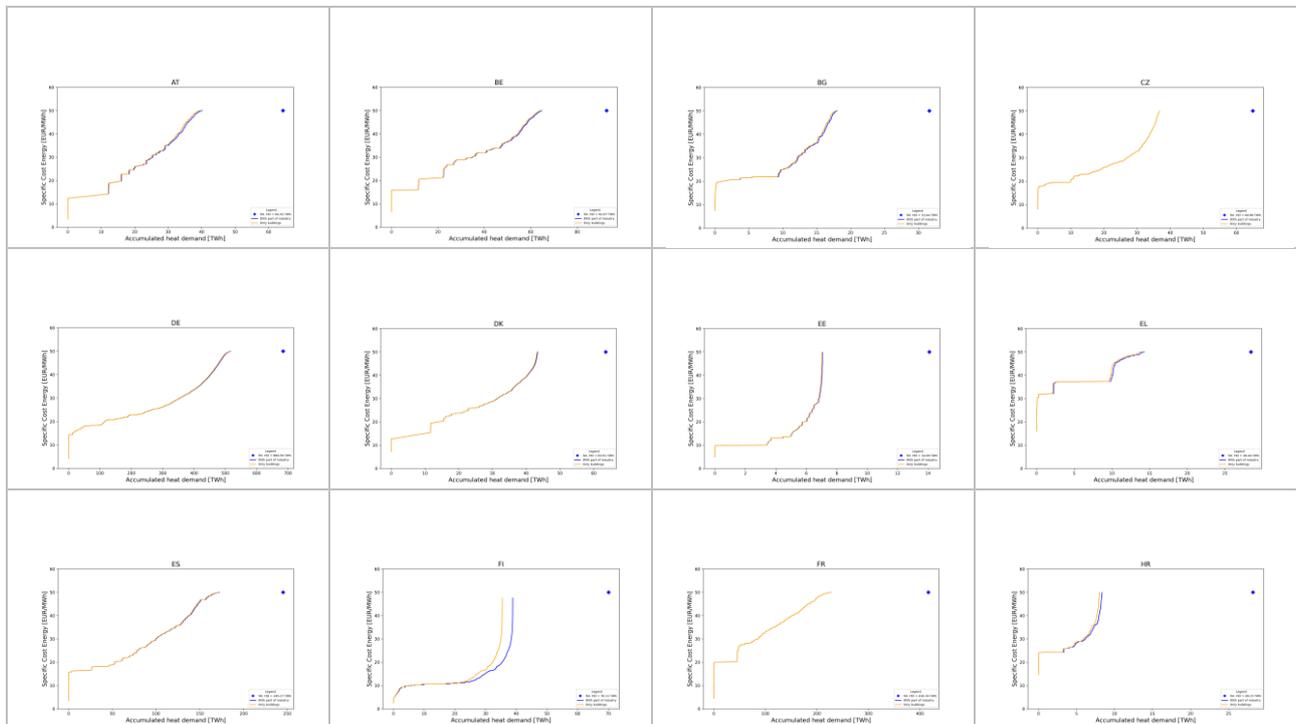

The approach for estimating district heating potential is based on the methodology described in (Fallahnejad et al., 2024) and calculated using the module available in (Fallahnejad, 2022). The module requires two grid layers representing the distribution of heat demand and floor area for the year under consideration to calculate the district heating potential. The module can run the calculation by using a heat demand in the beginning and another heat demand at the end of the year, representing e.g. implementing energy efficiency measures in buildings and lowering the demand over time. Since the energy efficiency in buildings is modeled in another model, this part is not considered in the district heating assessment module. Thus, the start- and end-year input data are based on the same heat density and floor area map for each country. Due to the spatial continuity of heat demand densities in several countries, such as the Netherlands, which resulted in the calculation of continuously connected district heating systems, we examined the distribution of district heating by FA and decided to exclude grid cells with a floor area of less than 400 m² from the district heating potential analysis.

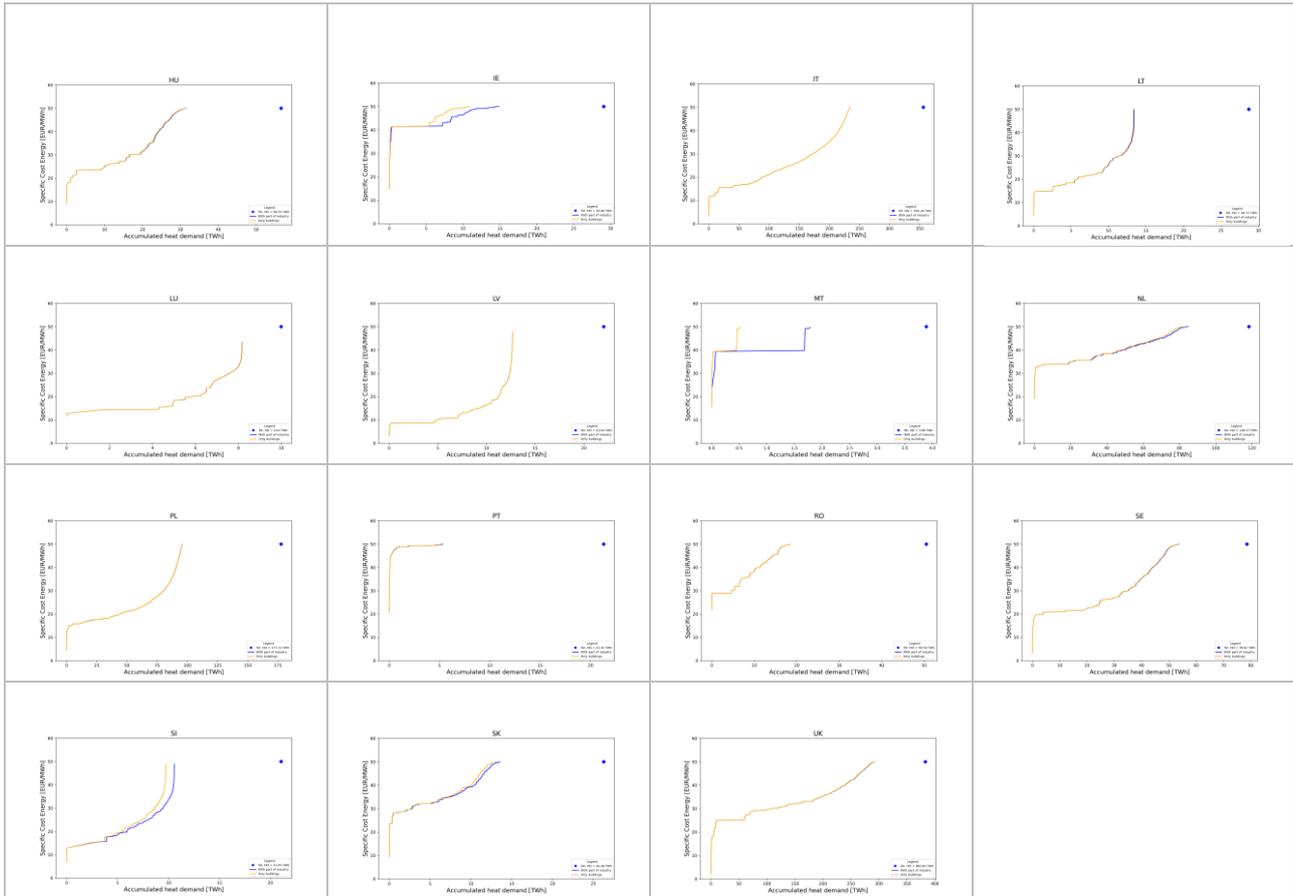

Further the model utilizes the accumulated heat demand by specific cost energy for industry, residential and service building, as shown on graphs in Table 60 Table 60.

Table 60: Accumulated heat demand by specific cost energy for industry, residential and service building.

The model requires district heating pipe costs as input; in the model, these are simplified to two factors c_1 [€/m] and c_2 [€/m²]. In practice, the costs vary between countries and cities, but to make the costs consistent with the energy system models, the district heating assessment is done with the same costs for all countries. The costs used for c_1 and c_2 are 664 €/m and 2610 €/m², respectively, and are based on the updated German costs from (Sánchez-García et al., 2022). The costs in €/m for various countries are illustrated in Figure 332, the dotted red line for Germany 2020 is the one used in this report. In the sEEnergies report (Sánchez-García et al., 2022), more cost curves can also be found to give a more detailed look into the costs.

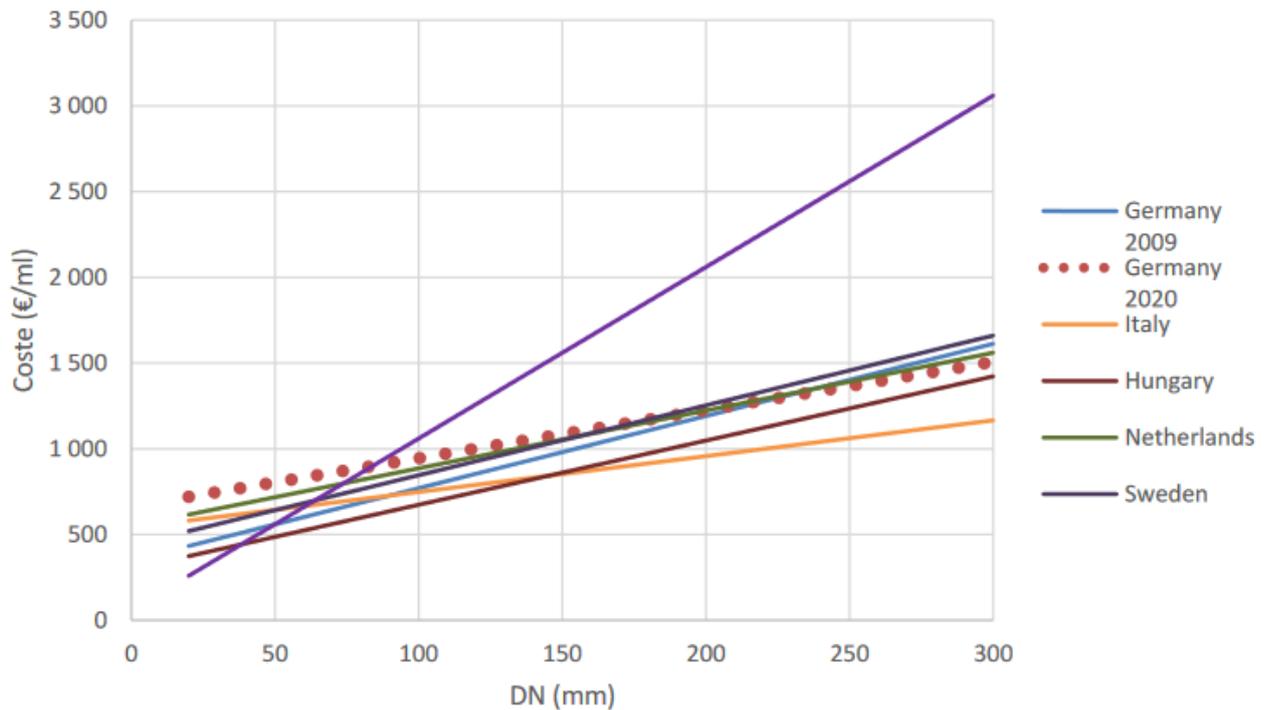

Figure 332 District heating costs in different countries. In this report the dotted line from Germany is used. The figure is taken from (Sánchez-García et al., 2022).

The aim of the analysis is to be able to identify potential district heating areas and create district heating cost curves per country to be used in the energy system analysis; in this aspect, we want to find the maximum district heating potential and then afterwards decide on how much district heating is feasible based on the energy system analysis. Therefore, in the mapping of district heating potentials, we only remove areas that would most likely never be relevant for district heating, while we keep areas that could have a potential if e.g. there are a lot of cheap heat sources.

The model identifies potential district heating areas based on two conditions: the average distribution grid costs in the area are below a predefined cost ceiling per country, and the annual heat demand in the area is above a predefined threshold. In this case, a cost ceiling of 50 €/MWh and an annual heat demand of 1 GWh to ensure that even small areas can be considered in the modelling. The model can also include different district heating connection rates, e.g., for a new district heating area starting at 0% in the beginning year and going to 80% connection rate in the end year. In this analysis, a connection rate of 88% at the start and 90% at the end of the year is assumed for all countries. This is done as the analysis aims to identify the technical potential of district heating, and using a lower connection rate would not identify the technical district heating potential.

In Figure 333 and Figure 334 the three different examples of identified potential district heating areas are shown.

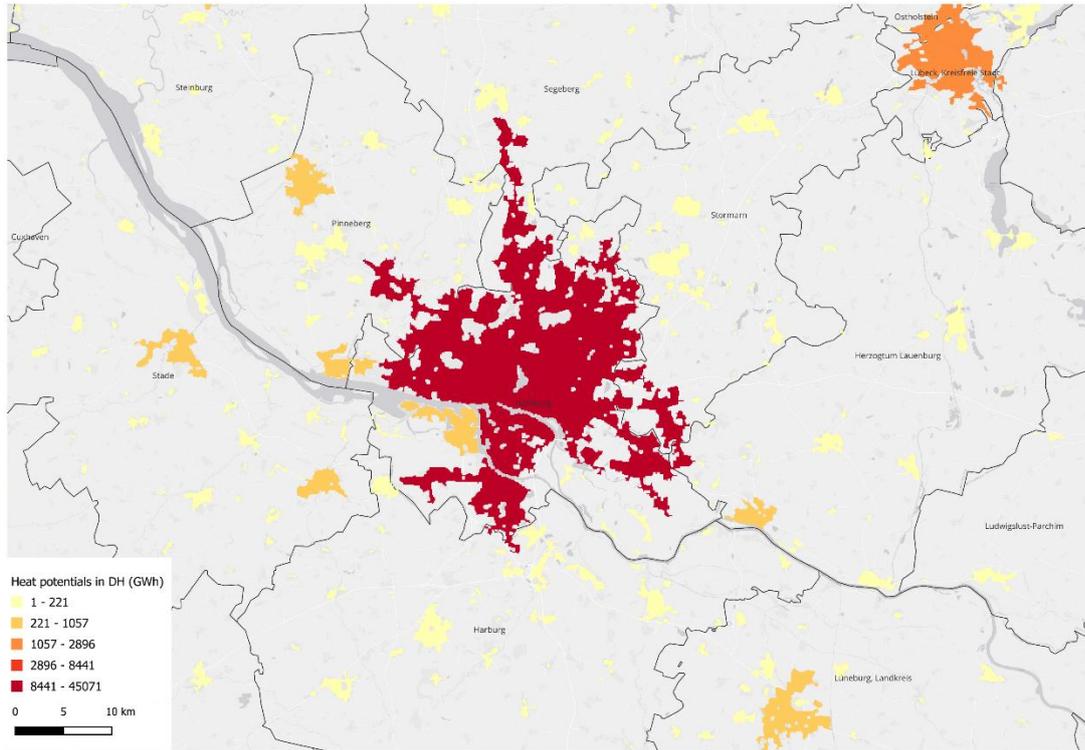

Figure 333 Identified district heating areas and heat potentials in Hamburg, Germany.

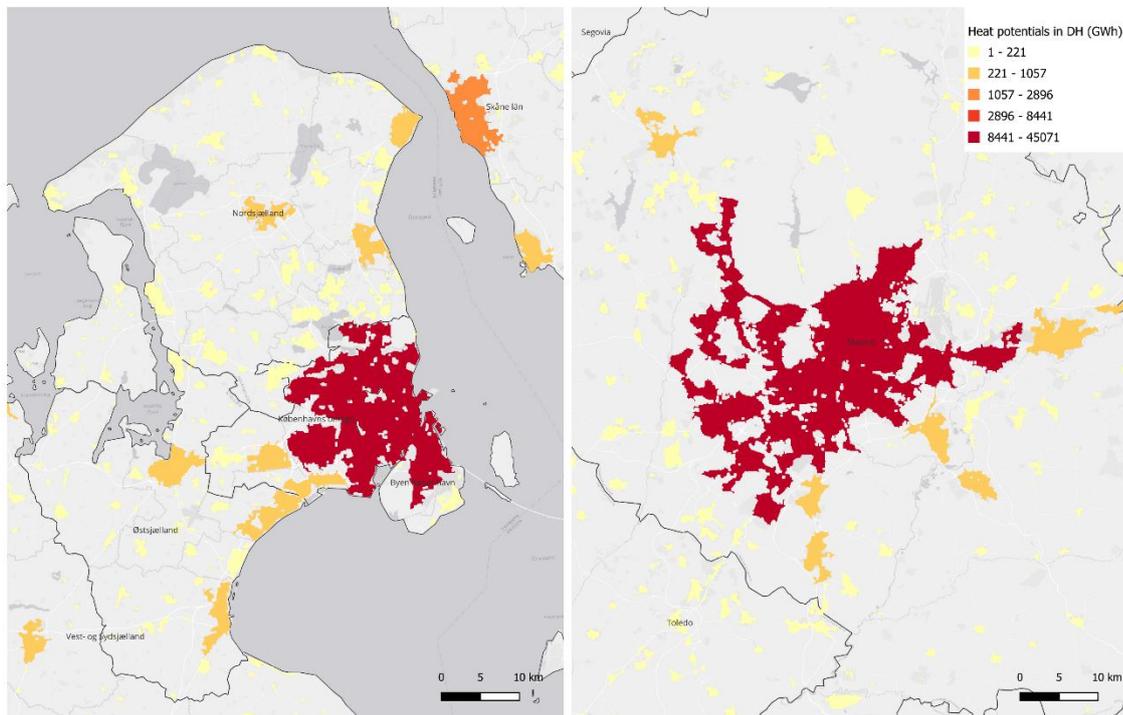

Figure 334 Identified district heating areas and heat potentials in Zealand, Denmark (left) and Madrid, Spain (right).

The original district heating model was not developed to examine the difference between 3rd and 4th-generation district heating or include heat losses. Therefore, we added these calculations to the model, so it now produces investment cost estimates and heat losses for 3rd and 4th-generation district heating. Heat loss for 3rd generation district heating was calculated using the linear heat density, calculated as the annual heat

demand [GWh] divided by the district heating network length of both distribution and service pipes. The linear heat density is shown in Figure 9.

The formula from (Nussbaumer & Thalmann, 2014) was used to estimate the annual heat loss in 3rd generation district heating:

$$\text{Annual heat distribution losses in [\%/a]} = 17 \cdot (\text{linear heat density})^{-0.5}$$

As there are also other losses than the distribution losses a 5% heat loss for district heating substations and heat exchangers was added to the heat distribution loss.

Figure 9 illustrates the heat loss as a function of linear heat density, including the 5% heat loss.

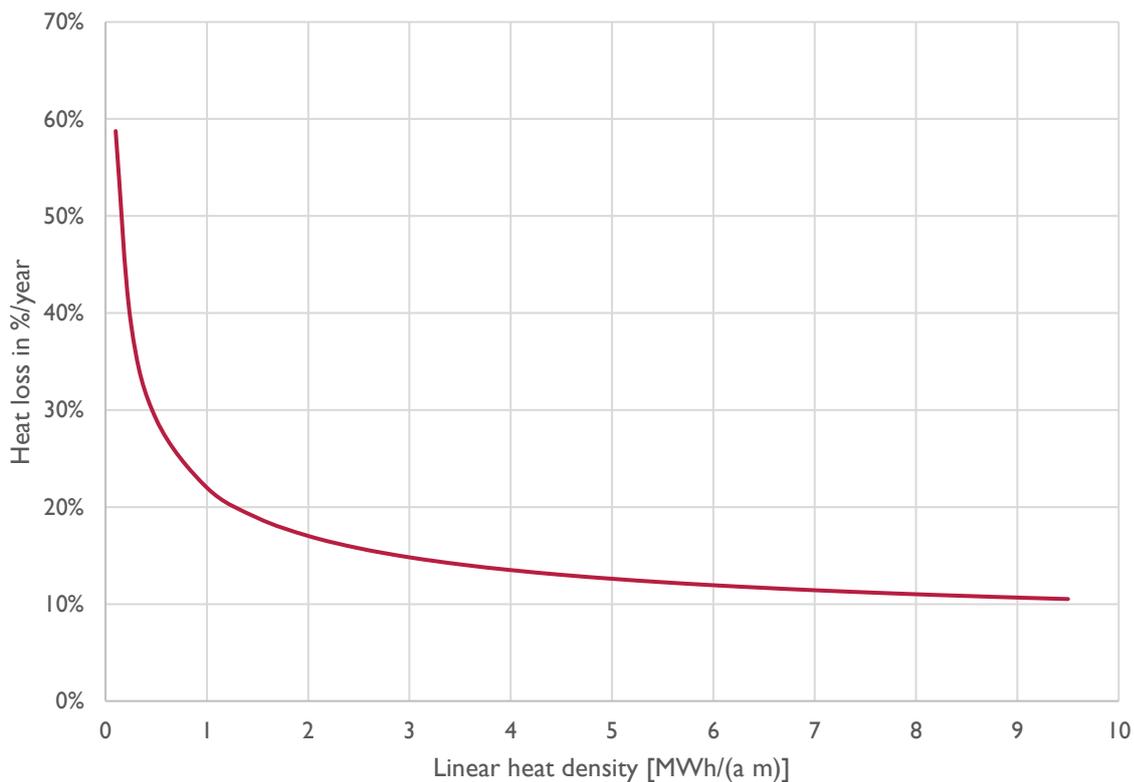

Figure 335 Heat loss as a function of linear heat density

The calculations for 4th generation district heating were done in a simplified way, based on the results from Heat Plan Denmark 2021 (Mathiesen, B. V. et al., 2021), where the 4th generation district heating heat loss was on average 3.1% lower than 3rd generation and the investment cost was on average 2.41% higher. The same averages have been applied in this model.

The output of the district heating model summarizes the heat potentials, grid investment costs and heat losses in each district heating area both for 3rd and 4th generation district heating.

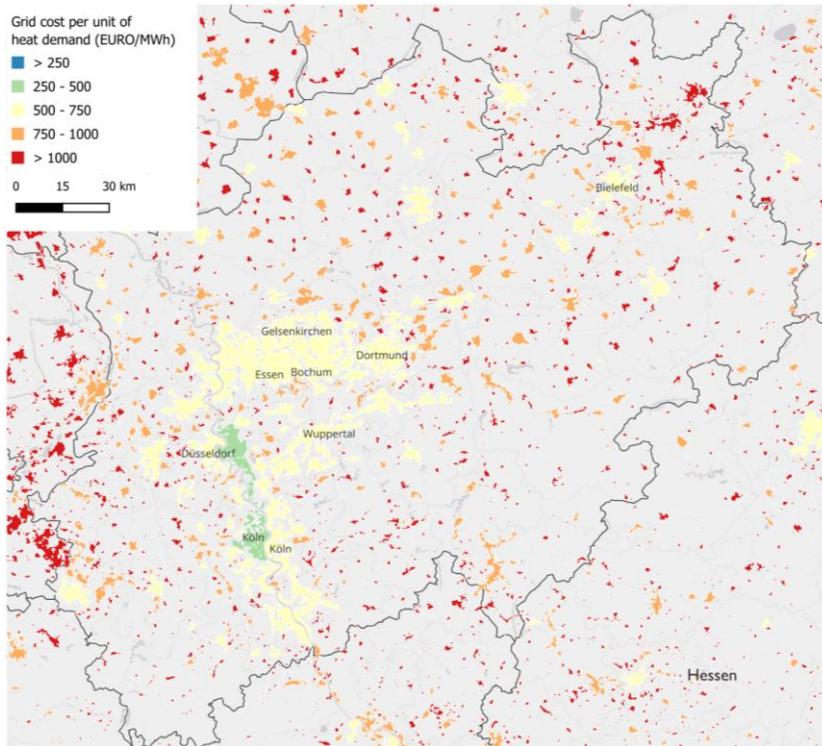

Figure 336 Mapping the grid cost per unit of heat demand in Nordrhein-Westfalen, Germany.

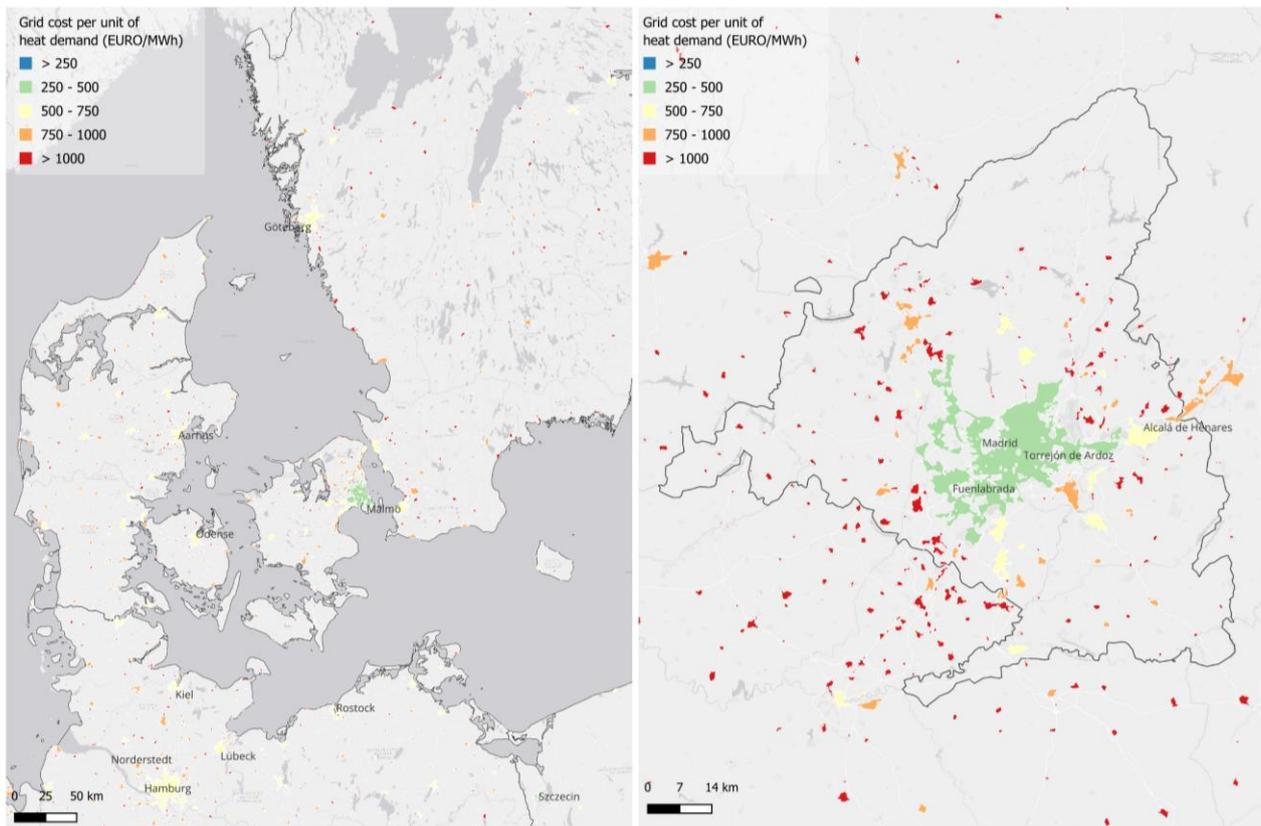

Figure 337 Grid cost per unit of heat demand in district heating systems in Denmark, southern Sweden and northern Germany (left) and Madrid, Spain (right).

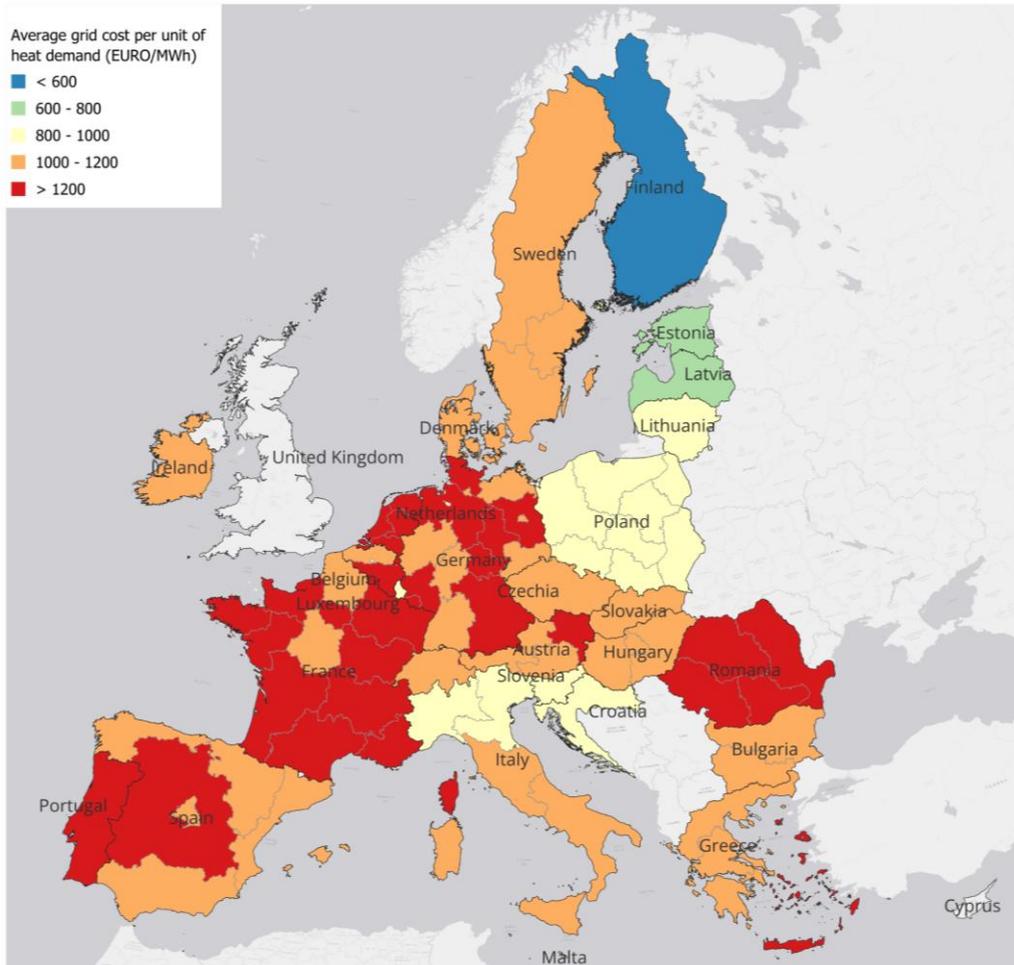

Figure 338 Grid cost per unit of heat demand aggregated at NUTS2 level as the mean of the grid cost per unit of heat demand in the district heating systems in the area.

Besides estimating the heat demand for the residential and service sectors, the district heating areas were further processed these results to include the heat demand for the industry in the corresponding district heating areas. We utilised the areas associated with industrial uses from the CORINE land cover (code I21) and distributed the national industrial heat demand (from EnergyPLAN) proportionally to the areas overlapping with the district heating areas. Section 3 shows the accumulated heat potentials in the district heating areas together with the specific energy costs for the residential and service buildings and for the industrial uses. The requirements for the formation of a district heating system are not met for Cyprus, so the district heating model does not produce the corresponding output areas.

6.3 Insights into the data of the district heating areas

Having modeled and mapped the potential district heating areas offers advantages in a comprehensive analysis of a gradual energy transition. However, these areas vary significantly in their geographic distribution, size, and capacity. For this reason, this section focuses on a holistic statistical presentation of the modeled areas and their characteristics, while section 3 takes a step further to assess the most suitable areas to prioritize based on their lower investment costs and their higher heat demand. This essentially means that the present section shows the maximum mapped and modeled potentials, while the results in the following section have been obtained after a prioritization analysis of the most suitable areas at the EU-27 level.

Section 3.1-3.3 present national summary statistics on the modeled areas and their corresponding attributes, such as heat demand (including the industrial demand), specific energy costs and total investment costs in the estimated district heating systems, (i.e., the average and median demand and costs encountered in the district heating areas of each country). Figure 12 shows the total number of the district heating areas modeled, the heat demand covered in these areas in relation to the current national district heating levels. This graph essentially shows the maximum potential of the modeled district heating areas based on the described district heating model and shows that the majority of the heat demand in most of the EU27 and United Kingdom countries can be covered by the modeled district heating areas. However, it is important to note cases such as Finland, Latvia and Estonia, where the maximum modeled potentials do not exceed or slightly exceed the current district heating levels.

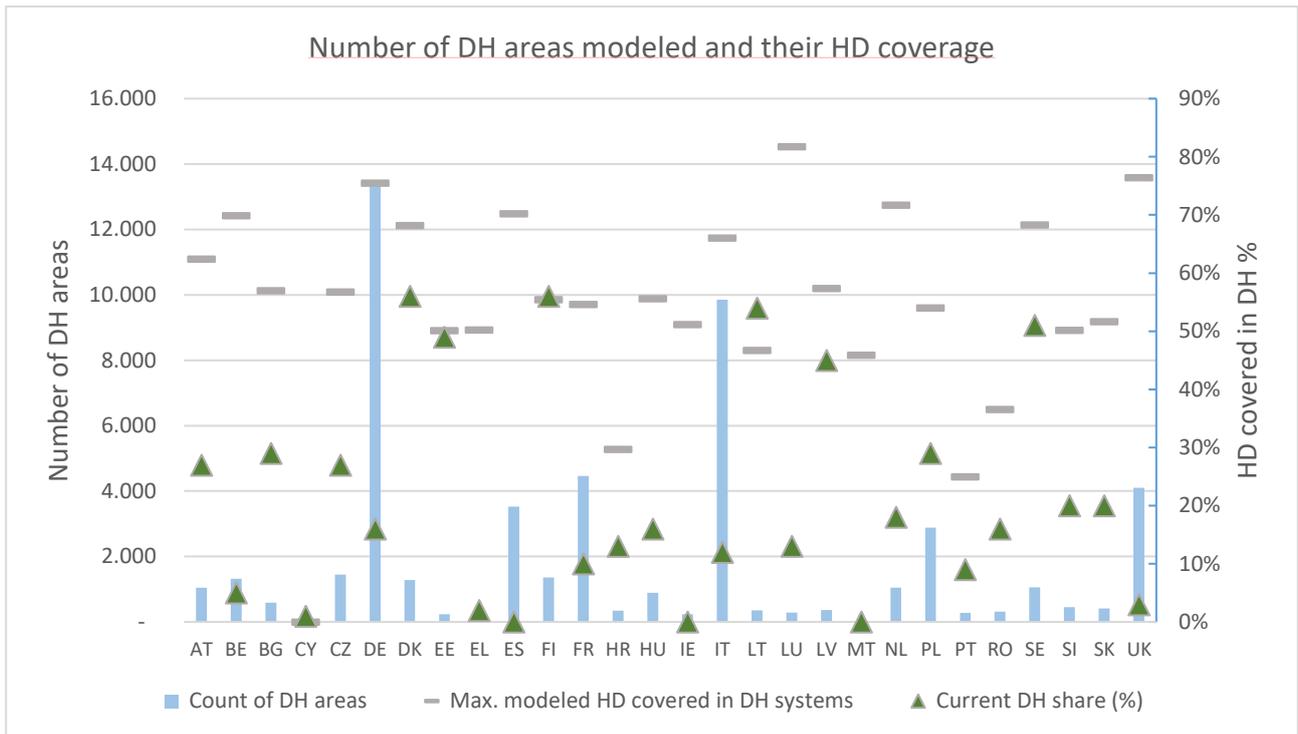

Figure 339 Number of estimated district heating areas by country and the gray linear markers show the proportion of heat demand that can potentially be covered out of the total future heat demands (incl. industrial demand). The green markers indicate the current district heating shares by country.

Specifically, based on section 3.4 and 3.5, the number of the estimated district heating systems and their coverage of total heat demand varies significantly between countries, with Malta having the smallest number of district heating systems (14 in total) covering 46% of its demand, and Italy and Germany having 9,853 and 13,435 systems, respectively, covering 66% and 75% of their annual heat demand. The capacity of individual district heating systems also varies among the countries with the largest systems found in the United Kingdom

(UK, 45.07 TWh), France (44.39 TWh) and Germany (24,56 TWh). On a national average, the largest systems are found in Malta, the Netherlands, the UK, Greece, and Ireland, while the lowest dispersion is noticed in Slovakia, Portugal, Slovenia and the Czech Republic. The low standard deviation values, where the values of heat demand in the national district heating systems are clustered closely around the mean, indicate consistent demand with relatively small fluctuations across locations and a national system with low variability, which could be easier to manage.

In terms of total investment costs, the lowest national costs per unit of heat demand are found in Malta, Finland, Latvia and Estonia. On a national average, the lowest specific energy costs are found in Latvia, Estonia, and Luxembourg (below 30 €/MWh) section 3.6 and 3.7. Again it is important to note that the results presented in this section do not respond to any proposed developments but summarize the maximum potentials of the characteristics modelled in the district heating model and represent a case where district heating would to be developed in all these areas— a case that is almost economically impossible.

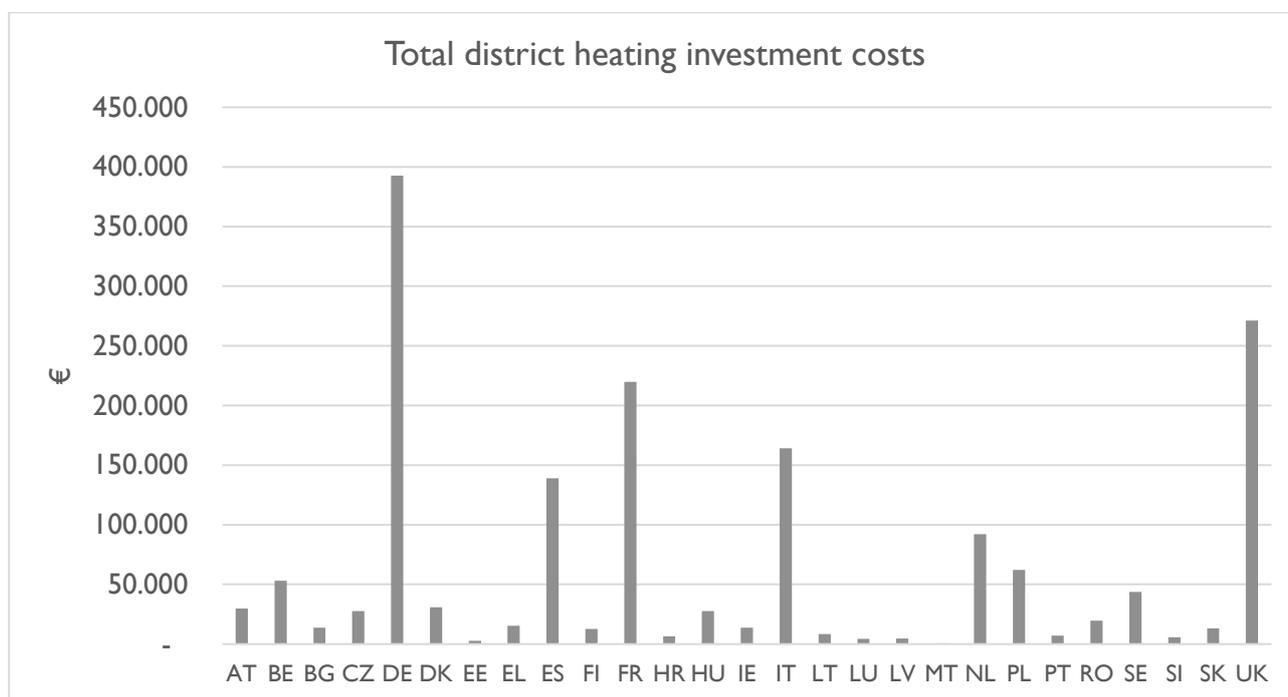

Figure 340 Total investments in district heating networks until 2050 per country.

Another aspect of the report is to estimate how many district heating systems would be required to achieve higher district heating shares. The methodology used here follows a principle tested in (Mathiesen, Brian Vad, Wild et al., 2023), which assumes that "larger urban areas will start with more district heating systems and develop gradually into larger unified systems". After estimating the geographic distribution and heat demand capacity of the district heating areas, the number of district heating plants required is estimated based on the volume of the heat demand in the area. Specifically, it is assumed that the district heating areas with a final heat demand of less than 10 PJ need to develop 1 district heating plant per 1 PJ, while the areas with a final heat demand between 10 -20 PJ and over 20 PJ need to develop 1 district heating plant per 2 PJ and 4 PJ, respectively.

Using this methodology, the required district heating plants have been estimated for all modeled areas and are included as a national count. As an example of the application for a city the size of Prague, 10 different district heating systems would have to be developed if district heating were to start there from nothing today. However, this assumption of the numbers of district heating systems is an approximation based on the demand of the modeled areas, while the actual number of district heating plants depends on various settings

in each area. District heating cities for each country are also distinguished in relation to waste heat ratio found in section 2.2.

6.4 Assessment of district heating systems at EU level

An effective strategy for phasing out natural gas and fossil fuel imports requires a comprehensive transformation of the energy system, with increased integration of district heating at both national and EU levels. This analysis assesses the required future market shares of district heating in different countries, based on a common EU27 assessment of the district heating shares and heat network systems required to meet the 2050 targets. The assessment aggregates district heating systems across the EU27 and ranks them according to their estimated costs, with the ranking criterion defined by the ratio of specific energy costs to heat demand within each corresponding district heating area. In contrast to previous similar exercises, which prioritized areas with the lowest specific energy costs, resulting in the selection of very small areas with low heat demand first, we now incorporate the size of the area into this factor, prioritizing larger areas with high heat demand and relatively higher costs. This is a more realistic approach because investments in such small, low heat density district heating systems are not as cost-effective as the larger ones.

The systems are grouped into intervals of 5% or 10% based on the achieved heat demand shares at the EU27 level, with the heat demand covered and the associated grid costs accumulated at each successive interval. Since these estimates depend on specific geographic regions with varying heat demands and costs, and the accumulation process follows a stair-step curve rather than a smooth trend, we apply an adjusted polynomial function to fit the provided data and estimate heat demand and costs at predefined intervals. However, we acknowledge limitations at higher levels of heat demand shares, as an upper cost limit of 50 €/MWh has been set at the district heating model. This constraint restricts the creation of regions with energy costs exceeding the threshold, thereby limiting further district heating expansion, and consequently the cost estimate for shares above 70%.

The results of this analysis are presented in . This table summarizes the heat demand, the specific energy cost and the grid cost for the 3rd and 4th generation of district heating at each interval of district heating share. Specifically, the first column shows the theoretical intervals and in parentheses the intervals achieved in practice, after ranking the district heating areas by the factor that takes into account the size of the heat demand. Then, the sum of heat demand covered by the district heating areas included in each interval is given, along with the average size of these areas. Correspondingly, the average value of the specific cost of energy is given together with the total and average values of the grid costs for the 3rd and 4th generation of district heating.

Table 15 shows the number of district heating areas included in the corresponding interval, the number of unique countries included, and provides an overview of the population that could benefit from the expansion of these district heating areas in the EU27, the population density of the systems, and their sizes in square kilometers.

Taken together, these two tables provide valuable insight into the characteristics of the selected district heating areas over different intervals. An example is provided to aid interpretation. Specifically, in the first interval, only five district heating areas - Madrid, Paris, Milan, Berlin and Essen - are needed to reach a 5% district heating share, spread over four countries. To reach the next 5% (for a cumulative 10% district heating share), an additional 13 systems are estimated to be required, spread across eight countries.

The 'Heat demand [GWh]' column shows the total and average heat demand of these systems. Notably, the 13 systems required to increase the district heating coverage from 5% to 10% add approximately 4 TWh of heat demand. However, these systems have significantly lower average heat demand (10,5 TWh) - less than half that of the first five (26,6 TWh). The 'Specific cost [€/MWh]' column shows the average specific cost of the systems, indicating that areas contributing to the 5-10% range are less expensive. This comes because of

the ranking factor, which serves as the basis for sorting and prioritizes areas based on their lowest specific cost per unit of heat demand. The additional columns provide population statistics based on the GHS-POP 2020 dataset, along with the average system size in square kilometers and the average national district heating shares covered within each interval. From this we can see that the firstly selected five areas are significantly larger in size and population compared to the rest of the areas selected in the following intervals.

Table 61 Suggested national level of district heating by 2030 (20% EU27), 2040 (33% EU27), and 2050 (55% EU27).

| Country | Year EU market share | 2030 (20%) | 2040 (33%) | 2050 (55%) |
|-----------------------|---------------------------------------|-----------------------------|-----------------------------|-----------------------------|
| Austria | | 26,64 | 38,09 | 53,54 |
| Belgium | | 30,02 | 42,29 | 62,44 |
| Bulgaria | | 11,69 | 25,08 | 48,84 |
| CY | | - | - | - |
| Czechia | | 11,05 | 19,00 | 46,81 |
| Germany | | 25,99 | 39,45 | 64,60 |
| Denmark | | 22,60 | 35,98 | 57,98 |
| Estonia | | 23,76 | 32,48 | 44,52 |
| Greece | | 24,46 | 31,38 | 46,27 |
| Spain | | 23,10 | 40,14 | 61,29 |
| Finland | | 23,78 | 34,73 | 49,66 |
| France | | 16,41 | 31,45 | 48,35 |
| Croatia | | 9,52 | 13,98 | 23,69 |
| Hungary | | 11,21 | 26,20 | 46,59 |
| Ireland | | 23,38 | 26,83 | 46,69 |
| Italy | | 17,32 | 28,38 | 52,73 |
| Lithuania | | 8,54 | 26,87 | 41,91 |
| Luxembourg | | 42,74 | 52,77 | 69,02 |
| Latvia | | 28,11 | 39,43 | 52,02 |
| Malta | | - | 41,37 | 44,17 |
| Netherlands | | 18,14 | 36,06 | 66,40 |
| Poland | | 13,05 | 25,65 | 47,58 |
| Portugal | | - | 9,26 | 19,09 |
| Romania | | 9,01 | 13,25 | 32,89 |
| Sweden | | 19,59 | 36,59 | 60,24 |
| Slovenia | | 12,68 | 23,93 | 41,65 |
| Slovakia | | - | 9,14 | 43,55 |
| United Kingdom | | 26,64 | 38,09 | 53,54 |

While the selection process does not prioritize systems with the lowest network or specific costs, the methodology ensures that the cheapest systems in terms of cost per heat demand are selected first. These systems tend to be larger in area and serve densely populated regions with higher heat demand, maximizing the efficiency of district heating expansion.

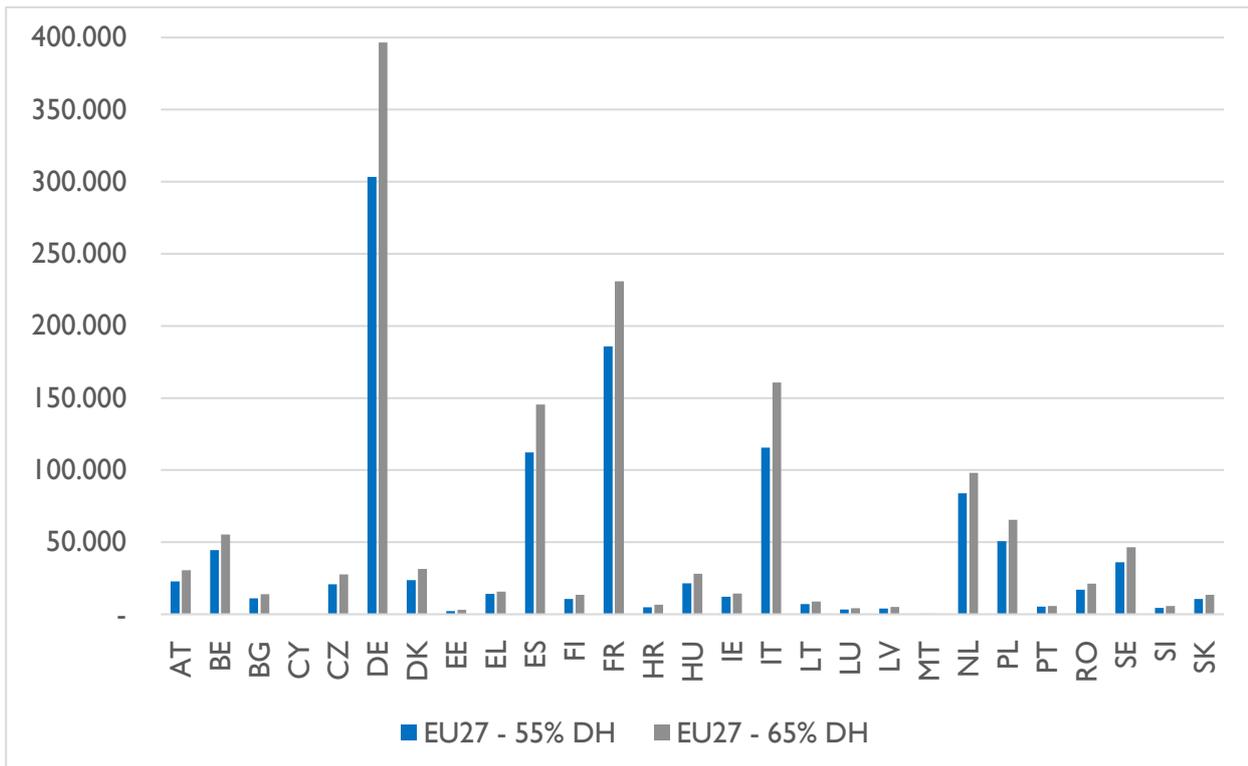

Figure 341 District heating grid cost per market share at 55% and 65%.

Having analyzed the distribution of district heating areas, heat demand values and grid costs at the individual district heating levels, the EU27 assessment follows a process of accumulated district heating shares and grid costs as presented in sections 3.6-3.7. The first table presents the national district heating shares achieved for the corresponding EU27 district heating level goals. The second table shows the associated accumulated grid costs at national level for achieving the EU27 levels. Table 2 shows the national shares of district heating suggested to be achieved by 2030, 2040 and 2050

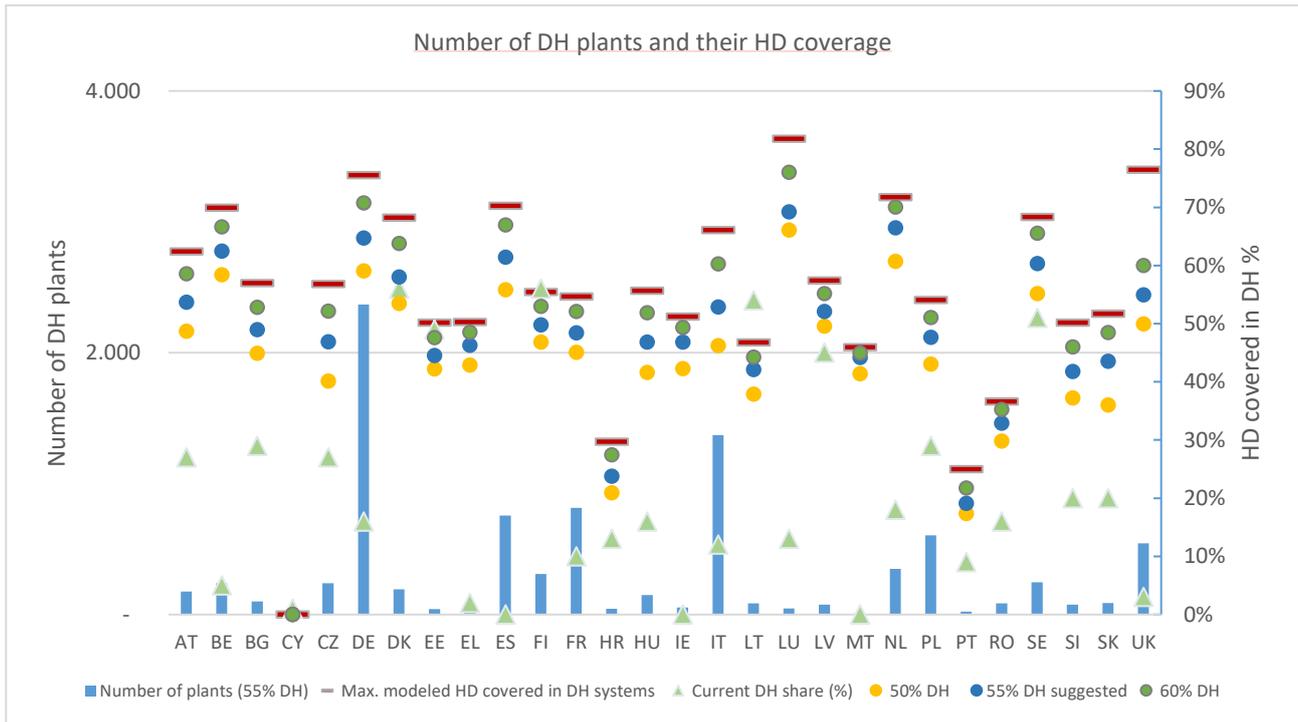

Figure 342 Number of estimated district heating plants by country at a 55% district heating EU27 level. and the gray linear markers show the proportion of heat demand that can potentially be covered out of the total future heat demands (incl. industrial demand). The green markers indicate the current district heating shares by country

6.5 Surplus and renewable heat sources

Several surplus heat sources can be used in district heating systems, either directly in the case of high and medium temperature heat sources, or in combination with heat pumps in the case of low temperature heat sources. The potential is limited to spatial availability and proximity to the district heating demand. In order to define the technical and utilization potentials of each of the sources for the district heating systems estimated, we first produce or pre-process existing datasets for the examined sources, then perform a spatial analysis and match the sources to the district heating areas, allocating their technical potentials based on an estimation of the baseload heat demand and a temperature and cost investment prioritization process. Then, the utilization potentials are calculated in several different waste heat scenarios, as described below.

6.6 Data and workflow

This appendix presents the data on waste heat potential and their spatial distribution in Europe. We have analyzed several heat sources and processed, combined or complemented existing datasets on their spatial distribution and potentials to produce a more complete dataset.

Table 2 provides an overview of the data on heat sources and details on the spatial and temporal resolution and their sources, divided into existing and potential future plants. Data on the location of existing plants has been provided by sEEnergies as point datasets together with the current waste heat potential. However, as the primary objective of this exercise was to produce datasets for the waste heat potentials in 2050, a top-down approach was followed spatially allocating national estimates for a series of waste heat sources to the estimated district heating areas. The newly estimated datasets and the production process are described below by category, including visualizations of the products. Since estimating the future locations of wastewater treatment plants, supermarkets, and metros is very challenging, we assume that their spatial distribution may change, but their technical potential will remain unchanged in the boundaries of the estimated district heating systems.

Table 62 Overview of waste heat potentials considered for district heating (DH).

| Plant status and data production process | Heat source | Spatial resolution | Temporal resolution | Considered source temperature | Maximum distance from source | Data source |
|--|---------------------------------|--------------------|---------------------|-------------------------------|---------------------------------------|---|
| Existing plants Bottom-up | Waste-to-Energy (WtE) | Points | Annual | High | Intersecting DH area | sEEnergies |
| | Industrial waste heat high °C | Points | Annual | High | National total distributed in DH area | sEEnergies |
| | Industrial waste heat medium °C | Points | Annual | Medium | Intersecting DH area | sEEnergies |

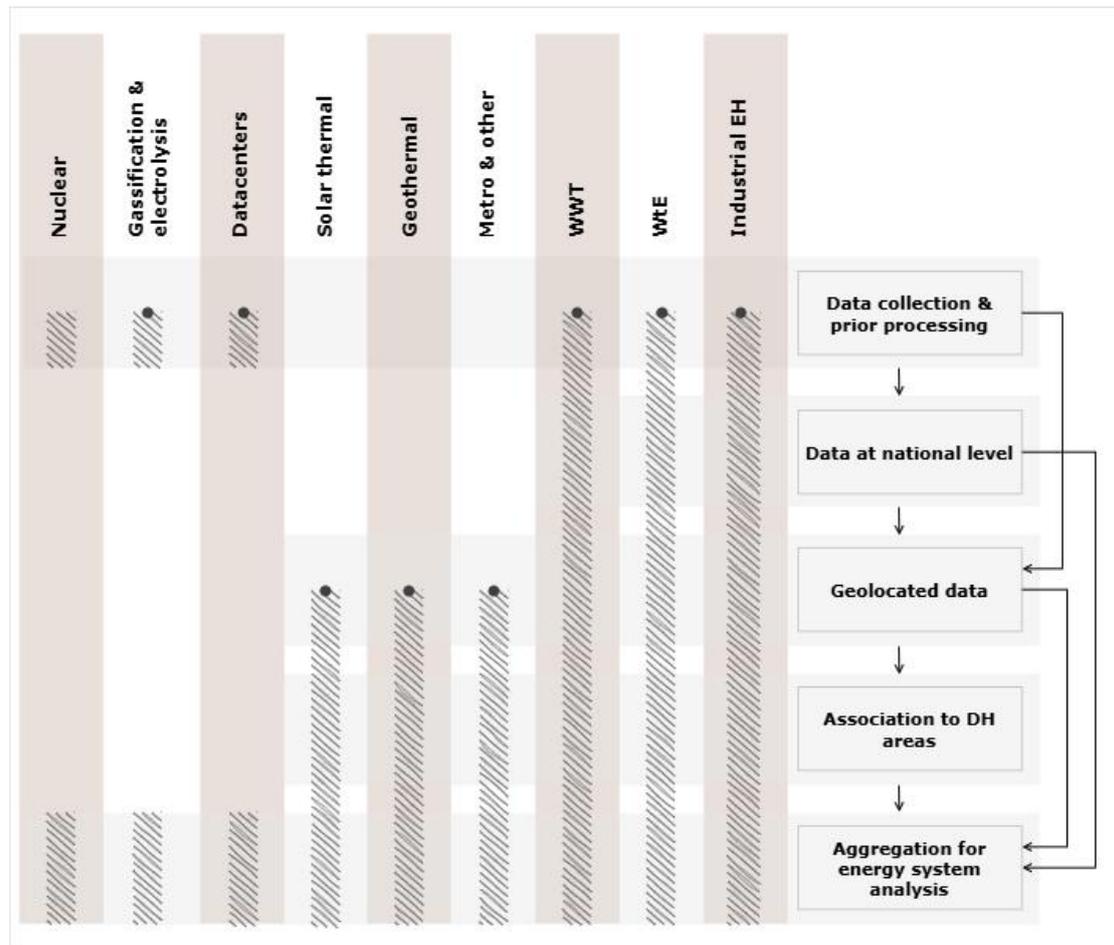

Figure 343 Workflow for surplus and renewable heat sources

6.7 Mapping future heat sources and individual technical potentials

This appendix presents the potential spatial matching of surplus and renewable heat sources to district heating areas. We have analyzed several heat sources and processed, combined or complemented existing datasets on their spatial distribution and technical potentials to produce a more complete dataset.

Table 2 provides an overview of the data on heat sources and details on the spatial and temporal resolution and their sources, divided into existing and potential future plants. Data on the location of existing plants has been provided by sEnergies as point datasets together with the current waste heat potentials. However, as the primary objective of this exercise was to produce datasets for the waste heat potentials in 2050, a top-down approach was followed spatially allocating national estimates for a series of waste heat sources to the estimated district heating areas. The newly estimated datasets and the production process are described below by category, including visualizations of the products. Since estimating the future locations of wastewater treatment plants, supermarkets, and metros is very challenging, we assume that their spatial distribution may change, but their technical potentials will remain unchanged in the boundaries of the estimated district heating systems.

i. Waste-to-Energy (WtE) and Industrial waste heat

Point datasets of the locations and capacities of existing sources of high, medium and low temperatures were available by sEnergies. The estimation however of the geographical distribution and potentials of future heat

sources required the production of new datasets based on the already estimated district heating areas, where a top-down approach was followed. Specifically, the pre-processing approach for these different heat source datasets, spatial matching to the district heating areas and technical potentials is as follows:

Waste-to-Energy (WtE)

In general, cities with large populations ensure the economic viability of a WtE plant while also having sufficient demand for heat and electricity, which increases the efficiency of the plant through cogeneration systems. In order to identify suitable areas for the development of future WtE plants, we examined cases of different city sizes (ranging from 45,000 to 80,000) and compared their future waste heat potentials to the current WtE potentials. The results of this sensitivity analysis examined by experts led to the selection of cities of at 60,000 inhabitants.

Specifically, the process first included the estimation of the cities sizes and boundaries using the continuously inhabited grid cells from the GHS POP layer (2020). The overlapping area of industrial uses from the CORINE land cover layer was then estimated on top of the city boundaries and a factor normalizing the population and the aerial size of the industrial areas was used to downscale the national WtE potentials to the city boundaries. Figure 13 illustrates the suitable areas for WtE plants and their potential waste heat in the corresponding district heating areas of Nordrhein-Westfalen in western Germany. As the WtE areas may overlap with more than one district heating area – as shown in the case of Koln, where the large WtE area overlaps not only with the district heating area with the highest demand, but also with some of the smaller surrounding district heating areas– the allocation of the waste heat is estimated in proportion to the heat demand of each district heating area.

Industrial waste heat

Divided into three categories of high, medium and low temperature, referred to here as industry (H), industry (M), and industry (L), the annual national technical potentials are estimated by IndustryPLAN (Johannsen et al., 2023; Mathiesen, Brian Vad, Johannsen et al., 2023) and allocated directly to district heating areas. The allocation of high temperature sources follows as a primary guide the locations of the existing high temperature industrial sources, while the medium and low temperature sources were allocated in proportion to the size of areas characterized by industrial uses in the CORINE land cover layer overlapping with district heating areas. Figure 14, Figure 15, and Figure 16 present examples of the distribution and size of the different categories of industrial waste heat in the estimated district heating systems in Germany and the Netherlands.

Other low and medium temperature waste heat sources

Point datasets for WWTP plants, supermarkets, and metros are provided from PETA5.2 and the ReUseHeat project. Figure 16 (right) and Figure 17 show the distribution of these medium and low waste heat sources in the Netherlands and Czech Republic. Their potential technical volume of waste heat was allocated to the district heating areas by spatial intersection.

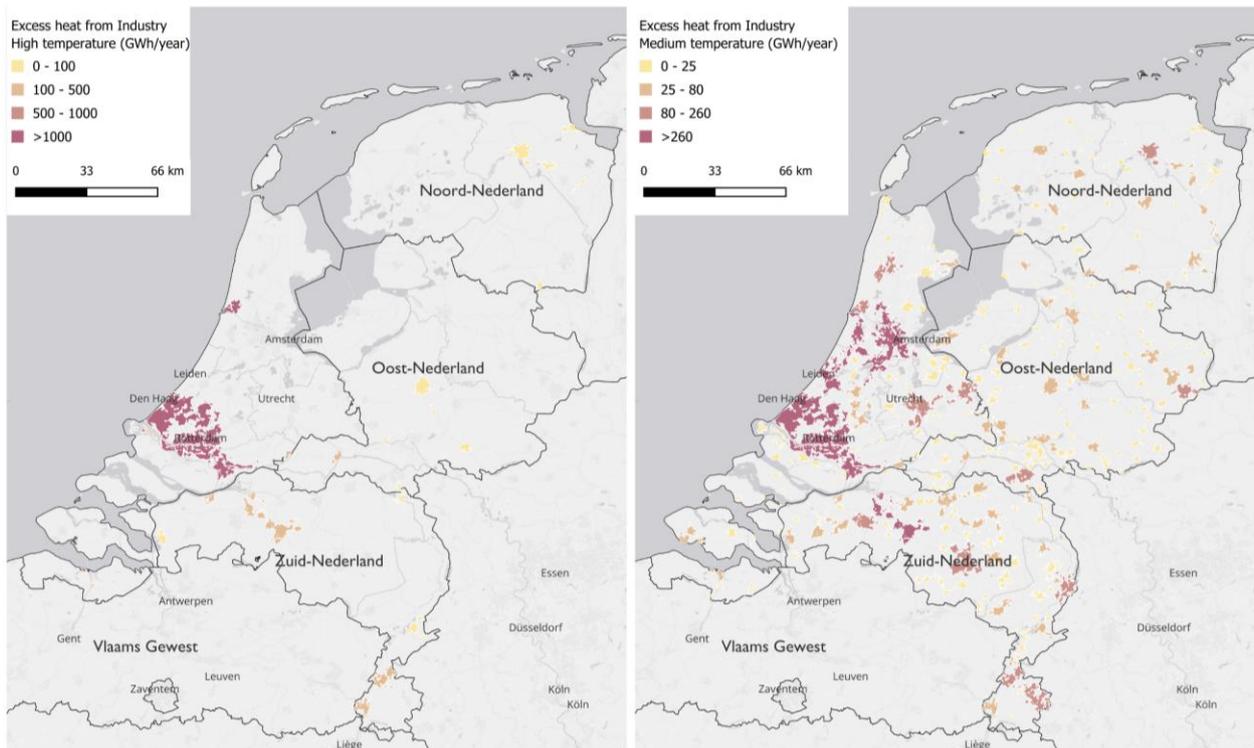

Figure 346 Industrial waste heat of high and medium temperatures in district heating areas in the Netherlands.

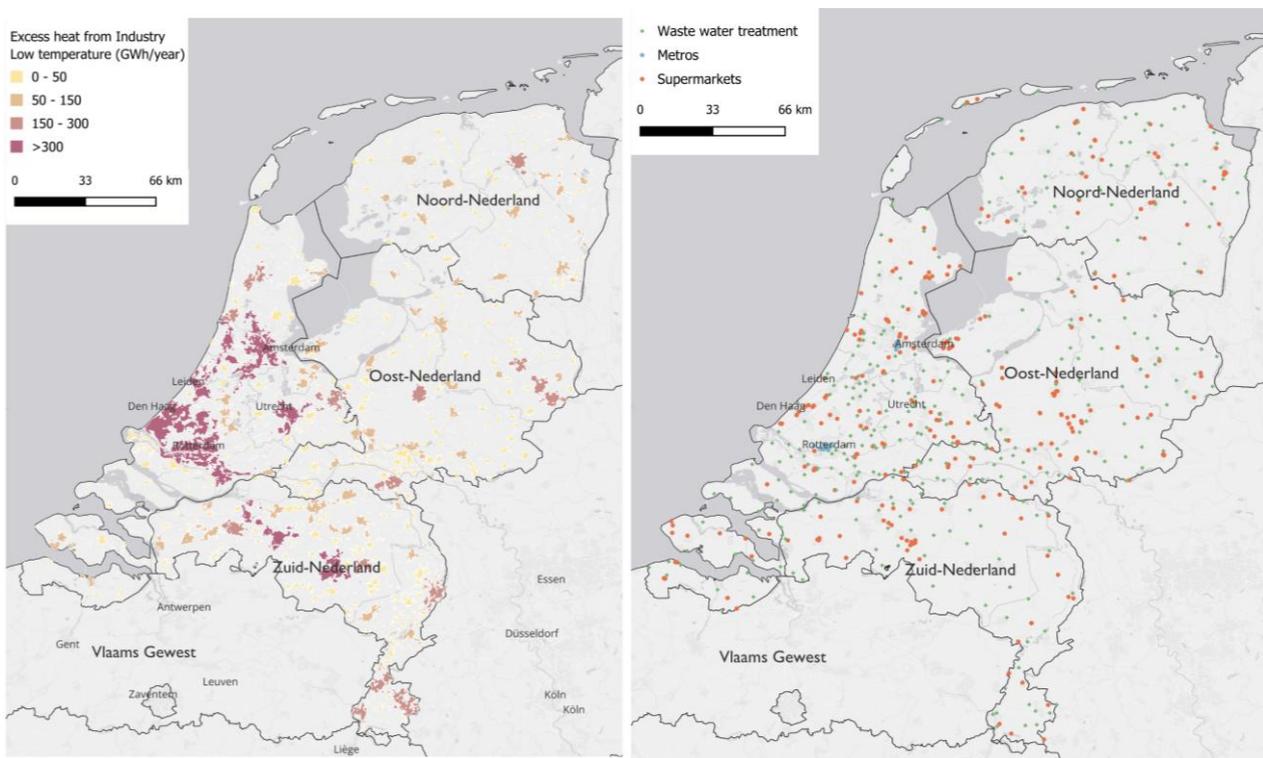

Figure 347 Low temperature excess heat in district heating areas in the Netherlands

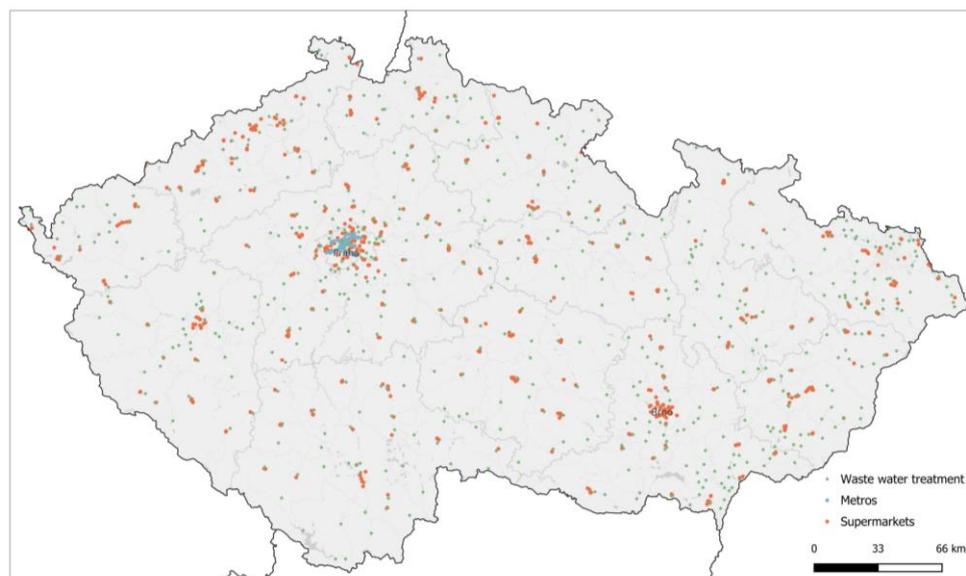

Figure 348 Distribution of heat sources of low and medium temperatures in Czech Republic.

ii. Geothermal and solar thermal energy

The full potential of geothermal energy is estimated proportionally to the population and the heat demand allocated in areas with geothermal resources.

Since the technical potentials of geothermal and solar thermal energy cannot be assessed in the same way as the above industrial and non-industrial sources - since their feasibility is not strictly limited by the location of existing industrial activities - the estimation approach for these sources is instead based on the evaluation of the baseload heat demand within each district heating area. Consequently, we first estimate the share of heat demand from residential and service buildings required for hot water. This is set at 20% of the heat demand for all countries except the southern European countries (i.e. Cyprus, Greece, Malta, Portugal) where it is set at 25%. The hot water demand is calculated by adjusting the district heating demand with the industrial heat demand within the district heating areas, multiplied by the above share. Finally, the base load heat demand is estimated by summing the district heating losses, estimated by district heating model, the hot water demand and the industrial heat demand within the district heating areas and then applying a factor of 1.1 to account for additional load considerations.

Regarding geothermal potentials, primary layers on areas suitable for hydrothermal and geothermal heat are retrieved from GeoDH map including also areas of Neogene basins. Due to the uncertainty of the accuracy of these layers and in order to keep track of the potential of the different types and sources of geothermal energy, six different categories/ layers were created and processed in the technical and utilization waste heat analysis. These categories are high and low temperature geothermal energy (hereof mentioned as Geo1, Geo2), high and low temperature hydrothermal energy (referred to as Geo3, Geo4), additional high and low temperature geothermal and hydrothermal areas (referred to as Geo5) and Neogene basins (referred to as Geo6). Figure 349 shows the distribution of the different types of geothermal energy in Europe.

The estimation of the technical potential of geothermal sources for each district heating system is based on the spatial intersection of the district heating system with the identified areas of geothermal potential and the assignment of the base load heat demand, assuming that the maximum heat demand of the system can be met by the appropriate geothermal sources. An additional criterion for estimating geothermal energy has been introduced based on the size of the district heating system, as investments in geothermal potential are not

recommended in small district heating systems due to their high cost. This criterion involves systems of minimum 40MW and 70MW capacity base load. The capacity is estimated as the base load per number of hours in a year. Table 23 presents the technical potentials by category of geothermal source when the restriction of 70MW is implemented at the size of the cities. The Data report includes the table for the corresponding potentials when the restriction of 40MW is implemented.

Correspondingly, given the national hourly solar thermal distribution, a solar factor is estimated as the fraction of the sum of the hourly distributions by the maximum. The solar factor is then multiplied by the hourly base load to obtain the solar thermal capacity per district heating area.

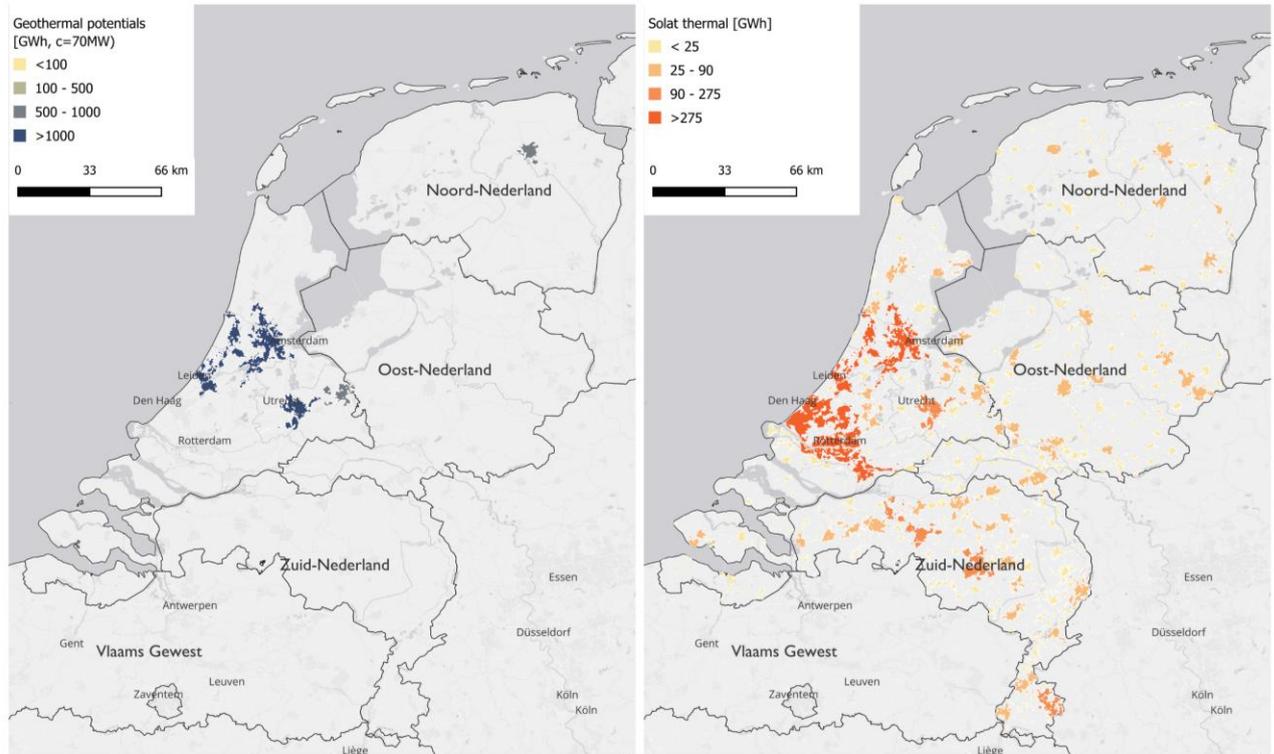

Figure 350 Geothermal (left) and solar (right) potentials in the Netherlands.

iii. Nuclear energy

Nuclear energy is an important but controversial part of the energy mix. In order to form a holistic overview of the sources and capacities of surplus heat, we also examined the distribution of nuclear powerplants in Europe. For the assessment of the technical potentials of nuclear energy being used in district heating systems, we downscaled the national estimates retrieved from the World Nuclear Association's (WNA, 2024) and the International Atomic Energy Agency's databases (IAEA, 2024) based on the point datasets retrieved from Nucleareurope and (Esri India Technologies Ltd, 2024; Nucleareurope).

The allocation of national estimates of the net capacity of the plants is based on the gross power of the plants while the technical potentials are estimated on the assumption that 66% of the waste heat could potentially be used in nearby district heating grids. For each nuclear power plant, the closest city with a population exceeding 45,000 was identified. If a city was located within a 50 km radius of a power plant, the share of the heat demand that could be supplied by the powerplant was estimated (Table 4). In cases where no large city (with population larger than 45,000) fell within the 50 km radius, the potential heat coverage was estimated for the modelled district heating areas—irrespective of size and cost—within the same radius. These outcomes are shown on Table 65 and as brown plant symbols on the map on Figure 351.

From these tables, it becomes evident that the surplus heat of nuclear power plants based on their current capacities could sufficiently cover the heat demand of nearby district heating systems. Some important remarks should be made though on the basis of the above tables and analysis. First, in the case of Cattenom in France and Krško NPP in Slovenia, their close distance to the national borders highlights the potential of providing heat potentials to cities in neighboring countries, as in the case of Schiffange in Luxembourg and Zagreb in Croatia. However, if this cross-border cooperation is not feasible, the distance from the Krško nuclear power plant to Ljubljana is above the threshold set at 79 km, while its low capacity, providing less than 12% of the district heating demand in either Zagreb or Ljubljana, makes it potentially not a suitable source for district heating.

A second note that should be made is about the plants that are not directly connected to a large city at a distance lower than 50km. In this case, and if the 50 km threshold is not strictly to be implemented, another 6 out of the 9 remaining plants have a distance between 50-70 km from a large city, which with their current capacities could cover an extension over 45% of the cities' district heating demand (e.g. Pael - Le Havre (52km); Belleville - Chalette-sur-Loing (56km); Kozloduy - Vratsa (62km); Penly - Rouen (62km)).

Table 65 Relation of nuclear power plant to their closest city of at least 45000 inhabitants and the heat demand covered by the technical potentials of the plant.

6.9 Prioritization pathways for waste heat sources in district heating systems

After ensuring the spatial matching of future heat sources and their technical potentials to the estimated district heating systems, a scenario-based prioritization analysis is investigated. Specifically, the process of estimating the utilization potential of each waste heat source by scenario involves the sequential allocation of heat demand from different sources along with the assessment of the remaining base load heat demand. For example, if waste heat from waste incinerators is allocated first, followed by each subsequent source (e.g., high and medium temperature industrial heat, WWTP, supermarkets, metros), the waste heat from these sources is assessed to determine if the remaining base load heat demand can accommodate the full potential of the source. If so, the full potential is allocated, otherwise the remaining baseload capacity is allocated. This continues for all sources considered in the scenario, ensuring that the total allocated potential does not exceed the baseload heat demand and that all sources are prioritized in the order given. An exception is considered for the solar thermal potentials, which are estimated independently of the prioritization of other sources as the total technical potentials for two different cases - for cities with capacity lower than 20MW and 40MW. However, solar thermal is prioritized and included in the assessment of the following sources.

Six different scenarios (A-F) are studied and produce inputs for the energy system modeling, as shown in Table 69. The results of only three of them are presented in this series of reports, namely scenarios A, C and D. Specifically, Table 5 shows the waste heat sources considered in the corresponding scenario, indicated by X when it refers to the use of 100% of the potentials, while with 50% when the potentials are considered with losses of this magnitude. The order of the rows indicates the priority order of the sources. Results for each country by national district heating level with the corresponding levels of waste heat are included in the data report.

Table 69 Scenarios and waste heat sources

considered: An 'X' indicates 100% utilization of the source potential, while '50%' reflects the consideration of the source with 50% losses. The rows are arranged by priority order of the sources.

| Sources | | Scenario A | Scenario B | Scenario C | Scenario D (EE) | Scenario E (RE) | Scenario F (EE+ RE) |
